The test substance CP67573 was evaluated for its acute intraperitoneal toxicity potential by a single injection to Wistar rats (10 animals/group/sex). The test substance was applied at a dose of 182, 255, 357, 422 and 500 mg/kg bw to males and 255, 357, 500, 700, 980 and 1372 mg/kg bw to females. The animals were observed for a period of 14 days. The behavioural and pathological findings suggest that the test substance acts on the central nervous system and digestive organs. The acute intraperitoneal LD_{50} in male and female rats was calculated to be 281 and 467 mg/kg bw, respectively.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	CP67573
Description:	White powder
Lot/Batch #:	Not specified

Purity:	98.4 % glyphosate
Stability of test compound:	Not specified
Vehicle and/ or positive control:	0.5 % tragant solution

Test animals:

Species:	Rat
Strain:	Wistar-Imamichi
Source:	[redacted] (not further specified)
Age:	5 weeks
Sex:	Males and females
Weight at dosing:	Male: 95 - 102 g; female: 94 - 100 g
Acclimation period:	Not specified
Diet/Food:	Fumabashi Mojyo Co., Ltd. chow, *ad libitum*
Water:	Drinking water, *ad libitum*
Housing:	Individual
Environmental conditions:	Temperature: 24 ± 1 °C Humidity: 50 - 60 % Air changes: 12/hours Photocycle: 14 hours light/10 hours dark cycle

B. STUDY DESIGN AND METHODS

In life dates: not specified

Animal assignment and treatment
The test substance suspended in 0.5 % tragant solution was prepared just prior to use in varying concentrations to maintain a dose volume of 0.5 mL/100 g bw.
The dose levels are shown in the following table below.

Table 5.8.2-54: Acute toxicity study (intraperitoneal injection) of CP67573 on the rats ([redacted] 1978): Dose levels

Sex	No. of rats	Dose level (mg/kg bw)
Male	10	182
	10	255
	10	357
	10	422
	10	500
Female	10	255
	10	357
	10	500
	10	700
	10	980
	10	1372

Observations for mortality and clinical signs of toxicity were made during the 14-day post-exposure period. Body weights of individual rats were measured on Day 0, 7 and 14. All rats were subjected to a grosspathological examination.

The LD_{50} and 95 % confidence limits were calculated by Lithchfield-Wilcoxon method used mortality of Day 7.

II. RESULTS AND DISCUSSION

A. MORTALITY

The occurrence of deaths is shown in the following table.

Table 5.8.2-55: Acute toxicity study (intraperitoneal injection) of CP67573 on the rats ([redacted], 1978): Mortality

Sex	No. of rats	Dose level (mg/kg bw)	Day									Mortality (%)	
			1			2	3	4	5	6	7	8-14	Days 0-7*	
			1 h	6 h	24 h									
Male	10	182	0	0	0	0	0	0	0	0	0	0	0/10	(0)
	10	255	0	0	0	0	2	1	0	1	0	0	4/10	(40)
	10	357	0	0	0	1	1	2	2	0	1	2	7/10	(70)
	10	422	0	0	0	3	4	1	0	0	0	2	8/10	(80)
	10	500	0	0	0	2	6	2	0	0	0	0	10/10	(100)
Female	10	255	0	0	0	0	0	0	0	0	0	0	0/10	(0)
	10	357	0	0	0	0	0	1	1	0	0	4	2/10	(20)
	10	500	0	0	0	1	4	0	1	0	0	1	6/10	(60)
	10	700	0	0	0	1	2	3	1	2	0	1	9/10	(90)
	10	980	0	5	0	3	0	0	0	1	0	1	9/10	(90)
	10	1372	0	10	0	0	0	0	0	0	0	0	10/10	(100)

* The LD_{50} was calculated after 7 days, due to further deaths in the second week the 14-day LD_{50} would have been lower in both cases.

B. CLINICAL OBSERVATIONS

Thirteen minutes after administration of CP67573, ventral posture, decrease of spontaneous activity, piloerection, salivation and decrease in skin temperature were observed in all animals of both sex. These signs were not observed on the followingmorning in the lowest dose groups of males and females (182 mg/kg bw and 255 mg/kg bw, respectively). In other dose groups, these symtoms were observed for 36 to 48 hours.

In dead animals disappearance of righting reflex and coma was observed. Animals died in ventral posture.

C. BODY WEIGHT

Body weights were not reported.

D. NECROPSY

Gross pathological findings present in deceased animals were increase in circumference of the abdomen; ascites, hyperplasia in intestine wall; adhesion, transformation and slight hypertrophy of liver lobes (with hypertrophy of peritoneum); haemorrhage of mucosa in fundamental stomach; spot haemorrhage in thymus and peyr patches; hyperemia in adrenals.

The signs observed at autopsy of the survivors were as follows: adhesion, slight hypertrophy and transformation of liver lobes and adhesion of stomach and pancreas, hyperplasia of spleen capsule in all animals. The animals that increased in circumference of the abdomen revealed a decrease in body weights and hypertrophy of cecum.

Since the changes of the liver were due to hyperplasia of peritoneum induced by mechanophysical stimulation of injected suspension, the observed findings in the liver were not attributed to a test substance specific induced toxicity.

Study conclusion
The acute intraperitoneal LD_{50} for the test substance CP67573 in males and females was calculated to be 281 mg/kg bw and 467 mg/kg bw, respectively. The 95 % confidence limits were 210 - 340 mg/kg bw and 383 - 592 mg/kg bw for males and females, respectively.

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
Acute intraperitoneal toxicity of glyphosate was tested in rats. There is no OECD guideline available for this endpoint. As to be expected, toxicity was higher by this route as compared to oral, dermal or inhalation exposure. Due to the route of exposure, this study provides only supplementary information. Based on the study results, the acute intraperitoneal LD_{50} is 281 mg/kg bw and 467 mg/kg bw in male and female rats, respectively.

Assessment and conclusion by RMS:

CA 5.8.2/014

Information on the study

Data point	CA 5.3.3
Report author	[redacted]
Report year	2012
Report title	Glyphosate acid - *In Vitro* Absorption through Abraded Rabbit Skin using [^{14}C]-glyphosate
Report No	JV2182-REG
Document No	Not reported
Guidelines followed in study	OECD 428 (2004)
Deviations from current test guideline (OECD 428, 2004)	None
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (E docs)	Category 2a

2. Full summary
The purpose of this study was to determine the *in vitro* percutaneous absorption of glyphosate acid through abraded rabbit skin following a 6-hour exposure period and subsequent 18 hour monitoring period. This study was designed to assess the potential dermal penetration of test material through rabbit skin and will be of use in estimating the systemic dose achieved in a previous *in vivo* rabbit dermal toxicity study (see CA 5.3.7/01, [redacted], 1982). Therefore, the application rate and exposure conditions used in this study

were calculated to be equivalent to 5000 mg/kg bw/day as applied to rabbits in the *in vivo* dermal study (CA 5.3.7/01).

^{14}C-glyphosate was incorporated into a wet cake preparation prior to application. The preparations were applied as a paste to abraded rabbit skin membranes at a rate of 79.8 mg/cm^2 (corresponding to 48.3 mg glyphosate acid/cm^2) and left un-occluded for an exposure period of 6 hours, after which the skin surface was washed. The absorption process was followed by taking samples of the receptor fluid (physiological saline) at recorded intervals throughout a total time-period of 24 hours. The distribution of glyphosate within the test system and a 24-hour absorption profile were determined. All samples were analysed by liquid scintillation counting (LSC).

The results of this *in vitro* study indicate the dermal absorption of glyphosate through abraded rabbit skin is slow. The vast majority of glyphosate will be washed off during normal washing procedures. The mean total amount of glyphosate absorbed after 24 hours was 2.42 % of the applied dose. The reported total potentially absorbable amount, represented by the mean absorbed dose together with the mean amount in the remaining dermis was 2.66 %.

Materials and methods

A. Materials

1. Test materials:

a) Non radio-labelled test substance:

Identification:	MON 77973 (glyphosate acid)
Description:	White wet cake
Lot/Batch #:	GLP-1103-21149-T
Chemical purity:	85.14 % as glyphosate acid (purity: 95.93 %)
Stability of test compound:	Expiry date: 2012-03-09

b) Analytical reference standard:

Identification:	Glyphosate acid
Lot/Batch #:	GLP-0810-1915-A
Chemical purity:	Not reported

c) Radio-labelled test substance

Identification:	^{14}C-glyphosate (as glyphosate acid) [phosphonomethylene-^{14}C]-Glyphosate
Lot/Batch #:	4675JJN002-1
Radiochemical purity:	96.7 % (confirmed by analysis)
Specific activity:	48 mCi/mmol; 1776 MBq/mmol; 2523µCi/mL; 9.35 MBq/mL

2. Test skin source:

Species:	Rabbit
Strain:	New Zealand White Albino
Source:	Harlan
Age:	At least 12 weeks
Type:	Complete pelt

B: Study design and methods

Preparation of skin samples:
Skin pelts from New Zealand White albino rabbits at least 12 weeks old were obtained from Harlan. The skin samples were transported on cold blocks and were stored on arrival at -20 °C, the day after sacrifice. The skin samples arrived clipped and excised and were examined for scars and blemishes. Any extraneous subcutaneous tissue was removed after defrosting and the pelts clipped further if necessary. The pelts were given an identifying number and individually stored frozen, at approximately -20 °C, on aluminium foil until required for use.

Test substance preparation
The doses were prepared, to mimic as closely as possible a 5000 mg/kg bw dose from a previous rabbit *in vivo* study (CA 5.3.7/01, [redacted], 1982). The dose equivalency was calculated on a dose per unit area of skin basis using an average *in vivo* rabbit weight of 2.78 kg. The doses were prepared as close to the time of application as was practicable.

Radioactive stock solution of ^{14}C-glyphosate
The radiolabelled ^{14}C-glyphosate was supplied as a solution in water.

Trial preparation of the radiolabelled glyphosate acid
Glyphosate acid trial preparation was prepared using the method described below, with the exception that a different volume or smaller amounts of radioactivity or unlabelled material were used, where applicable. Three individual vials were prepared as part of the trial preparation, to assess dosing methodology. The paste like composition of the dose preparation was investigated to ensure that it visually provided good skin contact during application to the membranes.

Preparation of radiolabelled glyphosate acid
Firstly 8008 mg of non-labelled glyphosate wet cake was added to a vial, followed by 4162 µL of radiolabelled glyphosate stock solution, providing a nominal 3.85 mg of glyphosate (40 MBq) radioactivity. 5 mL of water was then added and the preparation mixed thoroughly. The preparation was then freeze dried to remove the water added and the water present in the wet cake. When dry, the glyphosate wet cake preparation was then weighed to confirm the removal of all the water. Approximately 521 mg of the dried wet cake preparation was then added to 8 individual vials together with approximately 300 µL of saline to each vial to create a paste. A final weight of each vial was recorded and the preparation was thoroughly mixed with a spatula into a paste before dosing.

Preparation of non-labelled glyphosate acid
To demonstrate that the dose preparations have a close contact during the application procedure, an additional dose preparation without radiolabel was prepared according to the procedure described above.

Analyses of dose preparations
The radioactivity content of the stock solution was determined by liquid scintillation counting (LSC) analyses of sub-samples of solvent dilutions. The radiochemical purity of the radiolabelled stock solution of the test substance was determined by thin layer chromatography (TLC) using unlabelled test substance as reference standard.
The radioactivity content and homogeneity of the dose preparations were checked by LSC analyses. The radiochemical purity and stability was measured by TLC analyses.

Preparation of diffusion cells
The skin membranes were placed in static glass diffusion cells providing an exposure area of 2.54 cm^2 of skin. The cells had a receptor volume of approximately 4.5 mL.
An integrity test was performed by measuring the electrical resistance (ER) across the skin membranes. Non-abraded membranes with a resistance of 1.5 - 5 kΩ were considered having a normal integrity and used for the skin abrasion. Rabbit skin was abraded using a blunt spatula drawn over the skin area approximately six to eight times, in the form of a grid, in order to mimic 'Draize' abrasion as conducted in

the in vivo study (CA 5.3.7/01, [redacted], 1982). After the abrasion a further integrity test was performed by measuring the electrical resistance (ER) across the skin membranes. For abraded skin samples membranes with ER values in the range of 0.7 – 1.0 kΩ were selected for the study.
Cells were selected such that the application rate was represented by eight intact skin samples from five different animals. Physiological saline was chosen as receptor fluid. The skin surface temperature was maintained at 32 ± 1 °C using a water bath.

Test substance application and sampling
Prior to dosing a pre-treatment a sample of 500 µL was taken from each diffusion cell, and replaced by an equal amount of fresh receptor fluid.
Each dose formulation was applied to the abraded skin membrane as a dried glyphosate acid wet cake paste and spread over the skin surface using a spatula. The weight of each individual preparation and spatula were recorded before and after dosing to allow the applied dose to be calculated.

Each dose was applied at the nominal rate of 79.8 mL/cm^2 exposed skin area (202.8 mg/cell), corresponding to 48.3 mg glyphosate/cm^2. The applications were left un-occluded for 24 hours.
Receptor fluid samples (500 µL) were taken by an auto-sampler at 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 16, 20 and 24 hours after application. After each sampling the removed amount of receptor fluid was replaced by an equal amount of fresh receptor fluid.
After the 6-hour sampling, the skin samples were washed by gently swabbing the application site application site with at least three natural sponges pre-wetted with 3 % Teepol L® in water. Decontamination was shown to be complete following assessment of residual radioactivity levels on the skin surface with a Geiger counter. Two further sponges, pre-wetted with water, were used to further swab the surface.

Terminal procedures
After the last sampling, 24 hours after application the remaining receptor fluid was discarded. The receptor chamber was rinsed with receptor fluid that was also discarded.
The donor chamber was carefully removed and the underside wiped with a single natural sponge, pre-wetted with 3 % Teepol L® in water, which was added to the wash sponges. The donor chamber was washed with deionised water and a sample was taken for LSC analysis.
The epidermal surface of the skin was decontaminated by gently swabbing the application site with natural sponges pre-wetted with 3 % Teepol L® in water. Decontamination was shown to be complete following assessment of residual radioactivity levels on the skin surface with a Geiger counter. The skin surface was washed with further sponges pre-wetted with water. All the sponges were combined and digested in Soluene 350® and made up to a recorded volume. A sample was taken for analysis.

Due to the fragility of the abraded skin samples tape stripping could not be performed. Instead a heat separation technique was used to separate the epidermis from the dermis.

The skin was carefully removed from the receptor chamber and the flange area cut away and digested in Soluene 350® and aliquots taken for analysis by LSC.

The remaining skin disc was placed dermis side down, on cling film. A second piece of cling film was then used to cover the epidermis side. A 200 g weight was placed in a water bath at 65 ºC for an hour prior to use. The weight was placed onto the epidermal surface with moderate pressure for approximately 90 seconds. The epidermis was peeled away from the dermis using forceps. The dermis was digested in Soluene 350® and aliquots taken for analysis by LSC. The epidermis was digested in Soluene 350® and the whole sample analysed by LSC.

Analysis of samples
The radiochemical purity and stability of the ^{14}C-glyphosate preparations was determined by TLC using silica gel plates and methanol:water:acetic acid (6 : 3 : 0.5, v/v/v). Radioactivity on the TLC plates was measured using a Packard Instant Imager (SOP E003). Unlabelled material was visualised under UV light

at 254 nm.
For visualising the test material on the TLC plates a 2 % ninhydrine solution in acetone was used. In addition, for analyses of dose preparations K2 cellulose plates and a revised solvent system (methanol: water:acetic acid (8 : 1.5 : 0.5, v/v/v) was used.

Liquid samples of the receptor fluid, washing solutions, digested wash sponges, and digested dermis and epidermis were measured by LSC using a Packard 3100 TR LSC counter and Goldstar as scintillation fluid. Results of the analysis of the samples of receptor fluid collected in the study were expressed as amounts of glyphosate in the receptor solution in terms of µg/cm^2. The amounts absorbed, rates of absorption (µg/cm^2/h) and 'percentage of dose absorbed' were calculated. Membranes with absorption profiles that indicate membrane damage during the course of the experiment have been excluded from calculations. The results of the mass balance and distribution determinations were expressed in terms of amount absorbed and 'percentage of applied dose.
The absorbed dose was considered the glyphosate detected in the receptor fluid, while the potentially biologically available proportion of the dose was regarded as the sum of absorbed dose and the amount recovered from the dermis. The test material removed from the surface of the epidermis by the washing procedure, as well as the glyphosate recovered from the epidermis at the end of the exposure was considered unabsorbed.

Results

A. ANALYSES OF THE ^{14}C-GLYPHOSATE STOCK SOLUTION
TLC analysis of the ^{14}C-glyphosate stock solution confirmed a radiochemical purity of greater than 95 %. LSC analysis revealed a radioactivity content of 72.1 MBq, equivalent to a concentration of 0.924 mg/mL. The stock solution was homogeneous with a 1.31 % deviation between the replicates.

B. ANALYSES OF DOSE PREPARATIONS
LSC analyses confirmed the mean application rate to be 48.3 mg glyphosate/cm^2. The dose preparations had low variability between the replicates analysed (1.66 – 6.26 %) and, considering the physical nature of the preparation, the dose preparations were considered to have acceptable homogeneity.

C. MEMBRANE INTEGRITY CHECK
Based on the ER measurements eight cells with abraded skin samples were selected for the absorption study.

D. DERMAL ABSORPTION OF GLYPHOSATE
Absorption profiles were assessed from eight abraded skin samples. Since one skin sample showed an atypical absorption profile, this was excluded from the calculation of means and SD.

The determined distribution of radioactivity are summarised in the table **Error! Reference source not found.**below.

Table 5.8.2-56: Glyphosate acid - *In Vitro* Absorption through Abraded Rabbit Skin using [^{14}C]-glyphosate ([redacted], 2012): Summary of results for dermal absorption of ^{14}C-glyphosate

Dose preparation		
Applied dose "wet cake" [mg/cm^2]	79.8	
Applied dose glyphosate [mg/cm^2]	48.3	
Number of cells assessed	7	
	Distribution of radioactivity (mean values)	
	µg/cm^2	% of applied dose
Surface compartment		
Dermis (after heat separation)	118 ± 19.4	0.243 ± 0.040

Skin wash at 6 hours	42802 ± 3008	87.9 ± 6.30
Skin wash at 24 hours	1159 ± 1224	2.38 ± 2.51
Donor chamber	59.2 ± 56.9	0.121 ± 0.117
Receptor compartment		
Receptor fluid 0 – 24 h	1177 ± 244	2.42 ± 0.503
Total absorbed*	**1177**	**2.42**
Epidermis (after heat separation)	20.1 ± 9.97	0.041 ± 0.020
Flange area	132 ± 68.6	0.270 ± 0.141
Total potentially absorbable**	**1295**	**2.663**
Total recovery	**45468 ± 2096**	**93.3 ± 4.46**
Absorption rates 0 – 24h [µg/cm²/h]	53.1 ± 10.2	-

SD: Standard deviation; * Amount in receptor fluid; ** Total potentially absorbable = total absorbed + remaining dermis (after heat separation)

The total recovery of the individual cells was in the range of 87.3 % to 98.2 %, with an overall mean recovery of 93.3 % of applied dose.

The majority of the applied glyphosate acid (mean 87.9 %) was washed off the skin at 6 hours, with a further 2.38 % washed off at 24 hours. A small proportion (0.041 %) of the dose applied was recovered from the epidermis, with 0.243 % remaining in the dermis.

The mean rate of absorption of glyphosate acid between 0-1 hours was 47.0 µg/cm²/h, which increased to 166 µg/cm²/h between 1 – 4 hours. The mean absorption rate subsequently slowed to 72.3 µg/cm²/h between 4-10 hours and declined further to 13.3 µg/cm²/h for the remainder of the absorption period (10 – 24 hours). The overall absorption rate (0 – 24 hours) was 53.1 µg/cm²/h.

The mean amount of glyphosate acid that penetrated abraded rabbit skin into the receptor fluid over the entire 24-hour experimental period was 1177 µg/cm², corresponding to 2.42 % of the applied dose.

Considering that the amount found in the remaining dermis after 24 h was potentially available and could further penetrate through the skin, the total amount of glyphosate potentially available was 2.66 % of the applied dose.

3. Assessment and conclusion

Assessment and conclusion by applicant:

In this study, the *in vitro* percutaneous absorption of glyphosate acid through abraded rabbit skin was assessed following a 6-hour exposure period and a subsequent 18 hour monitoring period. The study was conducted according to OECD 428 (2004) and in compliance with GLP regulations. There were no deviations from OECD 428 (2004). Therefore, the study was considered valid.

The results of this *in vitro* study indicate the dermal absorption of glyphosate through abraded rabbit skin is slow. The vast majority of glyphosate will be washed off during normal washing procedures. The mean total amount absorbed after 24 hours was 2.42 % of the applied dose. The reported total potentially absorbable amount, represented by the mean absorbed dose together with the mean amount in the remaining dermis was 2.66 % of the applied dose. Applying this to the repeated dose rabbit dermal toxicity NOAEL of 5000 mg/kg bw/day in Johnson (CA 5.3.3/008) a systemic NOAEL in rabbit repeated dose studies is determined to be 133 mg/kg bw/day.

Assessment and conclusion by RMS:

RMS should indicate if they agree to the results and conclusions of the APPL.

Literature evaluation

A literature search for the active substance glyphosate was performed in accordance to the provisions of

the EFSA Guidance "Submission of scientific peer-reviewed open literature for the approval of pesticide active substances under Regulation (EC) 1107/2009" and updated Appendix to this Guidance document. The following publications were found relevant and reliable for this section and the summaries are thus presented below and are part of the general discussion at the beginning of the section.

Table 5.8.2-57: Publications on toxicological effects of glyphosate

2. Full summary

In this study the toxicity of glyphosate for liver and cardiac organoids was investigated in the concentration range from 25 µM to 25 mM. The endpoints considered were cell viability, ATP activity and beating rate of the cardiomyocytes. Glyphosate was shown to reduce organoid integrity and viability at doses from 250 µM to 2.5 mM. The IC_{50} values based on ATP activity of liver and cardiac organoids were found to be 10.53 and 10.85 mM, respectively. When cardiac organoids were exposed to glyphosate at 0.25 mM a non-statistically significant effect was found on beating rate. Exposure to 2.5 mM for 2 days resulted in all organoids stopping beating.

I. MATERIALS AND METHODS

Test material
The purity and source of glyphosate were not reported.

Liver and cardiac cell sources, culture and organoid formation
For liver organoids, all cells used were commercially sourced, human primary cells. Hepatic stellate cells (HSCs) were expanded in culture for two passages before cryopreservation for use in organoid formation. During expansion, HSCs were cultured in 90 % high glucose DMEM and 10 % fetal bovine serum on a rat tail collagen I coating (10 g/cm^2) at 37 °C with 5 % CO_2. Primary human hepatocytes were thawed according to the manufacturer's instructions using hepatocyte thawing medium. Kupffer cells were also thawed following the manufacturer's instructions. After thawing, primary human hepatocytes were plated on collagen coated (10 g/cm^2) 6-well culture plates, using hepatocyte plating medium at a density of ~ 150,000 cells/cm^2. Cells were incubated at 37 °C with 5 % CO_2 for 4 hours before adding matrigel as an overlay. Following further incubation for 24 hours, fresh HCM medium was added. For cardiac organoids,

induced pluripotent stem cell-derived cardiomyocytes (iPSC CMs) were commercially sourced from Axiogenesis (cat. #COR.4U Cardiomyocytes). Human primary cardiac fibroblasts were commercially sourced from ScienCell (cat. #6330). Prior to organoid formation, iPSC CMs were cultured on tissue culture plastic for 48 hours in COR.4U medium until cells began beating spontaneously. At this point, iPSC CMs were harvested using trypsin-EDTA. The liver cells were combined in a cell seeding mixture comprised of 90 % HCM medium, 10 % heat-inactivated fetal bovine serum, and rat tail collagen I (10 ng/µL). Liver organoids were produced with a mixture of 80 % hepatocytes, 10 % hepatic stellate cells, and 10 % Kupffer cells. Approximately 1,500 cells per 40 µL medium were used to form aggregates in each well of non-adherent, round-bottom, 96-well plates to produce spherical organoids. Cardiac organoids were produced similarly. IPSC CMs were suspended in cardiomyocyte maintenance medium. Fibroblasts were added as 10 % of the total cell number, and the volume was adjusted to reach a cell density of 10,000 cells/mL. 100 µL of cell suspension was pipetted into each well of non-adherent, round-bottom, 96-well plates to produce spherical organoids resulting in approximately 1,000 cells/organoid. Well plates were incubated and observed daily until organoid formation, and then immediately used in experiments.

Preparation of test item stock solutions
Glyphosate was dissolved in DI H_2O for environmental toxins to reach 50 mM. Serial dilutions were performed in media for each cell type until all concentrations were created at 2X final concentration. Glyphosate was assessed in the concentration range from 25 µM to 25 mM.

Live/dead staining
Organoids were isolated from 96-well low adhesion round bottom plates, suspended in Hystem hydrogel in a 20 µL construct, and placed into 12-well plates to immobilize organoids in a 3D extracellular matrix environment. Each concentration of glyphosate premixed at 1X concentration in media according to organoid type was added to individual wells and organoids were allowed to incubate under their respective conditions for 2 days at 37 °C with 5 % CO_2. Studies were performed using n = 5 or higher for all conditions. Medium was then removed and organoids were assessed by LIVE/DEAD® Viability/Cytotoxicity Kit assays. Specifically, 2.0 µM calcein AM and 4.0 µM ethidium homodimer in PBS was added to each well and was allowed to incubate for 1 hour. Imaging was then performed by macro-confocal microscopy and composite images were created with ethidium bromide red fluorescence representing dead nuclei and calcein AM green fluorescence representing live cells.

ATP activity assays
Glyphosate was added in a premix 2× concentration of 100 µL solution to each well of a 96-well plate containing an organoid with 100 µL of medium and allowed to incubate for 2 days at 37 °C with 5 % CO_2 with n = 6 or higher. Medium was then removed from each well leaving 100 µL of media remaining along with the organoid. Next, 100 µL of Cell-Titer Glo Luminescent Cell Viability Assay solution was added to each well along with 100 µL added to 100 µL DMEM in a Costar Black Polystrene 96-well assay plate and allowed to incubate for 10 minutes at room temperature shielded from light. The entire contents of the wells containing organoids were then added to the Costar Black Polystrene 96-well assay plate wells and the contents were read on a Vertias Microplate Luminometer using default settings. Values were then averaged among the different groups and graphed for analysis using Graph Pad Prism© software.

Heart beat assay
Fully formed cardiac organoids in the wells of a 96-well non-adhesive round bottom plate were placed under a Leica DMIL LED microscope to allow for the recording of natural beat rates in 20 s videos (n = 3). The plate was then returned to the 37 °C, 5 % CO_2 incubator for 5 minutes to ensure that organoids did not experience significant temperature decreases, which can detrimentally impact beating rates. The process was repeated until all experimental subject organoids under the test compound concentrations described above, but at varying time points, had been recorded. Glyphosate was added as 2 × 100 µL concentration to each well of a 96-well low adhesion round bottom plate containing 100 µL of normal medium with a cardiac spheroid, and allowed to incubate for 30 minutes at 37 °C. The plate was then recorded, 3 organoids at a time, in the process listed above until all organoids were recorded and the plate was returned to the incubator. The process was then repeated 24 and 48 hours later. The 20 s videos were then analyzed by

counting the beats for each video and multiplied by 3 to scale values to beats per minute. A beat was defined as the beginning of the contractile movement of the organoid. A beat did not need reach conclusion to be counted. If multiple beating regions were observed then the beating of the largest multi-cell structure was used to calculate the beating rate.

Statistics
The data are generally presented as the means of number of replicates ± SD. All data were graphed and analyzed for significance using a Student's T-test. For ATP activity assays p-values were considered significant when <0.01. For beating kinetic assays p-values were considered significant when <0.05. Data samples were eliminated from the experimental groups if they fell outside of two SDs from the experimental group averages. Sample sizes (generally n = 5 or n = 6, depending on the experiment as described) were determined based on preliminary experiments. These sample sizes, with the typically observed SDs, allowed statistical significance at $\alpha = 0.05$ with statistical power greater than 80 %. The IC_{50} was calculated using the Graph Pad Prism© software.

II. RESULTS AND DISCUSSION

Organoid production and viability
Liver organoids were successfully formed after 4 days whereas it took 7 days for the cardiac organoids to allow for self-propagating beating to occur. Viability for both was confirmed to be greater than 95 % using live/dead imaging.

Organoid viability
Live/dead staining of liver organoids was used to visualize indications of cytotoxicity due to exposure to glyphosate. Integrity and viability of liver organoids began to show a steady reduction when exposed to glyphosate concentrations from 250 µM to 2.5 mM. In contrast, cardiac organoids maintained integrity during all testing, but cell death occurred when exposed to glyphosate concentrations from 2.5 to 25 mM.

Organoid ATP activity
After testing original three doses (n ≥6) centered on doses described in the literature, two further trials narrowed the range containing the IC_{50}. The IC_{50} values were found to be similar for cardiac and liver organoids for glyphosate, i.e. 10.85 and 10.53 mM, respectively. For liver organoids, 10 mM of glyphosate resulted in a statistically significant decrease in ATP activity (p <0.001) and for cardiac organoids, 5 mM of glyphosate resulted in statistically significant decrease in ATP activity (p <0.001).

Cardiac organoid beating rates
The time points to test physiological reactions to glyphosate exposure were chosen based on previous studies testing calcium channel impairment in 2D cardiomyocyte populations and defined as immediate (30 minutes), short term (1 day), and long term (2 days). Although not statistically significant, glyphosate demonstrated toxicity at 250 µM and higher, with beat rates at 250 µM slowing on day one among all organoids and two of the three organoids ceasing beating on day 2. At 2.5 mM, exposure for one day caused two spheroids to cease beating entirely, with one-third showing a 50 % reduction in beat rate. By day 2 all organoids ceased beating.

Study conclusion
Glyphosate live/dead imaging varied greatly, with significant cell death in liver organoids and little cell death in cardiac organoids at 2.5 mM. ATP values recorded at 10 mM showed a large difference between liver and cardiac organoids (0.568 and 0.804, respectively), displaying a more gradual decrease in cell viability for the liver organoids as compared to the cardiac organoids. The IC_{50} values of liver and cardiac organoids were found to be similar i.e. 10.53 and 10.85 mM, respectively. When cardiac organoids were exposed to glyphosate at concentrations from 0.25 mM on an effect on beating rate was observed with a complete stop of beating at 2.5 mM after 2 days of exposure.

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study the toxicity of glyphosate for liver and cardiac organoids was investigated in the concentration range from 25 µM to 25 mM. The endpoints considered were cell viability, ATP activity and beating rate of the cardiomyocytes. Glyphosate was shown to reduce organoid integrity and viability at doses from 250 µM to 2.5 mM. The IC_{50} values based on ATP activity of liver and cardiac organoids were found to be 10.53 and 10.85 mM, respectively. When cardiac organoids were exposed to glyphosate at 0.25 mM a non-statistically significant effect was found on beating rate. Exposure to 2.5 mM for 2 days resulted in all organoids stopping beating.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate used was not characterized, no positive controls were used to validate the organoid test systems and the concentrations at which most of the effects have been observed are physiologically not feasible in *in vivo* experimental models.

2. Full summary

Currently, the health risk assessment of pesticides in the European Union and in the United States focuses almost exclusively on the stated active principle. Nonetheless, adjuvants can also be toxic in their own right with numerous negative health effects having been reported in humans and on the environment. Despite the known toxicity of adjuvants, they are regulated differently from active principles, with their toxic effects being generally ignored. Adjuvants are not subject to an acceptable daily intake, and they are not included in the health risk assessment of dietary exposures to pesticide residues. Here, this gap in risk assessment by reference to glyphosate, the most used pesticide active ingredient is illustrated. The case of neonicotinoid insecticides, which are strongly suspected to be involved in bee and bumblebee colony collapse disorder is also investigated. Authors of studies sometimes use the name of the active principle (for example glyphosate) when they are testing a commercial formulation containing multiple (active principle plus adjuvant) ingredients. This results in confusion in the scientific literature and within regulatory circles and leads to a misrepresentation of the safety profile of commercial pesticides. Urgent action is needed to lift the veil on the presence of adjuvants in food and human bodily fluids, as well as in the environment (such as in air, water, and soil) and to characterize their toxicological properties. This must be accompanied by regulatory precautionary measures to protect the environment and general human population from some toxic adjuvants that are currently missing from risk assessments.

I. MATERIALS AND METHODS

Test Material
Glyphosate (purity ≥96 %) was purchased from Sigma-Aldrich, Gillingham, Dorset, UK.

HepaRG cell culture
Differentiated HepaRG™ cells (HPR 116) were purchased from Biopredic International (Rennes, France). Cells were thawed, suspended and plated in general purpose medium (Williams' E medium + GlutaMAX™) containing the ADD670 supplement. Cells were kept in general purpose medium until day 8, when the culture becomes well organized and includes well-delineated trabeculae and many canaliculi-like structures. At this time, the culture is composed of primitive biliary epithelial cells and mature hepatocytes with basal metabolic activities similar to freshly isolated primary cells. From day 8 to day 14, cells were switched to the test medium composed of Williams' E medium + GlutaMAX™ supplemented with 2 % fetal bovine serum and 1 % DMSO, as well as different concentrations of glyphosate or solvent as a control. Glyphosate was tested at 0.06 µM (concentration representative of low environmental exposure), 6 µM, and 600 µM.

Library generation and RNA-sequencing
A 100 ng aliquot of total RNA from each sample was used to prepare total RNA libraries using the KAPA Stranded RNA-Seq Kit with RiboErase, and samples were randomised before preparation. Polymerase chain reaction (PCR) was performed for 14 cycles for final library amplification. Resulting libraries were quantified using the Qubit 2.0 spectrophotometer and average fragment size assessed using the Agilent 2200 Tapestation. The transcriptome of HepaRG cells exposed to glyphosate was sequenced employing this strategy, except that the libraries were prepared as previously described. A total of 3 separate sequencing pools were created using equimolar quantities of each sample with compatible indexes: 2 with 17 samples each, and one with 16 samples. Paired-end reads of 75bp were generated for each library using the Illumina NextSeq®500 in con-junction with the NextSeq®500 v2 high-output 150-cycle kit.

Mass spectrometry-based metabolomics
Approximately 5,000,000 hepaRG cells per sample were harvested from the 6 well-plates to obtain a sufficient quantity of material to perform the metabolomics experiment. Cells were detached using 0.05 % trypsin EDTA, and centrifuged to eliminate trypsin residues. Finally, cell pellets were frozen at -80 °C pending analysis. Metabolomics analysis of the frozen cell pellets was conducted by Metabolon Inc. The sample extracts were stored overnight under nitrogen before preparation for analysis. The resulting extract was analysed on four independent instrument platforms: two different separate RP/UPLC-MS/MS with positive ion mode electrospray ionization (ESI), a RP/UPLC-MS/MS with negative ion mode ESI, as well as by hydrophilic-interaction chromatography(HILIC)/UPLC-MS/MS with negative ion mode ESI as previously described. Compounds were identified by comparison to library entries of purified standards or recurrent unknown entities. Biochemical identifications are based on 3 criteria: retention index within a narrow retention time/index (RI) window of the proposed identification, accurate mass match to the library +/- 10 ppm, and the MS/MS forward and reverse scores between the experimental data and authentic standards. The use of all three data points can be utilized to distinguish and differentiate biochemicals. Peaks were quantified using the area-under-the-curve method.

Statistics
Metabolome data analysis was performed using in-house services of Metabolon Inc. Biochemical data were normalized with respect to protein concentration as determined by the Bradford assay. The Welch's two-sample t-test was used to test whether control and treatment group means are different from two independent populations. This version of the two-sample t-test allows for unequal variances. FDR methods and estimated q-values were used to account for the highest number of false positive results caused by the high number of statistical tests. The RNA-seq data analysis was performed using the new version of the Tuxedo protocol with HISAT2, StringTie and Ballgown. A standard linear model-based comparison of transcript abundance was performed without adjusting for other covariates to identify differentially

expressed transcripts for each group. Although 3 concentrations were tested for glyphosate, no multigroup comparisons were used because dose spacing was too large to allow reliable conclusions to be drawn from these methods. Instead, pairwise comparisons were used.

II. RESULTS AND DISCUSSION

Control, untreated cell cultures presented no visible signs of aging after a 6-day exposure. Transcriptome profiles of HepaRG cells were then determined using the Illumina-based RNA sequencing platform. The highest concentration of glyphosate tested caused significant changes in transcriptome profiles. Alterations in gene expression caused by the 2 lowest concentrations (0.06 and 6 µM) failed to pass the statistical threshold that took into account the high number of tests performed. A total of 7 transcripts had their levels altered ($p < 0.05$) with glyphosate at 600 µM. The number of genes disturbed by the exposure to glyphosate was insufficient to use a functional annotation tool for pathway enrichment analysis. It is not clear if glyphosate lacks hepatic toxic effects at these concentrations or if this experimental design lacks sensitivity to detect hepatic effects of weak toxicants. To further explore changes in liver metabolism caused by glyphosate in greater detail, a global metabolome profiling of HepaRG cells exposed to three concentrations of glyphosate was explored. The Metabolon HD4 platform detected 802 named biochemicals in the HepaRG samples. Overall, glyphosate did not cause significant alterations in metabolome composition. However, exposure did cause a significant decrease in long chain fatty acids (LCFAs) and polyunsaturated fatty acids (PUFAs). HepaRG cells exposed to the lowest concentration of glyphosate tested (0.06 µM) showed the most dramatic effects in the levels of these fatty acids as either significant or trends towards significant lower levels. At the higher glyphosate concentrations of 6 µM and 600 µM, lower lipid levels were also observed but these did not reach statistical significance.

Study conclusion

An in-depth investigation was conducted of transcriptome profile alterations in HepaRG human liver cells caused by exposure to pesticide active ingredients. Glyphosate was found to be only weakly toxic inducing little change in transcriptome profiles. Interestingly, a follow-up metabolomics analysis of HepaRG cells treated with the lowest (0.06 µM) concentration of glyphosate revealed a significant decrease in the levels of LCFAs and PUFAs. Although these findings from an *in vitro* tissue culture model system cannot be readily translated to effects *in vivo*, they are nevertheless indicative of differences in toxicity potency between pesticide ingredients. The exact nature of this low dose effect of glyphosate cannot be determined from this single experiment, but it is possible that at higher concentrations, more overtly toxic mechanisms are masking the effects on lipids. Another possibility is that a saturation effect is occurring once the low dose is exceeded bearing in mind that glyphosate levels found in the HepaRG cells during the metabolomics analysis increased by 3.7- and 336.35-fold at the intermediate and highest concentrations tested compared to the negative controls. Glyphosate was the least toxic of the compounds tested in this study.

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

Together with 3 other herbicide active ingredients (quizalofop-p-ethyl, isoxaflutole and mesotrione) the effect of glyphosate on the transcriptome and metabolome profile of differentiated HepaRG cells was investigated at 0.06, 6 and 600 µM. Glyphosate was found to be only weakly toxic inducing little change in transcriptome profiles when compared with the other herbicides tested. A follow-up metabolomics analysis of HepaRG cells exposed to glyphosate at 0.06 µM revealed a significant decrease in the levels of long chain fatty acids (LCFAs) and polyunsaturated fatty acids (PUFAs). At the higher glyphosate concentrations of 6 and 600 µM, lower lipid levels were also observed but these did not reach statistical significance. It is not clear, however, how these findings from an *in vitro* tissue culture model can be

translated to effects *in vivo*.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because no positive control was used and no cytoxicity tests were performed to optimise the concentration range to be explored.

Assessment and conclusion by RMS:

CA 5.8.3 Endocrine disrupting properties

Glyphosate was investigated for potential endocrine disrupting properties in several guideline- and GLP-conform *in vitro* and *in vivo* studies. In an androgen receptor binding assay, glyphosate did not show any activity for androgen receptor binding (CA 5.8.3/001). No interaction of glyphosate with the estrogen receptor (ER) was determined in an ER binding assay (CA 5.8.3/003); and no evidence of agonistic activity on the human ERα was identified in an ER transcriptional activation assay (CA 5.8.3/002). Further, a human recombinant aromatase assay revealed no inhibitory effect of glyphosate on aromatase activity (CA 5.8.3/004); and in a H295R steroidogenesis assay glyphosate was tested negative for changes in testosterone as well as 17β-estradiol production, demonstrating that glyphosate does not impact hormone production (CA 5.8.3/009).

A literature search resulted in six ~~four~~ publications, which investigated the effects of glyphosate exposure on granulosa, adipose stromal, TM4 Sertoli, MCF-7, MDA-MB-231, T47D, JEG3, VM7Luc4E2 and T47D-KBluc cells. The results of these non-guideline *in vitro* studies suggested that glyphosate partly interfered with main functional parameters of these cells (e.g. mitochondrial enzymatic activity; estrogen response element (ERE)-mediated transcription of genes, altered gene expression of genes involved in cell cycle regulation, stimulation by steroid hormones and cell death; ERα protein expression). No estrogenic activity was observed in two cell lines or via the two human estrogen receptor (hER) subtypes, hERα and hERβ. The effects of glyphosate on cell viability and cell proliferation were heterogeneous in these publications. For most of the effects no concentration-response relationship could be established. However, some authors concluded that glyphosate could affect reproductive function. Others stated that the effects were only observed at high concentrations *in vitro* and humans exposed to glyphosate would not exhibit effects at realistic exposure levels (CA 5.8.3/012; CA 5.8.3/013, CA 5.8.3/014, CA 5.8.3/015, CA 5.8.3/018). The six ~~four~~ publications on cellular effects of glyphosate are summarized in a table presented above the first publication in the respective summary section (CA 5.8.3/012).

The effects reported in the literature could not be corroborated by any *in vivo* regulatory toxicology study. In an uterotrophic assay in ovariectomized rats, glyphosate did not demonstrate biological activity consistent with agonism of natural estrogens when administered orally at doses up to 1000 mg/kg bw/day (CA 5.8.3/005). Similarly, a pubertal development and thyroid function assay in intact juvenile/peripubertal female rats did not reveal any glyphosate-related estrogenic or anti-estrogenic effects, nor was there any evidence of direct test substance-related effects on pubertal development or thyroid function following oral administration of glyphosate at doses up to 1000 mg/kg bw/day (CA 5.8.3/008). When male rats were orally exposed to glyphosate at doses up to 1000 mg/kg bw/day, neither in a Hershberger assay in peripubertal orchidoepididymectomized rats (CA 5.8.3/006) nor in a pubertal development and thyroid function assay in intact juvenile/peripubertal male rats (CA 5.8.3/007) any androgenic or anti-androgenic effects or evidence of primary glyphosate-related effects on pubertal development or thyroid function could be observed.

Further, an assessment on the potential endocrine disrupting properties of glyphosate in accordance with Commission Regulation (EU) 2018/605 and a (Q)SAR screening under the guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009 were performed. Glyphosate has not been shown to induce EATS-mediated adversity and no EATS-related endocrine activity was observed *in silico, in vitro,* and *in vivo* for humans and mammals as well as for non-target organisms (CA 5.8.3/010, CA 5.8.3/011).

In summary, glyphosate was negative for estrogen, androgen, thyroid, and steroidogenesis (EATS)-mediated endocrine disrupting properties based on the results of the regulatory endocrine-studies performed. The effects reported in a limited number of publications *in vitro* were not consistent with the findings of the valid OCSPP and OECD guideline studies.

Table 5.8.3-1: Studies on endocrine disrupting properties with glyphosate

Annex Point	Study	Study type	Substance(s)	Reference list- related category§	Result
CA 5.8.3/001	[redacted] 2012	*in vitro:* Androgen receptor binding assay	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	Glyphosate did not show any activity for androgen receptor binding.
CA 5.8.3/002	[redacted] 2012	*in vitro:* Estrogen receptor alpha transcriptional activation assay	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	Glyphosate did not act as an agonist of the human estrogen receptor alpha (hERα), showing less than 10 % of the induction potential of 17β-estradiol at the highest concentration tested.
CA 5.8.3/003	[redacted], 2012	*in vitro:* Estrogen receptor binding assay	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	Glyphosate did not show any activity for estrogen receptor binding.
CA 5.8.3/004	[redacted] 2012	*in vitro:* Aromatase assay	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	Increasing concentrations of glyphosate (10^{-10} M to 10^{-3} M) showed no decrease in aromatase activity. The mean aromatase activity at all tested glyphosate concentrations was ≥ 99.67 % compared to control. Therefore, glyphosate did not inhibit aromatase activity.
CA 5.8.3/005	[redacted], 2012	*in vivo:* Uterotrophic assay	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	Glyphosate did not demonstrate or mimic biological activities consistent with agonism of natural estrogens at all applied doses including the limit dose of 1000 mg/kg bw/day.
CA 5.8.3/006	[redacted] 2012	*in vivo:* Hershberger assay	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	Glyphosate was negative for androgenicity and anti-androgenicity in the Hershberger assay all applied doses including

					the limit dose of 1000 mg/kg bw/day.
CA 5.8.3/007	[redacted] 2012	*in vivo:* Pubertal development and thyroid function in intact juvenile/ peripubertal male rats, Crl:CD(SD)	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	There was no evidence of any direct glyphosate -related androgenic or anti-androgenic effect, nor was there any evidence of direct glyphosate-related effects on pubertal development or thyroid function at all applied doses including the limit dose of 1000 mg/kg bw/day.
CA 5.8.3/008	[redacted], 2012	*in vivo:* Pubertal development and thyroid function in intact juvenile/ peripubertal female rats, Crl:CD(SD)	Glyphosate acid (Batch: GLP-1103-21149-T, Purity: 95.93 % glyphosate acid, 85.14 % calculated glyphosate content)	Valid, Category 2a	There was no evidence of any glyphosate-related estrogenic or anti-estrogenic effect, nor was there any evidence of glyphosat-related effects on pubertal development or thyroid function at all applied doses including the limit dose of 1000 mg/kg bw/day.
CA 5.8.3/009	Hecker *et al.*, 2011	*in vitro:* Steroidogenesis assay	Glyphosate, not further specified	Valid, Category 2a	Glyphosate did not alter estradiol and testosterone production in the H295R steroidogenesis assay.
CA 5.8.3/010	[redacted] [redacted] [redacted]., 2020	Assessment on the endocrine disrupting properties of the active substance glyphosate in accordance with Commission Regulation (EU) 2018/605	Glyphosate	Valid, Category 1	Glyphosate has not been shown to induce EATS-mediated adversity or endocrine activity in humans, mammals, and non-target organisms.
CA 5.8.3/011	[redacted], 2020	(Q)SAR screening on endocrine disrupting potential of Glyphosate under the Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009	Glyphosate	Valid, Category 1	Five QSAR tools (OECD QSAR Toolbox, Vega, Endocrine Disruptome, Danish QSAR database and OPERA ToxCast COMPARA/CERAPP consensus models) were applied for predictions of potential endocrine activity of glyphosate. Overall, there is no indication that glyphosate has endocrine disrupting activity.

§: The category describes the acceptability/reliability of the study within the AIR 5 submission. This category does not describe

hazard classification. (for details please refer to the Doc ID: 110054-B-GRG_Jun_2020)

2. Full summary of the study according to OECD format

Executive summary

In this androgen receptor (AR) binding assay, ventral prostate cytosol from Sprague Dawley rats was used as source of AR to conduct both a saturation binding experiment and a competitive binding experiment. The saturation binding experiment was conducted to demonstrate that the AR isolated from rat prostate cytosol was present in reasonable amount and was functioning with appropriate affinity for the radiolabelled reference androgen (R1881) prior to routinely conducting AR competitive binding experiments. The competitive binding assay was conducted to measure the binding of a single concentration of [^{3}H]-R1881 (1 nM) in the presence of increasing concentrations of glyphosate (ranging from 10^{-10} to 10^{-3} M). The assay included dexamethasone as weak positive control and unlabelled R1881 as positive control (or non-labelled receptor ligand).

Three valid runs of the assay were completed. All concentrations were tested in triplicates. In the first valid,

independent run, the mean specific binding of [^{3}H]-R1881 was >95 % at every glyphosate concentration tested, except for 10^{-9} M, classifying it as a "non-binder" for this run. The mean specific binding of [^{3}H]-R1881 for 10^{-9} M glyphosate was 66.5 %. However, this was due to a clear outlier where the hydroxyapatite pellet might have been lost. Excluding this value, a mean specific binding of 96.0 % was determined, which concurs with the other runs. In the second and third valid runs, the mean specific binding of [^{3}H]-R1881 was >93 % and >92 %, respectively, classifying glyphosate as a "non-binder" in both runs. The weak positive control dexamethasone had a $LogIC_{50}$ of -4.6 M in each of the three runs. The $LogIC_{50}$ of R1881 was -9.0 M, -9.1 M and -9.0 M in the first, second, and third run, respectively.

Under the conditions of the present study, glyphosate was classified as a "non-binder" in all three valid runs resulting in a final classification of a non-binder to the androgen receptor.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6
Description:	White crystalline solid
Lot/Batch No.:	GLP-1103-21149-T
Purity:	95.93 % glyphosate acid 85.14 % calculated glyphosate content
Stability of test compound:	Not reported. Expiry 2012-03-09
Vehicle and positive controls:	
Solvent/vehicle used:	Low salt TEDG buffer (10 mM Tris, 1 mM sodium molybdate, 1.5 mM EDTA, 10 % glycerol, and 1 mM DTT, pH 7.4)
Positive Control (non-labelled receptor ligand):	R1881 Source: Sigma-Aldrich Lot/Batch No.: 060M4638 Purity: 98 % CAS No.: 965-93-5 Solvent used: DMSO
Weak Positive Control:	Dexamethasone Source: Sigma-Aldrich Lot/Batch No.: 1419230 Purity: 98.9 % CAS No: 50-02-2 Solvent used: DMSO
Radioactive receptor ligand:	
Identification:	[^{3}H]-R1881
Source:	Perkin-Elmer
Lot/Batch No.:	653698
Radiochemical Purity:	>97 %
Specific activity:	85.1 Ci/mmol, certification date 2011-02-24
Solvent used:	Working Assay buffer = TEDG+PI buffer (10 mM Tris, 1 mM sodium molybdate, 1.5 mM EDTA, 10 % glycerol, 1 mM DTT, and 0.5 % Protease Inhibitor (PI) (v/v), pH 7.4)

Test system: Rat ventral prostate cytosol was prepared from male Sprague Dawley rats (90 days of age) castrated at most one day prior delivery/ preparation. The prostate tissue was inspected for healthy appearance and excess fascia were trimmed if necessary. The prostates were weighed, placed in ice-cold TEDG buffer, and homogenized. The cytosol was isolated, pooled, and kept ice-cold. The protein concentration was 8.8 mg/mL.

Test concentrations: Serial dilutions of glyphosate, the reference standard R1881, and the weak positive control dexamethasone were prepared to achieve the concentrations shown in the table below.

Table 5.8.3-2: Glyphosate: Androgen Receptor Binding (Rat Prostate Cytosol) Screening Assay ([redacted] 2012): Competitor final molar (M) concentrations in competitive binding assay[1, 2]

Positive control R1881	Weak positive control Dexamethasone	Test substance Glyphosate
1×10^{-6}	1×10^{-3}	1×10^{-3}
1×10^{-7}	1×10^{-4}	1×10^{-4}
1×10^{-8}	1×10^{-5}	1×10^{-5}
1×10^{-9}	1×10^{-6}	1×10^{-6}
1×10^{-10}	1×10^{-7}	1×10^{-7}
1×10^{-11}	1×10^{-8}	1×10^{-8}
-	1×10^{-9}	1×10^{-9}
-	1×10^{-10}	1×10^{-10}

[1] Each sample contained 10 µL of the solvent control, positive control (non-radiolabelled R1881), weak positive control, or test substance (with the exception of tubes used to evaluate non-specific binding, which contained 30 µL (100X) of non-radiolabelled R1881), 50 µL of triamcinolone acetonide, 30 µL [^{3}H]-R1881, and 300 µL of prostate cytosol.
[2] Each concentration of each chemical was run in triplicate.

B. STUDY DESIGN AND TEST PERFORMANCE

Experimental dates: 2011-10-25 to 2011-11-01

Saturation (radioligand) binding experiment
A saturation binding experiment measuring total and non-specific binding of [^{3}H]-R1881 was performed to demonstrate that the AR was present in reasonable amount and had the appropriate affinity for the R1881 ligand. The methods and results from the saturation binding experiment were not included in the final study report. However, a statement of the laboratory verifying that the saturation binding curve data were acceptable according to the US EPA OPPTS/OCSPP 890.1150 (2009) was included in the appendix of the study report.

Competitive binding experiment
The competitive binding experiment was performed to measure the binding of a single concentration of [^{3}H]-R1881 (final concentration 1 nM), to the AR in the presence of increasing concentrations of glyphosate. A summary of the experimental conditions for the competitive binding experiment is presented in the table below. The specific activity of [^{3}H]-R1881 was adjusted for decay over time prior to each run. The adjusted specific activity was 82.0, 82.0, and 81.9 Ci/mmol for the first, second, and third run of the assay, respectively. Each assay consisted of three independent runs conducted on three different days, and each run contained triplicates at each concentration. In addition to glyphosate, concentrations of R1881

(positive control) and dexamethasone (weak positive control) were also evaluated in the competitive binding experiment to ensure that the test system was behaving as expected.

Table 5.8.3-3: Glyphosate: Androgen Receptor Binding (Rat Prostate Cytosol) Screening Assay ([redacted] 2012): Summary of experimental conditions for competitive binding experiment

Source of receptor		Rat prostate cytosol
Concentration of radioligand		1 nM
Concentration of receptor		6.8 mg/mL, sufficient to bind 10 - 15 % of
Concentration of glyphosate (as serial dilutions)		100 pM to 1 mM
Temperature		4 ± 2 °C
Incubation time		16 - 20 h
Composition of assay buffer (TEDG+PI)	Tris	10 mM (pH 7.4)
	EDTA	1.5 mM
	Glycerol	10 % (v/v)
	Protease Inhibitor	0.5 % (v/v)
	DTT	1 mM
	Sodium molybdate	1 mM

C. DATA ANALYSIS

Classification of test material

The classification of glyphosate as a binder or non-binder was made on the basis of the average results of three non-concurrent runs, each of which met the performance criteria. Each run was individually classified as follows:

Binder: The lowest point on the fitted response curve within the range of the data was <50 %.

Equivocal: The lowest point on the fitted response curve within the range of the data was >50 % but <75 % (i.e. radioligand displacement is ≥25 % but <50 %).

Non-Binder: The lowest point on the fitted response curve within the range of the data is >75 % (i.e. <25 % displacement of radioligand), or the data do not fit the model.

Descriptors for receptor binding

In circumstances when AR receptor binding was measured, the following parameters were determined.

- B_{max}: Maximal binding capacity
- K_d: Dissociation constant (nM), measures the affinity of the receptor for its natural ligand.
- IC_{50}: Concentration of the test substance at which 50 % of the radioligand is displaced from the receptor.

II. RESULTS AND DISCUSSION

A. SATURATION BINDING EXPERIMENT

Results from the saturation binding experiment were not provided in the final study report. However, the laboratory provided a statement in the appendix of the study report indicating that the saturation binding curve data were acceptable according to the US EPA OPPTS/OCSPP 890.1150 (2009). Reference control results included in the competitive binding experiment confirm that functional AR was present in sufficient amounts and functioning with appropriate affinity.

Summarised saturation binding data of the performing laboratory were submitted following a request by the US EPA (MRID 48843501). The dissociation constant (K_d) for [^{3}H]-R1881 was 0.613 ± 0.041 nM and the estimated B_{max} was 0.817 ± 0.049 fmol/100 µg protein for the single batch of prostate cytosol that was prepared. The mean and individual K_d values were below the range reported in the US EPA validation program (0.685 to 1.57 nM). However, confidence in these values is high according to the goodness of fit (R^2 = 0.957 - 0.984) and the small variation among runs.

B. COMPETITIVE BINDING EXPERIMENT

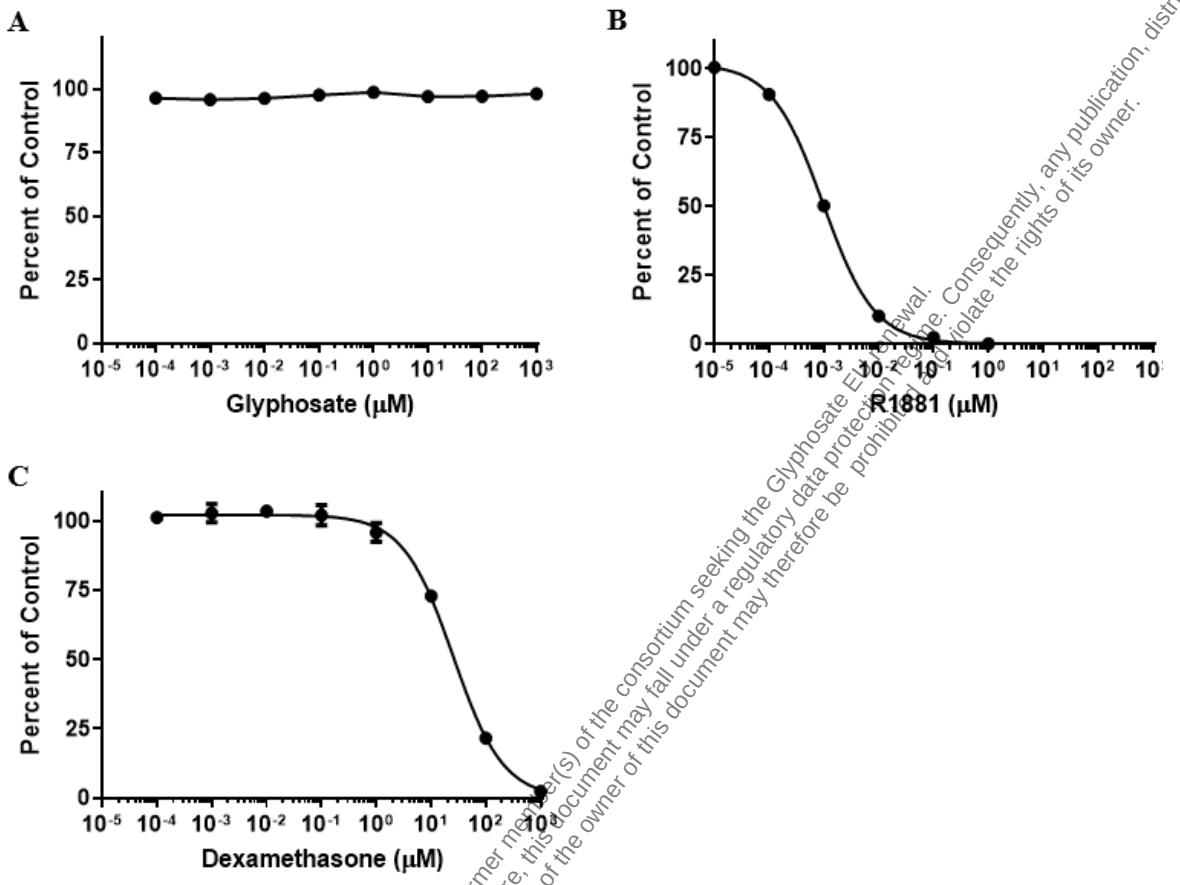
Results from three valid runs of the competitive binding experiment are presented in the table and the figure below. In the first valid, independent run, the mean specific binding of [^{3}H]-R1881 was >95 % at every soluble concentration tested for glyphosate, except for 10^{-9} M, classifying it as a non-binder for this run. The mean specific binding of [^{3}H]-R1881 for 10^{-9} M glyphosate was 66.5 %; however, this was due to a clear outlier where it appeared the hydroxyapatite (HAP) pellet might have been lost. Excluding this value yielded a mean specific binding of 96.0 %, which concurs with the other runs. In the second and third valid, independent runs, the mean specific binding of [^{3}H]-R1881 was >93 and >92 %, respectively, classifying glyphosate as a non-binder in both of these runs. The weak positive control dexamethasone had a $LogIC_{50}$ of -4.6 M in each of the three runs. The $LogIC_{50}$ of R1881 was -9.0 M, -9.1 M and -9.0 M in the first, second, and third run, respectively, demonstrating low variability.

Table 5.8.3-4: Glyphosate: Androgen Receptor Binding (Rat Prostate Cytosol) Screening Assay ([redacted] 2012): Competitive binding assay of glyphosate with androgen receptor from rat prostate cytosol

Parameter	Substance	Run 1[1]	Run 2[1]	Run 3[1]	Mean ± SEM
r^2 (unweighted)	R1881	NR	NR	NR	NA
	Dexamethasone	NR	NR	NR	NA
	Glyphosate	NR	NR	NR	NA
Log IC_{50} (M)	R1881	-9.0	-9.1	-9.0	9.03 + 0.019
	Dexamethasone	-4.6	-4.6	-4.6	-4.6
	Glyphosate	NA	NA	NA	NA
IC_{50} (nM)	R1881	1.0	0.7947	1.0	0.9316 + 0.039
	Dexamethasone	25100	25100	25100	25100
	Glyphosate	NA	NA	NA	NA

[1] The mean is reported for the concurrent replicates within each run.
r^2 = Goodness of fit (r^2 is more appropriately expressed as a range, as opposed to a mean). For the test substance, these parameters could not be calculated.
NR = Not reported.
NA = Not applicable since binding was not evident.

Figure 5.8.3-1: Glyphosate: Androgen Receptor Binding (Rat Prostate Cytosol) Screening Assay ([redacted] 2012): Percent [^{3}H]-R1881 bound to the androgen receptor in the presence of glyphosate (A), unlabelled R1881 (B, strong positive control), or dexamethasone (C, weak positive control) (mean of three valid runs ± SEM)



III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is performed in accordance with the current US OPPTS/OCSPP 890.1150 (2009). The study is therefore considered valid. In the conducted binding studies, glyphosate did not show any activity for androgen receptor binding in all three valid and independent runs of the assay. Thus, glyphosate was classified as a non-binder to the androgen receptor.

Assessment and conclusion by RMS:

CA 5.8.3/002

1. Information on the study

Data point:	CA 5.8.3
Report author	[redacted]
Report year	2012

Report title	Estrogen Receptor Transcriptional Activation (Human Cell Line (HeLa-9903)) Screening Assay with Glyphosate
Report No	6500V-100334ERTA
Document No	CTX-11-028
Guidelines followed in study	US OPPTS/OCSPP 890.1300 (2009), OECD 455 (2009)
Deviations from current test guideline (OCSPP 890.1300, 2009) (OECD 455, 2016)	No major deviations to US OPPTS/OCSPP 890.1300 (2009). Hill slope value for 17α-estradiol, $LogPC_{50}$ and $LogPC_{30}$ value for 17α-methyltestosterone were outside the required range. However, these deviations from the ranges were minor and were not considered to impact the interpretation of results. Following deviations were noted to the current OECD 455 (2016): no ER antagonist assay was performed; demonstration of proficiency was stated but no data were included in study report; vehicle control (DMSO) for positive control was not tested; and some values (see above) were outside the required range. However, these deviations were not considered to affect the final outcome of the ER agonist assay.
Previous evaluation	Yes, accepted in EFSA peer review on endocrine disrupting properties (2017).
GLP/Officially recognised testing facilities	Yes
Comment on GLP	The control and reference substances were not characterised in accordance with Good Laboratory Practice Standards, nor was the stability under storage conditions at the test site determined in accordance with Good Laboratory Practice Standards. However, the substances were purchased from commercial suppliers, and the manufacturers' certificates of analysis were used to define the purity. Verification of the test concentrations, stability and homogeneity of the test, control, and reference substances in the cell culture media were not determined in accordance with Good Laboratory Practice. The test, control, and reference substances were soluble in their vehicles, dosing solutions were prepared immediately prior to use and were shown to be solutions by visual inspection and the control and reference substances met their performance criteria. Therefore, these exceptions do not affect the validity of the study.

Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary of the study according to OECD format

Executive summary

The ability of glyphosate to act as an agonist of human estrogen receptor alpha (hERα) was evaluated in an estrogen receptor (ER) transcriptional activation assay using the hERα-HeLa-9903 cell line. In two valid runs, stably-transfected hERα-HeLa-9903 cells were exposed to glyphosate at concentrations of 10^{-10}, 10^{-9}, 10^{-8}, 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}, and 10^{-3} M in cell culture medium. Preliminary assessments showed that glyphosate concentrations up to 10^{-3} M did not result in any precipitation or cytotoxicity (≥20 % reduction in cell viability). The cells were exposed to the test substance for 24 ± 2 hours and luciferase activity was measured. Each assay run included 17β-estradiol as a positive control and strong estrogen reference substance, 17α-estradiol as a weak estrogen reference substance, 17α-methyltestosterone as a very weak agonist reference substance, and corticosterone as a negative control. The positive control and reference substances induced the appropriate responses, with minor exceptions (Hill slope value for 17α-estradiol,

$LogPC_{50}$ and $LogPC_{10}$ value for 17α-methyltestosterone were slightly outside the required range), and confirmed the sensitivity and performance of the assay.

Glyphosate demonstrated no evidence of interaction with the hERα over the concentration range tested in the HeLa-9903 model system, showing less than 10 % of the induction potential of 17β-estradiol at the highest concentration tested.

Thus, glyphosate was not identified as an agonist of human estrogen receptor alpha (hERα) under the conditions of the present study.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6

Test system: Stably-transfected hERα-HeLa-9903 cells were obtained from the Japanese Collection of Research Bioresources (JCRB) Cell Bank, Osaka, 567-0085, Japan. Cells were free of mycoplasma infection and were maintained in Eagle's Minimum Essential Medium (EMEM) without phenol red, supplemented with 60 mg/L of kanamycin (antibiotic) and 10 % dextran coated-charcoal-stripped foetal bovine serum (DCC-FBS), in a CO_2 incubator (5 % CO_2) at 37 ± 1 °C.
The cells used in the preliminary study, first valid run, and second valid run of the assay were passages 26, 27, and 16 (a new vial from cryopreservation), respectively.

Test concentrations: Six concentrations each of glyphosate, 17β-estradiol, 17α-estradiol, corticosterone, and 17α-methyltestosterone were included in each valid run of the assay as shown in the table below.

Table 5.8.3-5: Estrogen Receptor Transcriptional Activation (Human Cell Line (HeLa-9903)) Screening Assay with Glyphosate ([redacted], 2012): Concentration range of glyphosate and reference substances in the ER transactivation assay

Reference substance	CAS No.	Concentration range (M)	Class
Glyphosate	1071-83-6	10^{-10} - 10^{-3}	Test substance
17β-estradiol	50-28-2	10^{-14} - 10^{-8}	Strong estrogen
17α-estradiol	57-91-0	10^{-12} - 10^{-6}	Weak estrogen
Corticosterone	50-22-6	10^{-10} - 10^{-4}	Negative control
17α-methyltestosterone	58-18-4	10^{-11} - 10^{-5}	Very weak estrogen

B. STUDY DESIGN AND TEST PERFORMANCE

Experimental dates: 2011-09-20 to 2011-10-21

Preliminary cytotoxicity/ precipitation assays
In order to identify a suitable top concentration for use in the ER transcriptional activation assays, preliminary precipitation and cytotoxicity assays were conducted with glyphosate. Cytotoxicity (i.e. ≥20 % reduction in cell viability) was assessed using a two-read propidium iodide uptake assay at the following glyphosate concentrations: 10^{-2} [5], 10^{-6}, 10^{-5} [5], 10^{-5}, 10^{-4} [5], 10^{-4}, 10^{-3} [5], and 10^{-3} M; 125 µM digitonin was used as a positive control for cell death. No precipitation or cytotoxicity was observed by visual inspection at the highest glyphosate test concentration of 10^{-3} M.

ER transcription activation assay
The hERα-HeLa-9903 cells were plated in a 96-well culture plate at a density of ~1 x 10^4 cells/100 µL/well. After a 3-hour (minimum) post-seeding incubation period, the medium was replaced with 150 µL/well of culture medium containing vehicle control (VC), glyphosate, or the reference chemicals at the concentrations identified in the table above. The final concentration of DMSO in the culture medium for the reference substances was held constant at 0.1 % (v/v). Glyphosate dosing solutions were prepared in tissue culture medium. The tissue culture plates were incubated in an incubator under an atmosphere of 5 % CO_2 and at 37 ± 1 °C for 24 ± 2 hours prior to measuring luciferase activity.

C. DATA ANALYSIS

Relative transcriptional activity
Relative transcriptional activity of glyphosate was expressed as percent of the maximally inducing

concentration of the positive control, 1 nM 17β-estradiol.

Data interpretation

The data were interpreted according to the following steps (according to the test guideline):

1. Where appropriate, $LogPC_{50}$, $LogPC_{10}$, $LogEC_{50}$ and Hill slope values were calculated using XLfit from IDBS version 5.2.0.0 (Surrey, UK).
2. For the test substance, the maximum response relative to the positive control (RPC_{max}) was determined. In each individual run of the transcriptional activation assay, if RPC_{max} was <10 %, the test substance was considered to give a negative response for hERα agonism.
RPC_{max} = Maximum level of response induced by a test chemical, expressed as a percentage of the response induced by the positive control (17β-estradiol at 1 nM) on the same plate.
3. For each individual run of the transcriptional activation assay, the acceptability of the data was evaluated using the following criteria:
    a. The mean normalized luciferase signal of the PC (1 nM 17β-estradiol) should be at least 4-fold that of the mean VC on each plate.
    b. The fold induction corresponding to the PC_{10} value of the concurrent PC is greater than 1 + 2 SD of the fold induction value (=1) of the VC. [PC_{10} = Concentration of a test chemical at which the response is 10 % of the response induced by the positive control (17β-estradiol at 1 nM) in each plate.]
    c. The results of the four reference substances should be within acceptable ranges.
4. If the acceptability criteria outlined above were met, that run of the transcriptional activation assay was considered to be valid.
5. The test substance was considered negative if RPC_{max} <10 % in at least two valid runs of the transcriptional activation assay. The test substance was considered positive if RPC_{max} ≥10 % in at least two valid runs of the transcriptional activation assay.

II. RESULTS AND DISCUSSION

A. PRELIMINARY CYTOTOXICITY/ PRECIPITATION ASSAYS

Cytotoxicity for glyphosate did not exceed the defined threshold for cytotoxicity of 20 % reduced cell viability and precipitation of glyphosate was not observed at the highest test concentration of 10^{-3} M. Therefore, the final concentrations of glyphosate tested in the two valid runs of the transcriptional activation assay were 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}, 10^{-8}, 10^{-9}, and 10^{-10} M.

B. ER TRANSCRIPTION ACTIVATION ASSAY

In the main assays, cytotoxicity (≥20 % reduction in cell viability) and precipitation were not observed at any of the tested concentrations of glyphosate. In the two valid, independent runs of the assay, the highest mean induction values for glyphosate (RPC_{max}) were 2.4 ± 1.4 % and 0.8 ± 0.3 % over the concentration range tested in the first and second run (see table and figure below), respectively. These mean induction values were clearly below the criterion for a positive response (i.e. maximum response relative to the positive control, RPC_{max} of glyphosate was <10 % of the induction produced by 1 nM 17β-estradiol) over the concentration range tested. The mean response for 1 nM 17β-estradiol showed a concentration-dependent response with mean induction of approximately 120-fold.

In both valid runs of the assay, the positive control and reference substances induced the appropriate responses meeting the performance standards with some exceptions as follows:

- In the second valid run of the assay, the Hill Slope value for 17α-estradiol was slightly higher than the guideline suggested criteria (2.3 compared to the range of 0.9 to 2.0).
- In both valid runs of the assay, the Log PC_{50} value for 17α-methyltestosterone was not reached. However, induction was able to reach 40.8 - 42.6 % of the positive control.
- In both valid runs of the assay, the Log PC_{10} value for 17α-methyltestosterone was slightly higher than the guideline suggested criteria (-5.9 for both valid runs, compared to the

range of -6.2 to -8.0).

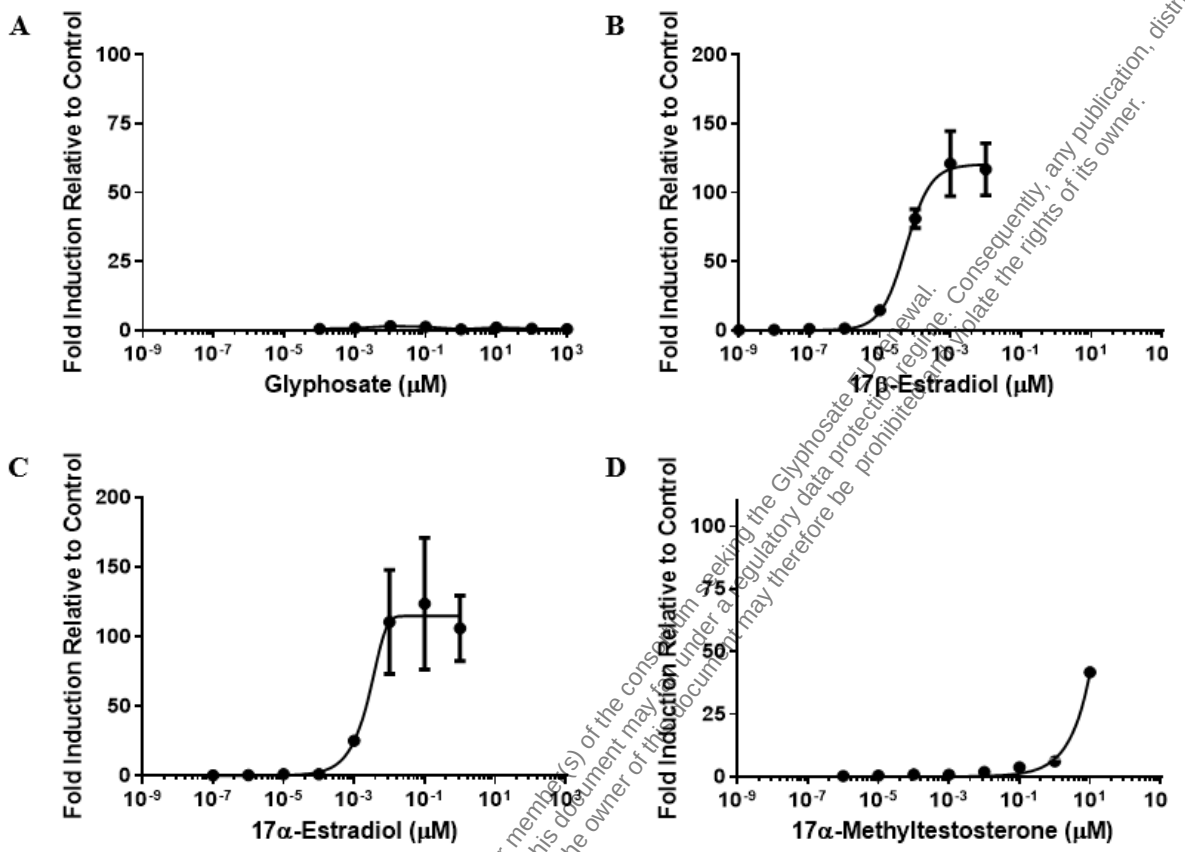
These exceptions were considered minor and not to have affected interpretation and final outcome of the assay results, as the responses of 17β-estradiol, 17α-estradiol, 17α-methyltestosterone, and corticosterone were characteristic of a strong estrogen, a weak setrogen, a weak agonist, and a negative compound, respectively. The US EPA convened a Scientific Advisory Panel (SAP) in 2013 to comment on the significance of minor deviations for performance criteria for the reference substances. The SAP concluded that minor deviations from the performance criteria do not affect the validity of these studies.

Table 5.8.3-6: Estrogen Receptor Transcriptional Activation (Human Cell Line (HeLa-9903)) Screening Assay with Glyphosate ([redacted] 2012): Relative transcriptional activation (RTA) induced by glyphosate

Parameter	RTA (mean ± SD); % of Positive Control (PC)			
	Run 1		Run 2	
Glyphosate concentration (M)	Mean	± SD	Mean	± SD
10^{-3}	0.5	0.8	0.5	0.3
10^{-4}	1.3	1.1	0.3	0.2
10^{-5}	2.4	1.4	0.7	0.3
10^{-6}	1.8	1.1	0.8	0.3
10^{-7}	0.8	1.0	0.0	0.3
10^{-8}	1.8	1.5	0.3	0.3
10^{-9}	1.2	1.6	0.0	0.3
10^{-10}	1.1	1.0	-0.1	0.3
RPC_{max}	2.4 ± 1.4 %		0.8 ± 0.3 %	
PC_{10}	NA		NA	

NA = not applicable and could not be calculated because all responses were below a PC_{10} indicating that glyphosate did not induce estrogen receptor-mediated transactivation.

Figure 5.8.3-2: Estrogen Receptor Transcriptional Activation (Human Cell Line (HeLa-9903)) Screening Assay with Glyphosate ([redacted] 2012): Percent induction following 24 ± 2 h of exposure to glyphosate (A), 17β-estradiol (B, strong positive control), 17 α-estradiol (C, moderately strong positive control), or 17 α-methyltestosterone (D, weak positive control) (mean of two valid assays ± SEM)



III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is performed in accordance with the current US OPPTS/OCSPP 890.1150 (2009) with no major deviations. The study is also performed in accordance with the current OECD 455 (2016), however the following deviations were noted: no ER antagonist assay was performed; demonstration of proficiency was stated but no data were included in study report and vehicle control (DMSO) for positive control was not tested. These deviations were not considered to affect the final outcome of the ER agonist assay. The study is therefore considered valid. Based on the results of the two valid transcriptional activation assays performed in the HeLa-9903 model system, glyphosate did not act as agonist of the human estrogen receptor alpha (hERα) over the concentration range tested (maximum concentration 10^{-3} M). The highest mean induction value of glyphosate was 2.4 ± 1.4 % (RPC_{max}), which is well below 10 % of the response of the positive control (1 nM 17β-estradiol) and represents a negative response for hERα agonism.

Thus, glyphosate was not identified as an agonist of human estrogen receptor alpha (hERα) under the conditions of the present study.

Assessment and conclusion by RMS:

CA 5.8.3/003

1. Information on the study

Data point:	CA 5.8.3
Report author	[redacted]
Report year	2012
Report title	Glyphosate: Estrogen Receptor Binding (Rat Uterine Cytosol) Screening Assay
Report No	6500V-100334ERB
Document No	CTX-11-029
Guidelines followed in study	US OPPTS/OCSPP 890.1250 (2009)
Deviations from current test guideline (OCSPP 890.1250, 2009) (OECD 493, 2015)	None to US EPA OPPTS/OCSPP Test Guideline 890.1250 (2009). Current OECD 493 (2015) is not applicable (present study obtained the estrogen receptor from rat uterine cytosol preparations; OECD 493 (2015) applies to two fully validated human recombinant receptor ERα (hrERα) *in vitro* test methods).
Previous evaluation	Yes, accepted in EFSA peer review on endocrine disrupting properties (2017).
GLP/Officially recognised testing facilities	Yes
Comment on GLP	The control and reference substances were not characterised in accordance with GLP standards, nor was the stability under storage conditions at the test site determined in accordance with GLP standards. However, the substances were purchased from commercial suppliers, and the manufacturers' certificates of analysis were used to define the purity. Verification of the test concentrations, stability and homogeneity of the test, control, and reference substances in the test system were not determined in accordance with GLP. The test, control, and reference substances were soluble in their vehicles, dosing solutions were prepared immediately prior to use, and the control and reference substances met their performance criteria. Therefore, these exceptions do not affect the validity of the study.
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary of the study according to OECD format

Executive summary

In this estrogen receptor binding assay, the ability of glyphosate to interact with the estrogen receptor (ER) was evaluated. Cytosol isolated from Sprague Dawley rat uteri was used as source of ER to conduct a saturation binding experiment and a competitive binding experiment according to US EPA OPTTS test guideline 890.1250 (2009). The saturation binding experiment was conducted to demonstrate that the ER contained in the rat uterine cytosol was present in reasonable amount and was functioning with appropriate affinity for the radiolabelled reference estrogen, [^{3}H]-17β-estradiol, prior to routinely conducting the ER competitive binding experiment. The competitive binding experiment was conducted to measure the binding of a single concentration of [^{3}H]-17β-estradiol (1 nM) to the ER, in the presence of increasing

concentrations of glyphosate (ranging from 10^{-10} - 10^{-3} M). All concentrations were tested in replicates of three. The duration of incubation was 16 - 20 hours at 4 °C.

Four runs were conducted, however, the first run was considered invalid because the results for 17β-estradiol (positive control) did neither fit the guideline-established acceptance criteria nor did they fall within the range of historical data. Mean specific binding was >81 %, >95 %, and >111 % at every concentration of glyphosate tested in the first, second, and third valid runs of the assay, respectively, and averaged >100 % across the concentration range. Glyphosate showed no evidence of competing with estradiol for the ER and was classified as "non-interacting" for all three valid runs.

The weak positive control, 19-norethindrone met the validity criteria for each of the runs, and each assay had a Log IC_{50} value of -5.5 M. The Log IC_{50} values for 17β-estradiol also met the validity criteria and were -9.1 M, -9.0 M and -8.9 M in the first, second, and third valid runs, respectively. The negative control octyltriethoxysilane was correctly concluded not to interact with the ER.

Based on the results of the present Estrogen Receptor Binding Assay, glyphosate is not a ligand for the ER and is classified as not-interacting with the ER.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6
Description:	White crystalline solid
Lot/Batch No.:	GLP-1103-21149-T
Purity:	95.93 % glyphosate acid 85.14 % calculated glyphosate content
Stability of test compound:	Not reported. Expiry: 2012-03-09
Vehicle, positive controls, and negative control:	
Solvent/vehicle:	Assay buffer, i.e. TEDG+PI buffer (composition: 10 mM Tris, 1.5 mM EDTA, 1 mM DTT, 0.5 % Protease Inhibitor (PMSF) (v/v), 10 % glycerol, pH ~7.4)
Positive Control (non-labelled receptor ligand):	17β-estradiol Source: Sigma-Aldrich Lot/Batch No.: 110M0138V Purity: 100 % CAS No.: 50-28-2 Solvent used: DMSO
Weak Positive Control:	19-norethindrone Source: Sigma-Aldrich Lot/Batch No.: 030M1359V Purity: 99 % CAS No.: 68-22-4 Solvent used: DMSO

Negative Control: Octyltriethoxysilane
Source: Sigma-Aldrich
Lot/Batch No.: 24996KK
Purity: 99.34 %
CAS No.: 2943-75-1
Solvent used: DMSO

Radioactive receptor ligand:

Identification: $[^3H]$-17β-estradiol

Source: Perkin-Elmer

Lot/Batch No.: 650702

Radiochemical purity: >97 %

Specific activity: 130.2 Ci/mmol, certification date: 2011-05-06

Solvent used: DMSO

Test system: Rat uterine cytosol prepared from 12 - 13-week old female Sprague Dawley rats ovariectomized seven days prior to being euthanized. Uterine tissue was inspected for signs of residual ovarian tissue after ovariectomy. The uteri were weighed, placed in ice-cold TEDG+PI buffer, and homogenized. The cytosol was isolated, pooled and kept ice-cold. The protein concentration of the cytosol was 1.1 mg/mL.

Test concentrations: Dilutions of glyphosate, 19-norethindrone, octyltriethoxylsilane, 17β-estradiol are shown in the table below.

Table 5.8.3-7: Glyphosate: Estrogen Receptor Binding (Rat Uterine Cytosol) Screening Assay ([redacted] 2012): Competitor final molar (M) concentrations in competitive binding assay[1, 2]

Positive Control 17β-Estradiol	Weak Positive Control 19-Norethindrone	Negative Control Octyltriethoxysilane	Test Substance Glyphosate
1.0×10^{-7}	1.0×10^{-4}	1.0×10^{-3}	1.0×10^{-3}
1.0×10^{-8}	3.16×10^{-5}	1.0×10^{-4}	1.0×10^{-4}
3.16×10^{-9}	3.16×10^{-6}	1.0×10^{-5}	1.0×10^{-5}
1.0×10^{-9}	1.0×10^{-6}	1.0×10^{-6}	1.0×10^{-6}
3.16×10^{-10}	3.16×10^{-7}	1.0×10^{-7}	1.0×10^{-7}
1.0×10^{-10}	1.0×10^{-7}	1.0×10^{-8}	1.0×10^{-8}
1.0×10^{-11}	3.16×10^{-8}	1.0×10^{-9}	1.0×10^{-9}
-	3.16×10^{-9}	1.0×10^{-10}	1.0×10^{-10}

[1] Each sample contains: 10 µL of either the test substance, weak positive control, negative control, solvent control, or positive control; 390 µL of TEDG+PI buffer with $[^3H]$-17β-estradiol; and 100 µL of uterine cytosol (with ER), for a total of 500 µL.
[2] Each concentration of each chemical was run in triplicate.

B. STUDY DESIGN AND TEST PERFORMANCE

Experimental dates: 2011-11-03 to 2011-12-03

Saturation (radioligand) binding experiment

A saturation binding experiment to measure total and non-specific binding of $[^3H]$-17β-estradiol was performed to demonstrate that the ER was present in reasonable concentrations and had appropriate affinity for the native ligand. The methods and results from the saturation binding experiment were not included in

the final study report. However, a statement of the laboratory verifying that the saturation binding curve data were acceptable according to the US OPPTS/OCSPP 890.1250 (2009) was included in the appendix of the study report.

Competitive binding experiment

The competitive binding experiment was performed to measure the binding of a single concentration of [^{3}H]-17β-estradiol (1 nM) to the ER in the presence of increasing concentrations of glyphosate. A summary of the experiment conditions for the competitive binding experiment is included in the table below. The specific activity of [^{3}H]-17β-estradiol was adjusted for decay over time prior to each run. The adjusted specific activity was 126.6, 126.5, and 126.1 Ci/mmol for the first, second, and third valid runs of the assay, respectively.

Each assay consisted of three independent valid runs, which were conducted on three different days, and each run of the assay consisted of triplicates at each test concentration. In addition to glyphosate, concentrations of 17β-estradiol, 19-norethindrone, and octyltriethoxysilane were also evaluated in the competitive binding experiment to ensure that the test system was behaving as expected.

Table 5.8.3-8: Glyphosate: Estrogen Receptor Binding (Rat Uterine Cytosol) Screening Assay ([redacted], 2012): Summary of conditions for competitive binding experiment

Source of receptor		Rat uterine cytosol
Concentration of radioligand		1 nM
Concentration of receptor		Sufficient to bind 10 - 15 % of radioligand
Concentration of glyphosate (as serial dilutions)		100 pM to 1 mM
Temperature		4 ± 2 °C
Incubation time		16 - 20 hours
Composition of assay buffer (TEDG+PI buffer)	Tris	10 mM (pH 7.4)
	EDTA	1.5 mM
	Glycerol	10 % (v/v)
	Protease Inhibitor (Phenylmethylsulfonyl fluoride (PMSF))	0.5 % (v/v)
	DTT	1 mM

C. DATA ANALYSIS

Classification of test material

The test material was classified based on the average of three valid runs of the assay. Each run was individually classified as follows:

Interactive = Lowest point on the fitted curve within the range of the data is <50 % (i.e. >50 % of the radiolabelled estradiol has been displaced from the ER).

Not interactive = There are usable data points at or above 10^{-6} M and either the lowest point on the fitted response curve within the range of the data is >75 % (i.e. <25 % of the radiolabelled estradiol has been displaced from the ER), or a binding curve cannot be fitted and the lowest average percent binding among concentration groups in the data is >75 %.

Equivocal up to the limit of concentrations tested = If there are no data points at or above a test chemical concentration of 10^{-6} M and either a binding curve can be fit but ≤50 % of the radiolabelled estradiol has been displaced from the ER, or a binding curve cannot be fit and the lowest average percent binding among concentration groups in the data is >50 %.

Equivocal = A run is classified as equivocal if it does not fall into any of the categories above.

Descriptors for receptor binding

In circumstances when ER receptor binding was measured, the following parameters were determined:

- B_{max}: Maximum specific binding number (fmol ER/100 µg cytosol protein) measures the concentration of active receptor sites.
- K_d: Dissociation constant (nM), measures the affinity of the receptor for its natural ligand.
- IC_{50}: Concentration of the test substance at which 50 % of the radioligand is displaced from the receptor.

II. RESULTS AND DISCUSSION

A. SATURATION BINDING EXPERIMENT

Results from the saturation binding experiment were not provided in the study report, although the laboratory provided a statement in the Appendix of the study report indicating that the saturation binding curve data were acceptable according to the respective US OPPTS/OCSPP 890.1250 (2009). Reference control results included in the competitive binding experiment confirmed that functional ER was present in sufficient amounts and functioning with appropriate affinity.

Summarised saturation binding data from the performing laboratory were submitted following a request by the Agency (MRID 48843501). The protein concentrations used in the saturation binding runs varied between each run, and were approximately 3- to 6-fold greater than recommended in the test guideline (160 to 320 µg versus 50 ± 10 µg, respectively). The K_d for [^{3}H]-17β-estradiol was 0.331 ± 0.061 nM, and the estimated B_{max} was 74.55 ± 3.03 fmol/100 µg protein for the prepared rat uterine cytosol. The K_d for each run was within the expected test guideline range of 0.03 - 1.5 nM.

B. COMPETITIVE BINDING EXPERIMENT

Four runs of the assay were conducted; however, the first run was considered invalid because the positive control 17β-estradiol did not meet the guideline-established acceptance criteria or was outside the range of historical control data. The remaining three runs met all acceptance criteria and are considered valid.

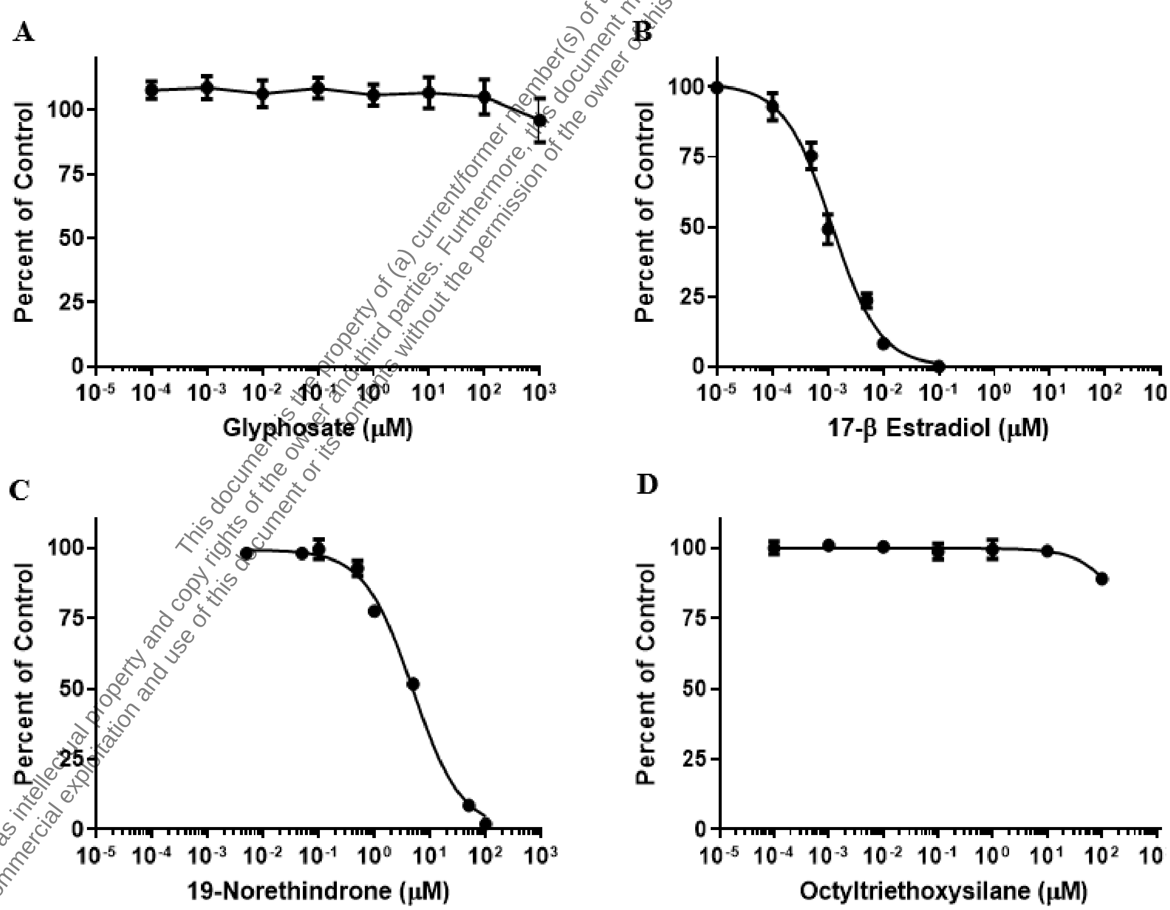
Results from the valid runs of the competitive binding experiment are presented in the table below. Specific binding was >81 %, >95 %, and >111 % at every concentration of glyphosate tested in the first, second, and third valid runs of the assay, respectively, and averaged >100 % across the concentration range (see figure below). Mean specific binding of the positive control, 17β-estradiol, and the weak positive control, 19-norethinodrone, met the guideline-established performance criteria for the assay in the three valid runs of the assay. The curve for the reference material showed that increasing concentrations of unlabelled 17β-estradiol displaced [^{3}H]-17β-estradiol in a manner consistent with one-site binding (see figure below). The Log IC_{50} of 17β-estradiol was -9.1 M, -9.0 M and -8.9 M in the first, second, and third valid run, respectively. 19-Norethindrone, had a Log IC_{50} of -5.5 M for each of the three valid runs. Confidence in these numbers is high due to the small variation. Mean specific binding of octyltriethoxysilane, the negative control, was >88 % at all concentrations except 10^{-3} M in the first and second valid assays, where the mean specific binding was 46.0 % and 47.4 %, respectively at 10^{-3} M. This phenomenon of lower mean specific binding observed in the first and second valid assays has previously been observed at the highest test concentration of octyltriethoxysilane and is associated with compound precipitation, rather than true competitive inhibition.

Table 5.8.3-9: Glyphosate: Estrogen Receptor Binding (Rat Uterine Cytosol) Screening Assay ([redacted] 2012): Results of competitive binding assay of glyphosate with estrogen receptor from rat uterine cytosol

Parameter	Compound	Run 1[1]	Run 2[1]	Run 3[1]	Mean ± SEM
r^2 (unweighted)	17β-estradiol	NR	NR	NR	NA
	19-Norethinodrone	NR	NR	NR	NA
	Glyphosate	NR	NR	NR	NA
Log IC_{50} (M)	17β-estradiol	-9.1	-9.0	-8.9	-9.0 ± 0.03
	19-Norethinodrone	-5.5	-5.5	-5.5	-5.5
	Glyphosate	NA	NA	NA	NA
IC_{50} (nM)	17β-estradiol	0.7947	1	1.26	1.02 ± 0.074
	19-Norethinodrone	3160	3160	3160	3160
	Glyphosate	NA	NA	NA	NA

[1] The mean is reported for the concurrent replicates within each run.
r^2 = Goodness of fit (r^2 is more appropriately expressed as a range, as opposed to a mean). For the test substance, these parameters could not be calculated.
NR = Not reported.
NA = Not applicable since binding was not evident.

Figure 5.8.3-3: Glyphosate: Estrogen Receptor Binding (Rat Uterine Cytosol) Screening Assay ([redacted] 2012): Relative amount of [³H]-17β-estradiol bound to the estrogen receptor in the presence of glyphosate (A), unlabelled 17β-estradiol (B, positive control), 19-norethindrone (C, weak positive control), or octyltriethoxysilane (D, negative control) (mean of three valid assays, ± SEM)



III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is performed in accordance with the current US OPPTS/OCSPP 890.1250 (2009). Deviations from the current OECD 493 (2015) is not applicable as the present study obtained the estrogen receptor from rat uterine cytosol preparations and the OECD 493 (2015) applies to two fully validated human recombinant receptor ERα (hrERα) *in vitro* test methods. The study is therefore considered valid. No interaction of glyphosate with the estrogen receptor was determined in the performed saturation and competitive binding experiment. Based on these results, glyphosate was classified as "non-interacting" in all three valid independent runs of the Estrogen Receptor Binding Assay. Thus, under the conditions reported, glyphosate was assigned a final classification of "non-interacting" for binding to the estrogen receptor.

Assessment and conclusion by RMS:

CA 5.8.3/004

1. Information on the study

Data point:	CA 5.8.3
Report author	[redacted]
Report year	2012
Report title	Glyphosate: Human Recombinant Aromatase Assay
Report No	6500V-100334AROM
Document No	CTX-11-027
Guidelines followed in study	US OPPTS/OCSPP 890.1200 (2009)
Deviations from current test guideline (OCSPP 890.1200, 2009)	None
Previous evaluation	Yes, accepted in EFSA peer review on endocrine disrupting properties (2017).
GLP/Officially recognised testing facilities	Yes
Comment on GLP	The positive control substance was not characterised in accordance with GLP standards, nor was the stability under storage conditions at the test site determined in accordance with GLP standards. However, the substance was purchased from commercial supplier, and the manufacturers' certificate of analysis was used to define the purity. Concentrations of test substance and control substances were not verified using analytical methods. In view of the short-term nature of studies of this type, no analyses of stability, homogeneity or achieved concentration(s) were conducted on preparations of the test substance or positive control chemicals, either before or after the treatment phase.

	This exception is not considered to have affected the integrity of the study and is not required in the US OPPTS 890.1200 guideline. For the reference control compounds, stability was demonstrated by an appropriate response in the assay system. Proficiency testing done to certify analysts was not performed under GLP and the results of proficiency testing are not included in the final report. However, the raw data was provided to US EPA by the test facility and support the expected designations of inhibitor or non-inhibitor for each of the proficiency chemicals (econazole, fenarimol, nitrofen, and atrazine) as well as the positive control (4-OH ASDN).
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary of the study according to OECD format

Executive summary

Glyphosate was evaluated for the potential to inhibit aromatase catalytic activity. In an *in vitro* aromatase (CYP19) assay, glyphosate was incubated with human recombinant aromatase (human CYP19 [Aromatase] and P450 reductase Supersomes^{TM}) and tritiated androstenedione ([^{3}H]ASDN) at concentrations of 10^{-10} M to 10^{-3} M for 15 minutes to assess the effect of glyphosate on aromatase activity. The solvent vehicle was 0.1 M sodium phosphate buffer for glyphosate, ethanol for ASDN, and dimethylsulfoxide (DMSO) for the positive control inhibitor 4-hydroxyandrostenedione (4-OH ASDN).

Aromatase activity was determined by measuring the amount of tritiated water produced at the end of a 15-minute incubation for each concentration of the used substances. Four independent runs of the assay were conducted; however, the first run was unacceptable because of incorrect standard preparation. Each run included a full activity control, a background activity control, a positive control series (10^{-10} M to 10^{-5} M) using the known inhibitor 4-OH ASDN in duplicate per concentration, and the test substance series (10^{-10} M to 10^{-3} M) in triplicate per concentration.

Aromatase activity in the full activity controls was 0.593 nmol/mg protein/min, which was greater than the minimum recommended aromatase activity of 0.1 nmol/mg protein/min. The response of the full activity controls and background controls was acceptable for each run.

For the positive control substance (4-OH ASDN), aromatase activity results were within the recommended ranges for the performance criteria. The estimated Log IC_{50} for 4-OH ASDN averaged -7.29 M and the Hill slope was -0.96.

For glyphosate, mean aromatase activity was 99.67 ± 1.86 % of vehicle control at the lowest tested concentration of 10^{-10} M and 109.3 ± 5.53 % of the vehicle control at the highest tested concentration of 10^{-3} M. The average aromatase activity was ≥99.67 % of the control at all tested glyphosate concentrations for all runs. Hill slope estimates were not determined for glyphosate because it never achieved >25 % inhibition. Thus, in three independent runs of the assay, increasing concentrations of glyphosate showed no decrease in aromatase activity.

Based on the data of the present study, glyphosate did not inhibit aromatase activity under the reported experimental conditions, and was therefore classified as a non-inhibitor of aromatase activity.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6
Description:	White crystalline solid
Lot/Batch No.:	GLP-1103-21149-T
Purity:	95.93 % glyphosate acid 85.14 % calculated glyphosate content
Stability of test compound:	Not reported. Expiry: 2012-03-09
Vehicle, non-labelled substrate, and positive control:	
Solvent/vehicle used:	0.1 M sodium phosphate buffer (pH 7.4)
Non-radio labelled aromatase substrate:	4-Androstene-3,17-dione (ASDN) Source: Steraloids, Inc. Lot/Batch No.: L1712 Purity: 99.8 % CAS No.: 63-05-8 Solvent used: Ethanol
Positive control (aromatase inhibitor):	4-hydroxyandrostendione (4-OH ASDN) Source: Sigma-Aldrich Lot/Batch No.: 081K2133 Purity: 99.6 % CAS No.: 566-48-3 Solvent used: DMSO

Radiolabelled substrate:

Identification:	[1β-^{3}H]-Androstenedione ([^{3}H]ASDN)
Source:	Perkin-Elmer
Lot/Batch No.:	619344
Radiochemical purity:	>97 %
Specific activity:	26.3 Ci/mmol, certification date 2010-08-06
Concentration of stock:	15 - 30 Ci/mmol
Solvent used:	Ethanol

Test system:

Identification:	Human CYP19 (Aromatase) and P450 reductase Supersomes™ (BD Gentest™, BD Biosciences)
Lot/Batch No.:	19701
Protein concentration:	3.7 mg/mL
Cytochrome C reductase activity:	540 nmol cytochrome C reduced/mg protein/min
Aromatase activity:	5.7 pmol product/pmol P450/min
Test concentrations:	Dilutions of glyphosate and the positive control 4-OH ASDN were tested as shown in the table below. A full activity control (containing all test components plus solvent control) and a background activity control (containing all test components except NADPH plus solvent control) were also performed.

Table 5.8.3-10: Glyphosate: Human Recombinant Aromatase Assay ([redacted] 2012): Competitor Final Molar (M) Concentrations in Aromatase Assay[1]

Positive control 4-OH ASDN	Test substance Glyphosate
1×10^{-5}	1×10^{-3}
1×10^{-6}	1×10^{-4}
$1 \times 10^{-6\,5}$	1×10^{-5}
1×10^{-7}	1×10^{-6}
$1 \times 10^{-7\,5}$	1×10^{-7}
1×10^{-8}	1×10^{-8}
1×10^{-9}	1×10^{-9}
1×10^{-10}	1×10^{-10}

[1] In each run of the assay, the full activity control and background activity control were run in replicates of four; the positive control was run in duplicate, and glyphosate was run in triplicate.

B. STUDY DESIGN AND TEST PERFORMANCE

Experimental dates: 2011-10-17 to 2011-10-21

Proficiency Testing
Proficiency testing of the CYP19 aromatase assay was conducted in three independent assay runs using the same methods as described below for the aromatase assay. Each run included evaluation of the positive control (4-OH ASDN) and the four recommended proficiency chemicals: econazole, fenarimol, nitrofen, and atrazine.

Aromatase Assay
Three types of control samples were included for each run. These included: 1) full enzyme (aromatase) activity controls (consisting of substrate [^{3}H]ASDN, NADPH, propylene glycol, buffer, microsomes, and vehicle [used for preparation of test substance solutions]); 2) background activity controls (all components that are in the full aromatase activity controls except NADPH); and 3) positive control (4-OH ASDN, run at eight concentrations, as indicated in the table above, in duplicate).

Four full activity controls and four background activity controls were included with each run of the assay (two tubes of each at the beginning of the assay and two tubes of each at the end of each assay).

Propylene glycol, [^{3}H] ASDN, NADPH, and assay buffer was combined in test tubes, with or without glyphosate or the positive control substance 4-OH-ASDN, for a total volume of 1 mL. The final concentrations for the major components of the assay are presented in the table below. The test tubes and microsomal suspensions were placed at 37 ± 2 °C in the water bath for five minutes prior to the initiation of the assay by the addition of 1 mL of the diluted microsomal suspension. The total assay volume was 2 mL. Subsequently, the tubes were incubated for 15 minutes at 37 ± 2 °C. The reactions were terminated and the unreacted ASDN extracted. The amount of ^3H_2O in the aqueous fraction was quantified for each assay tube by liquid scintillation counting, and aromatase activity was reported in units of nmol/mg protein/min.

Table 5.8.3-11: Glyphosate: Human Recombinant Aromatase Assay ([redacted] 2012): Summary of aromatase assay components and preparations

Assay Factor	Value

Sodium phosphate buffer (pH 7.4)	0.1 M
Microsomal protein	0.004 mg/mL[1]
NADPH	0.3 mM
[^{3}H]ASDN	100 nM
Propylene glycol	5 %
Temperature	37 ± 2 °C
Incubation time	15 min

[1] The concentration of microsomal protein was optimized for microsomes that produce ~540 pmol product/mg protein/min and 5.7 pmol product/pmol P450/min.

C. DATA ANALYSIS

Statistics

The response curve was fitted by weighted non-linear regression analysis using a four-parameter logistic regression model. For each run, the individual percent of control values were plotted versus logarithm of the test chemical concentration. In order to determine the consistency among runs, the slope and $LogIC_{50}$ for the positive control and test chemical(s) were compared across runs based on one-way random effects analysis of variance (ANOVA), with the runs treated as random effects. The parameters were graphed within each run with associated 95 % confidence intervals based on the within-run standard error, and the average across-run standard error, with the associated 95 % confidence interval incorporating run-to-run variation.

Classification of test material

The test material was classified based on the average of three valid runs of the assay. Each run was individually classified as follows:
Inhibitor = Average curve across runs crossed 50 %.
Non-Inhibitor = Average lowest portion of curve across runs is >75 % activity, or data do not fit the model.
Equivocal = Average lowest portion of curve across runs is between 50 % and 75 % activity.

II. RESULTS AND DISCUSSION

A. AROMATASE ASSAY

Mean aromatase activity in the full activity controls was 0.593 nmol/mg protein/min (range: 0.584 - 0.771 nmol/mg protein/min) for the three assay runs, which was greater than the minimum required aromatase activity of 0.1 nmol/mg protein/min according to guideline. The response of the full activity controls and background controls was acceptable for each run.

Aromatase assay results for glyphosate and the positive control 4-OH ASDN are shown in the table below and illustrated in the figure below.

For the positive control substance 4-OH ASDN, mean aromatase activity was 98.77 ± 1.54 % of vehicle control (VC) value at the lowest tested concentration of 10^{-10} M, and 0.67 ± 0.04 % of VC at the highest tested concentration of 10^{-5} M. Mean $LogIC_{50}$ for 4-OH ASDN was -7.29 M (range: -7.28 to -7.30 M) and mean Hill slope was -0.96 (range: -0.92 to -1.00). Therefore, the aromatase activity results for the positive control substance were within the recommended ranges for the performance criteria.

For the test substance glyphosate, mean aromatase activity was 99.67 ± 1.86 % of VC at the lowest tested concentration, 10^{-10} M and 109.3 ± 5.53 % of VC at the highest tested concentration, 10^{-3} M. $LogIC_{50}$. The Hill slope estimates were not determined for glyphosate because it never achieved >25 % inhibition. Based on these results, glyphosate does not inhibit the enzyme aromatase under the conditions of the present aromatase assay.

Table 5.8.3-12: Glyphosate: Human Recombinant Aromatase Assay ([redacted] 2012): Effect of 4-OH ASDN and glyphosate on aromatase activity. Data are presented as mean activity in percent compared to control (mean ± SD).

Substance	Concentration (M)	Run 1	Run 2	Run 3	Overall Mean (% of control)

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is performed in accordance with the current US OPPTS/OCSPP 890.1200 (2009). The study is therefore considered valid. In three independent runs of the present assay, increasing concentrations of glyphosate showed no decrease in aromatase activity. The mean aromatase activity at all tested glyphosate concentrations was ≥ 99.67 % compared to control.
Based on these data, glyphosate did not inhibit aromatase activity under the reported experimental conditions, and was therefore classified as a non-inhibitor of aromatase activity.

Assessment and conclusion by RMS:

CA 5.8.3/005

1. Information on the study

Data point:	CA 5.8.3
Report author	[redacted]
Report year	2012
Report title	A Uterotrophic Assay of Glyphosate Administered Orally in Ovariectomized Rats
Report No	[redacted]-843002
Document No	Not reported
Guidelines followed in study	US EPA OPPTS/OCSPP 890.1600 (2009) OECD 440 (2007)
Deviations from current test guideline (OCSPP 890.1600, 2009) (OECD 440, 2007)	None
Previous evaluation	Yes, accepted in EFSA peer review on endocrine disrupting properties (2017).
GLP/Officially recognised testing facilities	Yes
Comment on GLP	The characterization of the positive control substance, 17α-ethinyl estradiol, was not conducted according to GLP standards. However, the commercial provider characterized 17α-ethinyl estradiol and the certificate of analysis was included in the appendix of the final study report.
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary of the study according to OECD format

Executive summary

A uterotrophic assay was conducted in 66 - 67-day old female Crl:CD(SD) Sprague Dawley rats to screen for potential estrogenic activity of glyphosate. Groups of six ovariectomized rats each were administered

glyphosate in 0.5 % methylcellulose (in deionized water) orally via daily gavage at dose levels of 0 (vehicle control), 100, 300, and 1000 mg/kg bw/day for three consecutive days. The high dose level represents the limit dose for the assay. A positive control group of six rats was administered a daily dose of 17α-ethinyl estradiol (EE) in corn oil at 3 µg/kg bw/day by subcutaneous (s.c.) injection. All rats were ovariectomized 17 - 18 days prior to substance administration.

All rats survived to scheduled necropsy 24 hours following the last substance administration. No test substance-related clinical findings were noted at the daily examinations or four hours following dose administration at any dose level. No clinical findings were noted in the positive control group. No macroscopic findings were noted in the uterus at 100, 300, or 1000 mg/kg bw/day glyphosate or in the positive control group.

No test substance-related effects on mean body weights or mean body weight gains were noted in glyphosate treatment groups compared to concurrent control. Mean, absolute and relative, uterine weights (wet and blotted) of treatment groups were similar to control group values.
In positive control group animals, a mean body weight loss (-5.6 g) was observed at the end of the treatment period in contrast to a mean body weight gain (+11.3 g) in control group animals over the same period. Higher mean wet and blotted uterine weights (8.6- and 3.6-fold, respectively) were noted in the positive control group compared to control. These increases in uterine weights demonstrated the expected estrogenic effect of the positive control 17-α-ethinyl estradiol.

Based on the lack of effects on mean uterine weights (wet and blotted), glyphosate did not demonstrate or mimic biological activities consistent with agonism of natural estrogens when administered orally to ovariectomized female rats at dosage levels of 100, 300, and 1000 mg/kg bw/day. The positive control substance (17α-ethynylestradiol) elicited the expected increases in wet and blotted uterine weights.

The absence of effects on uterine weights demonstrated a lack of estrogenicity for glyphosate at all dosage levels evaluated up to and including the limit dose of 1000 mg/kg bw/day.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6
Description:	White powder
Lot/Batch No.:	GLP-1103-21149-T

Species:	Rat
Strain:	Crl:CD(SD) Sprague Dawley
Source:	[redacted]
Age at ovariectomy:	49 days of age; ovariectomy was performed at Charles River Laboratories
Age at dosing:	66 - 67 days of age; vaginal lavages were performed daily for five consecutive days (beginning at least 12 days after ovariectomy) prior to assignment to study groups, to ensure females were in persistent diestrus
Sex:	Female
Weight at dosing:	245.6 – 301.2 g
Acclimation period:	11 days
Diet/ Food:	2016*CM* Teklad Global 16 % Protein Rodent Diet (mean total isoflavones: 29.0 ppm), *ad libitum*
Water:	Reverse osmosis-purified tap water, *ad libitum*
Housing:	Individually housed in clean, stainless steel wire-mesh cages suspended above cage-board
Environmental conditions:	Temperature: 21.3 - 21.6 °C Humidity: 51.8 - 55.2 % Air changes: 10/hour Photocycle: 12 hours light/ 12 hours dark cycle

B. STUDY DESIGN AND METHODS

In life dates: 02 Jul to 04 Jul 2011 test substance administration; 05 Jul 2011 necropsy

Animal assignment and treatment
Animals were assigned to groups using a WTDMS™ computer program that randomised the animals based on stratification of body weights in a block design. The experimental design consisted of one vehicle control group, three test substance-treated groups, and one positive control group, each composed of six rats.

The vehicle and test substance formulations were administered orally by gavage once daily during study days 0 - 2. The oral dosage volume for all groups was 5 mL/kg bw. The positive control substance, 17α-ethinyl estradiol, was administered by bolus subcutaneous (s.c.) injection in the scapular region at a dosage volume of 5 mL/kg bw. Dosing sites were rotated clockwise between three distinct scapular sites daily. Individual dosages were based on the most recently recorded body weights.

Table 5.8.3-13: A Uterotrophic Assay of Glyphosate Administered Orally in Ovariectomized Rats ([redacted] 2012): Study design of uterotrophic assay with glyphosate, administered orally to female Sprague Dawley rats

Test group	Dose (mg/kg bw/day)[1]	No. of females
Control (vehicle)[2]	0	6

Low dose[2]	100	6
Mid dose[2]	300	6
High dose[2]	1000	6
Positive control 17α-ethinyl estradiol (EE)[3]	0.003	6

[1] Dosing volume: 5 mL/kg bw; a correction factor of 85.14 % was used to account for glyphosate purity.
[2] Exposure route: oral (gavage).
[3] Exposure route: subcutaneous (injection).

Dose Preparation and analysis
The test substance formulations were prepared once as single formulations for each dose level, divided into aliquots for daily dispensing, and stored at room temperature. A stock solution of 17α-ethinyl estradiol (0.05 mg/mL) in corn oil was prepared one day prior to the initiation of dosing. The positive control formulation was prepared by serial dilution of the stock solution in corn oil. The test substance and positive control formulations were prepared at separate stations to avoid cross contamination and were stirred continuously throughout the preparation, sampling and dose administration procedures. Samples for concentration analysis were collected from the middle stratum of each dosing formulation (including the positive control group) prepared during the in-life phase of the study. Homogeneity, resuspension homogeneity, and stability of the test substance formulations were demonstrated in a preceding, seperate study.

Observations
All rats were observed (cage-side) twice daily for clinical signs of toxicity, moribund condition and mortality. Individual clinical observations (hand-held physical examination) were recorded daily (prior to dose administration during the treatment period) through the day of necropsy. Animals were also observed for signs of toxicity approximately four hours following dose administration. Animals of the positive control group were examined for potential erythema, swelling, or other dermal findings at the injection site.

Body weight
Individual body weights were recorded on the day of randomization, daily prior to test substance administration, and on the day of euthanasia. Mean body weight changes were calculated for each corresponding interval and for study days 0 - 3.

Food consumption
Food consumption was not evaluated.

Sacrifice and measurement of uterine weight
All females were euthanized by carbon dioxide inhalation approximately 24 hours following administration of the last dose in the same order of dosing. Macroscopic examination was conducted for the uteri; full necropsies were not conducted. The uterus was carefully dissected and trimmed, being careful to retain the luminal fluid. Each "wet" uterus was weighed intact (with the luminal fluid) to the nearest 0.1 mg, then opened longitudinally and blotted with filter paper to remove the luminal fluid. Subsequently, the blotted uterus was weighed to the nearest 0.1 mg. Any loss in luminal content was reported.

Microscopic Examination
Microscopic examinations were not conducted. However, the uterus and vagina were preserved in 10 % neutral-buffered formalin for possible future histopathologic examination.

Statistics
Each endpoint was tested for homogeneity of variance using Levene's test. Homogeneity of variance was confirmed for each endpoint ($p > 0.01$) and no data transformation was required.

Uterine weights: In the first stage, the 17α-ethinyl estradiol group was compared to the vehicle control

group. An analysis of covariance (ANCOVA) was performed using the body weight at necropsy as the covariate. Both groups were compared to each other in a one-sided test using p = 0.05 to declare significance, looking for significant increases from the vehicle control.

The second stage of the analysis compared the various glyphosate-treated groups to the vehicle control group. An ANCOVA was performed using the body weight at necropsy as the covariate. Comparisons of each treatment group with the vehicle control group were made with a one-sided Dunnett's test using p = 0.05 to declare significance, looking for significant increases from the vehicle control group.

Body weights and cumulative body weight change: The statistical analysis of body weight and body weight change was identical to the uterine weights with the following exception: there was no covariate in the statistical model (ANOVA) and the testing was two-sided rather than one-sided.

II. RESULTS AND DISCUSSION

A. MORTALITY
All animals survived until scheduled necropsy.

B. CLINICAL OBSERVATIONS
No test substance-related clinical findings were noted at the daily examinations at any dose level. No clinical findings were noted four hours following dose administration at any dose level. No clinical observations were noted in the positive control group. Slight and/or very slight edemas were noted at the injection sites of positive control animals.

C. BODY WEIGHT
No test substance-related effects on mean body weights or body weight changes were noted in the 100, 300, and 1000 mg/kg bw/day glyphosate-treated groups. The values in the test substance-treated groups were similar to and not statistically significantly different from the vehicle control group.

In the positive control group, a significant ($p < 0.0001$) mean body weight loss (-5.6 g) was noted when the overall treatment period (study days 0 - 3) was evaluated compared to a mean body weight gain in the vehicle control group (+11.3 g). This resulted in a decreased mean terminal body weight in the positive control group (-5.24 %) compared to the vehicle control group on study day 3. The difference was not statistically significant. Body weights and body weight changes are presented in the table below.

Table 5.8.3-14: A Uterotrophic Assay of Glyphosate Administered Orally in Ovariectomized Rats ([redacted] 2012): Mean group body weight and body weight change in the uterotrophic assay in Sprague Dawley rats. Females were exposed to glyphosate for three days via gavage (n=6).

Dose (mg/kg bw/day)	Body weight (g), mean ± SD				Body weight change (g)
	Study Day 0	Study Day 1	Study Day 2	Study Day 3	
0	277.0 ± 19.18	279.7 ± 19.50	286.4 ± 21.12	288.3 ± 20.96	11.3
100	277.6 ± 14.63	282.4 ± 15.81	288.2 ± 16.34	292.9 ± 15.98	15.3
300	275.2 ± 15.61	279.2 ± 16.88	284.8 ± 15.54	284.3 ± 19.40	9.1
1000	278.3 ± 15.48	282.8 ± 16.64	287.5 ± 16.50	291.6 ± 17.53	13.3
0.003 EE	278.7 ± 18.79	280.2 ± 21.06	278.2 ± 19.36	273.2 ± 20.92	-5.6

SD, standard deviation; EE, 17α-ethinyl estradiol (positive control)

D. NECROPSY
At scheduled necropsy, no macroscopic findings in the uterus were observed at dosage levels of 100, 300,

and 1000 mg/kg bw/day glyphosate or in the positive control group.

E. UTERINE WEIGHTS

Mean wet and blotted uterine weights were unaffected by test substance administration at dose levels of 100, 300, and 1000 mg/kg bw/day. Differences from the vehicle control group were slight and not statistically significant. Mean blotted uterine weight in the vehicle control group was less than 0.04 % of the final body weight, indicating acceptable results.

The positive control substance produced the expected estrogenic response. Mean wet and blotted uterine weights in this group were significantly ($p < 0.0001$) higher (8.6- and 3.6-fold, respectively) than the vehicle control group values. Results of wet and blotted uterine weights are presented in the table below.

Table 5.8.3-15: A Uterotrophic Assay of Glyphosate Administered Orally in Ovariectomized Rats ([redacted] 2012): Uterine weights in the uterotrophic assay Sprague Dawley rats treated orally with glyphosate for three days.

Dose (mg/kg bw/day)	0	100	300	1000	0.003 EE
Parameter	**Uterine weight (mean ± SD)**				
Terminal body weight	289 ± 20.9	293 ± 16.2	284 ± 19.1	292 ± 17.5	273 ± 21.0
Wet, absolute (mg)	111.0 ± 10.80	110.7 ± 12.45	118.3 ± 16.49	113.6 ± 9.66	953.1* ± 90.44
Wet, relative (%)	0.038 ± 0.0025	0.038 ± 0.0056	0.042 ± 0.0061	0.039 ± 0.0044	0.352* ± 0.0546

Blotted, relative (%)	0.034 ± 0.0024	0.034 ± 0.0048	0.036 ± 0.0040	0.035 ± 0.0038	0.129* ± 0.0173

SD, standard deviation; EE, 17α-ethinyl estradiol (positive control); * Significantly different from control at $p < 0.0001$

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is performed in accordance with the current US EPA OPPTS/OCSPP 890.1600 (2009) and OECD 440 (2007). The study is therefore considered valid. Oral administration of glyphosate at dosage levels up to 1000 mg/kg bw/day did not produce any indication of toxicity. In addition, mean uterine weights (wet and blotted) in the glyphosate-treated groups were similar to control group values. The absence of effects on uterine weights demonstrated a lack of estrogenicity for glyphosate at all dose levels evaluated up to and including the limit dose of 1000 mg/kg bw/day in the present uterotrophic assay. The positive control 17α-ethinyl estradiol elicited expected, significant increase in absolute wet and blotted uterine weights compared to the control group, demonstrating the sensitivity of the assay. Based on these results, glyphosate did not demonstrate or mimic biological activities consistent with agonism of natural estrogens at all applied doses including the limit dose of 1000 mg/kg bw/day.

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

Executive summary

The objective of this study was a mechanistic *in vivo* screen for potential androgenic activity of the test substance glyphosate. To screen for potential androgenic activity, glyphosate (in 0.5 % methylcellulose in deionized water) was administered daily for ten days via gavage to 54 - 55-day old, castrated male Crl:CD(SD) Sprague Dawley rats (six per dose group) at dose levels of 0 (vehicle control), 100, 300, or 1000 mg/kg bw/day. The high dose represents the limit dose for this assay. An androgenic positive control group consisted of six castrated rats exposed to 0.2 mg/kg bw/day testosterone propionate (TP) by subcutaneous (s.c.) injection. To screen for potential anti-androgenic activity, glyphosate in 0.5 % methylcellulose (in deionized water) was administered daily for ten days via gavage to 54 - 55-day old, castrated male Crl:CD(SD) Sprague Dawley rats (six per dose group) at dose levels of 0 (vehicle control), 100, 300, or 1000 mg/kg bw/day, in conjunction with a daily dose of the reference androgen TP at 0.2 mg/kg bw/day by s.c. injection. An anti-androgenic positive control group consisted of six castrated rats exposed to 0.2 mg/kg bw/day TP by s.c injection, and to 3 mg/kg bw/day flutamide (FT) by oral gavage. TP alone was used as the anti-androgenic negative control.

All animals were observed twice daily for mortality and moribundity. Clinical observations and body weights were recorded daily. The bulbourethral glands, glans penis, levator ani and bulbocavernosus (LABC) muscle group, seminal vesicles with coagulating glands, and ventral prostate were examined, weighed, and retained in 10 % neutral-buffered formalin.

All males survived to scheduled euthanasia on study day 10. There were no test substance-related clinical or macroscopic findings noted at any dose level. No test substance or control substance-related effects on

mean body weights or body weight change were noted. No test substance-related androgenic effects on the weights of male accessory sex organs (bulbourethral glands, glans penis, LABC muscle group, seminal vesicles with coagulating glands, and ventral prostate) were noted compared to the vehicle control group. Co-administration of TP with the test substance did not reveal an anti-androgenic effect (i.e. decreased mean organ weights) when compared to the TP control group. Administration of the androgenic positive control substance (TP) resulted in the expected higher mean male accessory sex organ weights. Co-administration of the anti-androgenic positive control substance flutamide (FT) with TP inhibited the androgenic response, resulting in lower mean organ weights compared to the TP control group.

Based on the results of the present Hershberger assay, glyphosate was negative for androgenicity and anti-androgenicity under the reported conditions.

B. STUDY DESIGN AND METHODS

In life dates: 27 Jun to 06 Jul 2011 test substance administration; 07 Jul 2011 necropsy

Animal assignment and treatment
Males were assigned to groups using a WTDMST™ computer program which randomized the animals based on body weight stratification in a block design. The experimental design consisted of two assays: one for androgen agonist activity and one for anti-androgen activity. In the androgen agonist assay, there was one vehicle control group, one positive control group and three test substance-treated groups, each composed of six rats. In the anti-androgen assay, there was one vehicle control group, one androgen treated negative control group, one androgen and anti-androgen treated positive control group, and three test substance-treated groups (co-treated with the androgen TP), each composed of six rats.

In the Hershberger assay to screen for potential androgenic activity, the test substance glyphosate was administered daily for ten days via oral gavage to castrated male rats at doses of 100, 300, or 1000 mg/kg bw/day (at a dosing volume of 5 mL/kg bw).

In the Hershberger assay to screen for potential anti- androgenic activity, glyphosate was administered daily for ten days via gavage to castrated male rats at the same doses (100, 300, or 1000 mg/kg bw/day) in conjunction with a daily dose of TP (0.2 mg/kg bw/day) by s.c. injection.

A concurrent vehicle control group received the dosing vehicle by gavage for the same duration. In another group, TP was administered via s.c. injection at a dose level of 0.2 mg/kg bw/day and a dosing volume of 0.5 mg/mL. This treatment served as an androgenic positive control group in the androgen agonist assay as well as an anti-androgen negative control in the anti-androgen assay (same animals). In the anti-androgen positive control group, males received 0.2 mg/kg bw/day TP by s.c. injection in conjunction with 3 mg/kg bw/day of flutamide (FT), a known anti-androgenic substance, by oral gavage (at a dosing volume of 5 mL/kg bw) for ten days.

Table 5.8.3-16: A Hershberger Assay of Glyphosate Administered Orally in Peripubertal Orchidoepididymectomized Rats ([redacted] 2012): Study design of Hershberger assay with glyphosate in male Sprague Dawley rats

Test group	Dose[1] (mg/kg bw/day)	No. of males	Dosing volume (mL/kg bw/day)
Androgen agonist assay			
Control (vehicle)	0	6	5
Low	100	6	5
Mid	300	6	5
High	1000	6	5
Positive Control (TP, s.c.)	0.2	6	0.5
Anti-androgen assay			
Control (vehicle)	0	6	5
Negative Control (TP, s.c.)	0.2	6	0.5
Low (+ TP, s.c.)	100 (+ 0.2)	6	5 (+ 0.5)
Mid (+ TP, s.c.)	300 (+ 0.2)	6	5 (+ 0.5)
High (+ TP, s.c.)	1000 (+ 0.2)	6	5 (+ 0.5)
Positive Control (FT, gavage) (+ TP, s.c.)	3 (+ 0.2)	6	5 (+ 0.5)

s.c. = subcutaneous; TP = Testosterone propionate; FT = Flutamide
[1] To calculate the glyphosate dose a correction factor of 85.14 % was used to account for the purity.

Dose Preparation and Analysis
The test substance formulations were prepared approximately weekly as single formulations for each dose level, divided into aliquots for daily dispensation, and stored at room temperature. The test substance formulations were stirred continuously throughout the preparation, sampling, and dose administration procedures.

The positive control substance formulations were prepared once, as follows. The appropriate amount of the positive control substance (TP or FT) was dissolved in a minimal amount of 95 % ethanol and diluted to the final concentration with corn oil. The FT formulation was then divided into aliquots for daily use. Aliquots of the TP formulation were dispensed into sterile septum vials for daily use. The positive control substance formulations were stored at room temperature and were stirred continuously throughout the preparation, sampling, and dose administration procedures.

The vehicle was prepared approximately weekly for administration to the vehicle control group and for preparation of the test substance formulations; aliquots were prepared for daily dispensation to the control group and stored at room temperature. The vehicle was mixed throughout the preparation, sampling, and dose administration procedures.

Clinical observations
All rats were observed (cage-side) twice daily for moribund condition and mortality. Individual clinical observations (hand-held physical examinations) were recorded daily (prior to test substance administration during the treatment period) through the day of scheduled necropsy. Each male was also observed for signs of toxicity at approximately four hours following dose administration. The injection sites for males receiving s.c. injections were examined daily from the initiation of dose administration for erythema, swelling, and other dermal findings. Erythema and swelling were evaluated in accordance with a four-step grading system of very slight, slight, moderate, and severe.

Body weight
Individual male body weights were recorded on the day of randomization, daily prior to test substance administration, and on the day of scheduled necropsy. Mean body weight changes were calculated for each corresponding interval and for study days 0 - 10.

Food consumption
Food consumption was not recorded.

Blood collection
Blood samples (3 mL/animal) were collected from the vena cava following anaesthesia by isoflurane inhalation approximately 24 hours following administration of the last dose. The blood samples were allowed to clot at room temperature, serum was separated by centrifugation, and the samples stored frozen (approximately -70 °C) for possible future hormone analysis.

Sacrifice, measurement of accessory sex organ weights and pathology
Males were euthanized by exsanguination on study day 10. Full necropsies were not conducted. The following tissues and organs were excised, trimmed free of adhering tissue, and weighed fresh (unfixed) and placed in 10 % neutral-buffered formalin:

- Bulbourethral glands (Cowper's gland)[1, 2]
- Glans penis
- Levator ani and bulbocavernosus (LABC) muscle group
- Seminal vesicles with coagulating glands[1, 2]
- Ventral prostate[2]

[1] = Paired organs were weighed together.
[2] = Care was taken to minimize fluid loss from these organs; loss of fluid was documented.

Microscopic examinations were not conducted.

Statistics
Each endpoint was tested for homogeneity of variance using Levene's test. If that test was significant at p = 0.01, then a log transformation was applied and Levene's test conducted on the transformed data. Homogeneity of variance was confirmed for each endpoint (p >0.01).

Androgen agonist assay:
Organ weights (vehicle control vs. TP): The one-sided t-test was performed using p = 0.05 to declare significance, looking for significant increases from the vehicle control group.
Organ weights (vehicle control vs. glyphosate groups): An analysis of variance (ANOVA) was conducted on the raw or log transformed data. A one-sided Dunnett's test was conducted using p = 0.05 to declare significance, regardless of the outcome of the ANOVA, looking for significant increases in the glyphosate groups when compared with the vehicle control group.
Body weight and body weight change: The statistical analysis was identical to that for organ weights with the exception that the testing was two-sided, rather than one-sided, using p = 0.05 to declare significance.

Anti-androgen assay:
Organ weights (TP vs. TP + FT): A one-sided t-test was performed using p = 0.05 to declare significance, looking for significant decreases from the TP group.
Organ weights (TP vs. glyphosate + TP groups): An ANOVA was conducted on the raw or transformed data, as appropriate. A one-sided Dunnett's test was conducted using p = 0.05 to declare significance, regardless of the outcome of the ANOVA, looking for significant decreases in the glyphosate + TP groups when compared with the TP group.
Body weight and body weight change: The statistical analysis was identical to the organ weights with the exception that the testing was two-sided, rather than one-sided, using p = 0.05 to declare significance.

Performance criteria
Because the organ weights of different strains of rats vary, absolute organ weights are not used as the performance criteria in the Hershberger assay. Rather, the performance criteria are based on the coefficient of variance (CV) for each organ. For negative outcomes, the CVs from the control and high dose group were examined to determine if the maximum CV performance was exceeded. To meet the performance criteria, the maximum allowable CV for each organ as set out in the test guideline was applied.

II. RESULTS AND DISCUSSION

A. MORTALITY

There were no mortalities. All animals survived until scheduled necropsy.

B. CLINICAL OBSERVATIONS

No test substance- or positive control-related clinical findings were noted. Single occurrences of very slight erythema, very slight edema, and slight edema were noted in animals receiving s.c. injection of TP. One animal with desquamation was noted in the TP positive control group.

C. BODY WEIGHT

No test substance-related effects on mean body weights or body weight changes were noted in the 100, 300, and 1000 mg/kg bw/day glyphosate-treated groups compared to the control group (see tables below). In the test substance-treated groups co-administered TP, mean body weights and body weight changes were similar to those of the TP control group. Mean body weights and body weight changes in the TP/FT group were similar to those of the TP control group throughout the study. In the TP control group, mean body weights and body weight changes were similar to those of the vehicle control group. Altogether, no statistically significant differences were noted.

Table 5.8.3-17: A Hershberger Assay of Glyphosate Administered Orally in Peripubertal Orchidoepididymectomized Rats [redacted] 2012): Body weight (bw) and cumulative body weight change in the androgen agonist assay in Sprague Dawley rats administered glyphosate via oral gavage for ten days

D. ACCESSORY SEX ORGAN WEIGHTS

No evidence of androgenic agonism was noted in the 100, 300, or 1000 mg/kg bw/day glyphosate treated groups based on the lack of higher mean weights of the bulbourethral gland, glans penis, LABC muscle group, seminal vesicles/coagulating gland, and ventral prostate (see Table 5.8.3-19). Differences from the vehicle control group were slight and were not statistically significant.

No evidence of androgenic antagonism (anti-androgenic activity) was noted in the 100, 300, or 1000 mg/kg bw/day glyphosate treated groups co-administered TP (see Table 5.8.3-19). Slight differences of glyphosate +TP dose groups from the TP control group were not statistically significant. The androgenic positive control substance (concurrently the anti-androgenic negative control) TP elicited the expected response; statistically significant higher mean bulbourethral gland ($p < 0.0001$), glans penis ($p = 0.0007$), LABC muscle group ($p < 0.0001$), seminal vesicles/coagulating gland ($p < 0.0001$), and ventral prostate ($p < 0.0001$) weights compared to the vehicle control group. The anti-androgenic positive control FT inhibited the androgenic effect of co-administered TP, resulting in statistically significantly ($p \leq 0.0001$) decreased mean bulbourethral gland, glans penis, LABC muscle group, seminal vesicles/coagulating gland, and ventral prostate weights compared to the TP control group. All CV values were within the range of the assay's performance criteria.

Table 5.8.3-19: A Hershberger Assay of Glyphosate Administered Orally in Peripubertal Orchidoepididymectomized Rats (2012): Accessory sex organ weights of the androgen agonist assay in Sprague Dawley rats administered glyphosate via oral gavage for ten days

III. CONCLUSION

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is performed in accordance with the current US EPA OPPTS/OCSPP 890.1400 (2009) and OECD 441 (2009). The study is therefore considered valid. Glyphosate did not have androgenic or anti-androgenic activity in the Hershberger assay at dose levels of 100, 300, or 1000 mg/kg bw/day. In the androgen agonist assay, the positive control TP elicited the appropriate responses of increased androgen-dependent organ weights. In the anti-androgen assay, the positive control FT inhibited TP induced increases in androgen-dependent organ weights when compared to the TP control group. Organ weights of glyphosate treated animals were not affected when compared to the appropriate control group. Glyphosate alone dose groups were not androgenic compared with the vehicle control group. Glyphosate + TP dose groups were not anti-androgenic compared with the TP alone anti-androgenic negative control group. Based on these results, glyphosate was negative for androgenicity and anti-androgenicity in the Hershberger assay.

Assessment and conclusion by RMS:

CA 5.8.3/007

1. Information on the study

Data point:	CA 5.8.3
Report author	[redacted]
Report year	2012
Report title	A Pubertal Development and Thyroid Function Assay of Glyphosate Administered Orally in Intact Juvenile/Peripubertal Male Rats
Report No	[redacted]-843005
Document No	Not reported
Guidelines followed in study	US EPA OPPTS/OCSPP 890.1500 (2009)
Deviations from current test guideline (OCSPP 890.1500, 2009)	Some values of the control group were outside the guideline performance criteria range (mean body weight at time of weaning (PND 21), CV value for body weight at attainment of PPS, CV value for mean TSH level, and mean thyroid gland and kidney weights). However, CV values of mean body weight (PND 21) and thyroid and kidney weights; mean body weight at the attainment of PPS and the mean/CV value for the age of attainment of PPS; and mean TSH value were in the acceptable guideline performance criteria range. Thus, these deviations were not considered to affect the interpretation of the results.

Previous evaluation	Yes, accepted in EFSA peer review on endocrine disrupting properties (2017).
GLP/Officially recognised testing facilities	Yes
Comment on GLP	None

Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary of the study according to OECD format

Executive summary

The objective of the present study was to assess the potential effects of glyphosate on the endocrine system, by identifying effects on pubertal development and thyroid function in the juvenile/peripubertal male rat. For this purpose, juvenile/peripubertal male Crl:CD(SD) Sprague Dawley rats (15 per dose group) were treated daily via oral gavage with glyphosate in 0.5 % methylcellulose in deionized water at doses of 0 (vehicle control), 100, 300, or 1000 mg/kg bw/day from postnatal day (PND) 23 to 53. Animals were observed twice daily for mortality and moribundity throughout the study period. Clinical observations and body weights were recorded daily. Animals were examined daily for preputial separation (PPS) beginning on PND 30. Age and weight at day of PPS were recorded. Following sacrifice on PND 53, blood was taken for total thyroxine (T4), testosterone, thyroid stimulating hormone (TSH), and clinical chemistry analysis. A gross necropsy was conducted for all animals and body and organ weights (epididymides, ventral prostate, dorsolateral prostate, adrenal glands, kidneys, liver, levator ani plus bulbocavernosus muscles, testes, pituitary, thyroid, seminal vesicle with coagulating gland) were recorded. Histopathological evaluation was performed on the thyroid, kidneys, testis and epididymides.

One male in the 1000 mg/kg bw/day dose group was found dead prior to dosing on PND 24. This death was considered treatment-related. All other males survived until scheduled sacrifice on PND 53. Rales were noted in a dose-related manner in the 300 and 1000 mg/kg bw/day dose groups approximately four hours post dosing throughout the treatment period. This finding persisted to the daily examinations for the 1000 mg/kg bw/day dose group. Terminal body weight was statistically significantly decreased for 300 and 1000 mg/kg bw/ day dose group animals (-6.63 % and -10.36 %, respectively) compared to control. Body weight change (PND 23 to 53) was significantly decreased in the 300 and 1000 mg/kg bw/day dose group (-7.5 % and -12.4 %, respectively), reaching statistical significance in the highest dose group compared to control. Clinical signs of toxicity together with clearly reduced body weight/ body weight change are indicative of overt systemic toxicity. At an EPA FIFIRA Scientific Advisory Panel in 2013, the panel was asked to comment on the validity of including treatments demonstrated overt systemic toxicity to assess effects of potential endocrine interaction. On the issue of overt systemic toxicity, the panel stated that little, if any, weight should be placed on signs of endocrine disruption in the presence of overt systemic toxicity. All effects in endocrine sensitive tissues should be evaluated in terms of primary interactions with the endocrine system versus secondary effects related to toxicity in non-endocrine organs or overall disruptions in homeostasis. Decreases in body weight gain approaching or above 10 % for the pubertal assays have been shown in the open literature to significantly confound the interpretation of the results of an adverse effect through an endocrine mechanism.

A delay in the mean age of attainment of preputial separation (not statistically significant), decreased reproductive organ weights (epididymides, seminal vesicle with coagulating gland, and ventral prostate) (statistically significant), and a decreased mean testosterone level (not statistically significant) were noted in the 1000 mg/kg bw/day dose group. These observations were considered treatment-related but were considered to be a secondary non-specific consequence of the described systemic toxicity indicated by lower mean body weight in this dose group. No treatment-related effects on organ weights were observed at lower dosages. T4 and TSH levels were lower than those in the control group in all treated groups and

testosterone was lower at 300 and 1000 mg/kg bw/day. However, these changes were not statistically significant and were not associated with any histopathological finding and were therefore not considered as compound-related. At 1000 mg/kg bw/day, the increases in ALT (also at 300 mg/kg bw/day), sodium, albumin, ALP, AST, chloride, phosphorous, and total protein, and the decrease in urea nitrogen were considered to be related to treatment and indicative for systemic toxicity. No adverse effects were noted on clinical pathology parameters at dosage levels of 100, 300, and 1000 mg/kg bw/day. No test substance-related macroscopic or microscopic findings were noted at any dose level.

There was no evidence of any glyphosate-related androgenic or anti-androgenic effects, nor was there any evidence of primary glyphosate-related effects on pubertal development or thyroid function in the juvenile/prepubertal male rat at dose levels of 100, 300, and 1000 mg/kg bw/day.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6
Description:	White powder
Lot/Batch No.:	GLP-1103-21149-T
Purity:	95.93 % glyphosate acid 85.14 % calculated glyphosate content
Stability of test compound:	Stable at room temperature
Vehicle:	Methylcellulose Source: Spectrum Chemical Manufacturing Corporation, New Brunswick, NJ, USA Lot/Batch No.: ZQ0344 CAS No.: 9004-67-5 Final concentration: 0.5 % in deionized water

Test animals:

Species:	Rat
Strain:	Crl:CD(SD) Sprague Dawley
Source:	[redacted]
Age at start of dosing:	23 days
Sex:	Male
Weight at dosing:	44.3 - 56.6 g
Acclimation period:	Time-mated female Crl:CD(SD) rats (43 females) were received from Charles River on 23 August 2011. Animals used in the present study were born at the testing facility. Weaning and study group assignment took place on PND 21.
Diet/Food:	Harlan Laboratories basal diet (2016*CM* Teklad Global, 16 % Protein Rodent Diet; 11.0 ppm of total isoflavones (genistein + daidzein + glycitein), *ad libitum*
Water:	Reverse osmosis-purified drinking water, *ad libitum*
Housing:	Dams and littermates in plastic maternity cages with nesting material until weaning on PND 21. After weaning, juveniles were housed two males per cage throughout the study.

Environmental conditions:	Temperature:	21.2 - 22.2 °C
	Humidity:	40.1 - 58.9 %
	Air changes:	10/h
	Photocycle:	14 hours light/ 10 hours dark cycle

B. STUDY DESIGN AND METHODS

In life dates: 23 Aug 2011 delivery of pregnant rats; 29 Sep to 30 Oct 2011 test substance administration to male offspring

Animal assignment and treatment:
Offspring of time-mated female rats were weaned and weighed on PND 21. Animals were assigned using a WTDMS™ computer program which randomized the animals based on stratification of body weights in a block design. Littermates were not placed in the same group. The treatment groups included one vehicle control group and three glyphosate dose groups of 100, 300, and 1000 mg/kg bw/day.

All doses were administered once daily by oral gavage from PND 23 through PND 53, in a volume of 5.0 mL/kg bw. Dosing was performed daily, between 7:00 AM and 9:00 AM.

Table 5.8.3-21: A Pubertal Development and Thyroid Function Assay of Glyphosate Administered Orally in Intact Juvenile/Peripubertal Male Rats ([redacted] 2012): Study design of glyphosate administration to juvenile male Sprague Dawley rats

Test group	Dose (mg/kg bw/day)[1]	No. of males	Dosing volume (mL/kg bw)
Control (vehicle)	0	15	5
Low	100	15	5
Mid	300	15	5
High	1000	15	5

[1] A correction factor of 85.14 % was used to account for the active substance.

Dose Preparation and Analysis
The vehicle (0.5 % methylcellulose in deionized water) was prepared approximately weekly for administration to the control group and for preparation of the test substance formulations; aliquots were prepared for daily dispensation to the control group and stored at room temperature.

The test substance formulations were prepared approximately weekly as single formulations for each dosage level, divided into aliquots for daily dispensation, and stored at room temperature.

Analyses to demonstrate homogeneity, resuspension homogeneity for suspensions, and stability of the test substance formulations for up to 15 days at room temperature storage at concentrations of 1 and 200 mg/mL were conducted prior to the start of dose administration in a separate study ([redacted]-843004). Dosing formulations were analysed five times during the study (September 27, 2011 and October 4, 11, 18 and 25, 2011). Analysed concentrations ranged from 97.5 - 102 % of nominal for the low dose, 99.7 - 104 % of nominal for the mid dose, and 104 - 114 % of nominal for the high dose group. The analytical data indicated that the variation between nominal and actual dose to the animals was acceptable.

Mortality
All animals were examined twice daily, once in the morning and once in the afternoon, for mortality and moribundity.

Clinical observations
Clinical examinations were conducted on the day of randomization and daily through the day of necropsy. Animals were observed for signs of toxicity in the morning prior to test substance administration and

approximately 4 hours following test substance administration.

Body weight
Animals were weighed on the day of randomization, daily prior to test substance administration during the treatment period and on the day of necropsy.

Food consumption
Food consumption was not evaluated.

Preputial separation (PPS)
Beginning on PND 30, all animals were examined daily for onset of PPS. Age and body weight on the day at which complete PPS was observed was recorded for each animal. In addition, the appearance of a partial or complete PPS or a persistent thread of tissue between the glans and prepuce was recorded. If any animal within any group showed incomplete separation (persistent threads) for greater than three days, a separate second analysis was conducted using the age at which incomplete separation was first observed. Examination of the males was continued daily until complete PPS was attained or until euthanasia. When an animal did not attain PPS prior to necropsy, PND 54 (last study day + 1) and body weight at necropsy were used as the age and body weight at PPS, respectively.

Haematology and clinical chemistry
On PND 53 at least two hours post-dosing, rats were removed one at a time from their home cages to a separate room for euthanasia by decapitation without anaesthesia, to not induce stress-related responses in other animals, which may affect hormone measurements. All animals were euthanized by approximately 01:00 PM. Blood from the trunk of the animals was collected immediately into three serum separation tubes. One tube of serum samples was used for serum chemistry evaluation. The remaining two tubes of serum samples for each animal were used for T4, TSH, and testosterone analyses. Samples were analysed fresh or stored frozen (≤ -20 °C).

The following clinical chemistry parameters were examined: calcium, chloride, phosphorus, potassium, sodium, albumin, creatinine, urea nitrogen, total cholesterol, globulin (calculated), albumin/globulin ratio (calculated), glucose, total bilirubin, total protein, triglycerides, bile acids, alkaline phosphatase (ALP), alanine aminotransferase (ALT, also SGPT), aspartate aminotransferase (AST, also SGOT), gamma glutamyltransferase (GGT).

Testosterone and thyroxine (T4) concentrations were analysed using an electrochemiluminescent immunoassay. To determine the concentration of TSH in serum samples, a [^{125}I]rTSH kit was used.

Sacrifice and pathology
On PND 53 at least 2 hours post-dosing, rats were removed one at a time from their home cages to a separate room for euthanasia by decapitation without anaesthesia. Gross necropsy was performed for all animals. The necropsy included examination of the external surface, all orifices, the external surface of the brain and the abdominal, thoracic, and pelvic cavities, including viscera. Any tissues with gross lesions were saved in 10 % neutral-buffered formalin for possible future histopathologic examination. The following organs were collected and weighed: testes (left and right separately), epididymides (left and right separately), seminal vesicle with coagulating glands (with and without fluid), ventral prostate, dorsolateral prostate, levator ani plus bulbocavernosus (LABC) muscle complex, kidneys (paired), thyroid (paired, after fixation), liver, adrenal glands (paired), and pituitary gland. Subsequently, testes and epididymis were fixed in Bouin's solution overnight, then placed in 70 % ethanol until processing. The thyroid and kidneys were fixed in 10 % buffered formalin for at least 24 hours, then placed in 70 % ethanol until histopathological processing. Testes, epididymis, thyroid, and kidneys were routinely, histotechnically processed and haematoxylin and eosin stained slides were microscopically examined.

The thyroid sections (minimum of two sections) were subjectively evaluated for follicular epithelial height and colloid area and any abnormalities/ lesion were noted.

Performance criteria
Performance criteria as set out in the OCSPP test guideline 890.1500 were applied to evaluate measured values of the vehicle control group.

Statistics
Organ weights, organ weight to necropsy body weight ratio (liver, kidneys, pituitary, and adrenal glands), daily body weights (including necropsy body weight), cumulative body weight gain, serum hormones, serum chemistry parameters, and balanopreputial separation data each were tested for homogeneity of variance using Levene's test. For the purposes of this analysis, gamma glutamyltransferase values under range were assigned a value of 0.1 (half the lower limit of quantitation) for statistical analysis and reporting. Except for some daily body weight values and testosterone concentrations, all data were found to be homogeneous. For the non-homogenous data, a nonparametric test, as described below, was used to analyse the data.

When variances were homogeneous, an analysis of variance (ANOVA) was conducted on the raw data. The statistical model contained a factor for treatment group and a blocking factor based on the time of necropsy. A two-sided Dunnett's test was conducted using $p = 0.05$ to detect statistical significance, regardless of the outcome of the ANOVA, looking for significant differences in the test substance- treated groups when compared with the control group. For data that were not homogenous, the nonparametric Kruskal-Wallis test was used, ignoring the blocking factor, followed by Dunn's test, to compare each of the test substance-treated groups with the control group. The tests were two-sided at the 0.05 significance level, looking for significant differences from controls.

In addition, organ weights and balanopreputial separation data were subject to the following analyses: 1) Analysis of covariance (ANCOVA) with Dunnett's test. The model was as described above for ANOVA with the exception that PND 21 body weight was included as a covariate. 2) Linear trend test using the ANOVA model. 3) Linear trend test using the ANCOVA model.

Histopathology findings presented as a dichotomous response were analysed using pairwise Fisher's Exact tests to compare each treated group with the control. The tests were one-sided at the 0.05 significance level (testing for an increase). Histopathology findings presented as a graded response were analysed with pairwise Mann-Whitney U tests to compare each test substance-treated group with the control group. The tests were one-sided at the significance level testing for increased severity. The tests were two-sided for graded responses presented on a Grade 1-5 scale at the 0.05 significance level testing for increased or decreased severity. Exact p-values were calculated for the Mann-Whitney U test.

II. RESULTS AND DISCUSSION

A. MORTALITY
One animal of the 1000 mg/kg bw/day dose group was found dead in the morning on PND 24 (after one dose of glyphosate). Because clinical signs of toxicity and reduced body weight/ body weight change were dose-dependently observed in the 300 and 1000 mg/kg bw/day dose groups already following the first day of dosing, it cannot be excluded that this death was test substance-related. In addition, a death was observed in the 1000 mg/kg bw/day group in the 7-day pilot study. Thus, the unscheduled death observed at 1000 mg/kg bw/day was considered as test substance-related. All other males survived to scheduled necropsy.

B. CLINICAL OBSERVATIONS
A test substance-related clinical finding of rales was noted in a dose-related manner for males in the 300 and 1000 mg/kg bw/day dose groups approximately four hours post dosing (see table below). This condition persisted to the daily examinations primarily in the 1000 mg/kg bw/day dose group. This finding was noted on the first day of test substance administration, and continued sporadically throughout the treatment period until the day prior to necropsy. No other treatment-related clinical signs were noted in the dose groups

compared to control.

C. BODY WEIGHT

Terminal body weight was statistically significantly decreased for 300 and 1000 mg/kg bw/day dose group animals (-6.63 % and -10.36 %, respectively) compared to terminal control group body weight (see table below). Mean body weights were 5.07 % and 8.08 % lower in the 300 and 1000 mg/kg bw/day group than in the control group towards the end of the treatment period (PND 44-53), respectively whereas mean body weights for the 1000 mg/kg bw/day group were 5.09 % to 11.06 % lower generally throughout the treatment period (PND 24 - 53); differences were occasionally statistically significant at 1000 mg/kg bw/day and were statistically significant during PND 50 - 53 at 300 mg/kg bw/day. Body weight gain (PND 23 - 53) was significantly decreased in the 300 and 1000 mg/kg bw/day dose group (-7.5 % and -12.4 %, respectively), reaching statistical significance in the highest dose group, compared to control.

No test substance-related effects on mean body weights, daily body weight gains, or cumulative body weight gain were noted in the 100 mg/kg bw/day dose group.

The mean body weight value at the time of weaning (PND 21) in the control group (44.7 g) was slightly lower than the minimum value in the performance criteria (45.472 g), however, the coefficient of variation (CV) value was within the US EPA OPPTS 890.1500 guideline performance criteria range and the mean body weight value in the control group was similar to those in the test substance-treated groups on this day. Therefore, this out of range value was not considered to have affected interpretation of the body weight data.

D. PREPUTIAL SEPARATION

On the day of attainment of complete PPS, mean body weights in all treatment groups were similar to the control group value. For the mean age of attainment of complete PPS, a not statistically significant delay was observed in the 1000 mg/kg bw/day dose group (48.0 days) when compared to the control group (45.9 days) (see table below). A statistically significant linear trend ($p \leq 0.0178$), which resulted from both the ANOVA (unadjusted value) and ANCOVA (adjusted value) models in the 1000 mg/kg/day dose group, was reported. When a second analysis was performed, adjusting the day of attainment for those males with three or more consecutive days of incomplete separation (persistent threads), no statistically significant delay in the mean age of attainment of preputial separation was noted for the 1000 mg/kg bw/day dose group when compared to the control group. There were 6, 11, 9, and 9 males in the control, 100, 300, and 1000 mg/kg bw/day dose group, respectively, with incomplete PSS for more than three days.

No test substance related effects were observed at doses ≤300 mg/kg bw/day.

The CV value for the body weight at the attainment of PPS in the control group (9.77 %) was above the maximum value in the performance criteria (7.57 %). However, the mean body weight value at the attainment of PPS and the mean and CV value for the age of attainment of PPS in the control group were within the acceptable US EPAOPPTS 890.1500 guideline performance criteria range.

It was previously demonstrated in the literature (Ashby and Lefevre, 2000[40]) that body weight differences of approximately 12 % can result in a delay of PPS of one to two days. The delay observed in the 1000 mg/kg/day group occurred at a dose that produced a 10.36 % lower final body weight. Thus, the observed reduced body weights of the 1000 mg/kg bw/day dose group may account for the delayed age at PPS, which would indicate rather a secondary than a primary treatment-related effect.

E. HAEMATOLOGY AND CLINICAL CHEMISTRY

Blood clinical chemistry

Several serum chemistry parameters were statistically significantly changed (see table below). Higher mean

[40] Ashby J., & Lefevre, P.A. (2000). The peripubertal male rat assay as an alternative to the Hershberger castrated male rat assay for the detection of anti-androgens, oestrogens and metabolic modulators. *J. Appl. Toxicol*. 20:35-47.

alanine aminotransferase (ALT, 22.0 % and 50.8 %) and sodium (1.4 % and 2.1 %) levels were noted in the 300 and 1000 mg/kg bw/day groups, respectively, compared to control. Increased mean albumin (4.9 %), alkaline phosphatase (ALP, 22.4 %), aspartate aminotransferase (AST, 35.1 %), chloride (4.0 %), phosphorus (6.9 %), and total protein (5.1 %) levels were measured at 1000 mg/kg bw/day. Decreased (-16.9 %) urea nitrogen level was noted in the 1000 mg/kg bw/day group compared to the control group. The changes were of a degree not to be considered toxicologically significant. In addition, the lower urea nitrogen was in a direction opposite to that normally associated with toxicological effects, and therefore was considered to represent normal biologic variability. The elevated albumin, sodium, and chloride may suggest dehydration, which is a nonspecific sign of systemic toxicity.

No other statistically significant differences from the control group were noted.

None of the alterations was regarded to be adverse or indicative for specific (target organ) toxicity in addition to the reported general systemic toxicity (reduced body weight gain).

Hormone Levels

There were no test substance-related alterations in mean serum T4, TSH, and serum testosterone parameters compared to control (see table below). Mean serum T4 and TSH levels were decreased in all treatment groups compared to the control. However, none of the changes reached statistical significance and were not associated with any histological changes. TSH values were not dose-dependently changed. In addition, it was previously reported in literature (Laws *et al.*, 2007[41]; Trentacoste *et al.*, 2001[42]) that lower hormone levels may be due to lower body weights, and the association of lower hormone levels that are secondary to lower body weights have been reported in feed restricted rats during pubertal development.

The CV value for the mean TSH level in the control group (75.059 %) exceeded the maximum value in the performance criteria (58.29 %). However, the mean TSH value in the control group (8.30 ng/mL) was within the acceptable range in the US EPA OPPTS 890.1500 test guideline performance criteria (4.212 ng/mL to 24.112 ng/mL). Thus, this deviation was not considered to affect the final outcome of the study.

G. NECROPSY

Organ weights

Organ weights at necropsy are presented in the table below. Animals receiving 1000 mg/kg bw/ day glyphosate showed statistically reduced absolute liver (-15.1 %), pituitary gland (-15.6 %), LABC muscle (-15.9 %), ventral prostate (-22.6 %), and seminal vesicles with coagulating gland (-18.5 %, with fluid) weights, when compared to control. Animals receiving 300 mg/kg bw/ day glyphosate showed statistically reduced absolute liver (-9.8 %) and dorsolateral prostate (-14.3 %) weights, compared to control. Organ weight changes were considered secondary to reduced body weights, rather than indicative for specific target organ toxicity of the test substance, because no histopathological correlates were identified. Other statistically significant differences from the control group were not observed in a dose-related manner, and therefore, were not considered test substance- related.

The mean thyroid gland (13.73 mg) and kidney (1.93 g) weights in the control group were below the minimum values (14 mg and 2.242 g, respectively) of the US EPA OPPTS 890.1500 test guideline performance criteria; however, the CV values were within the acceptable range. These deviations are not considered to affect the final outcome or validity of the present study.

Gross pathology

At scheduled necropsy, no test substance-related macroscopic findings were noted for treated animals, compared to control.

[41] Laws S.C., Stoker, T.E., Ferrell, J.M., *et al.* (2007). Effects of altered food intake during pubertal development in male and female Wistar rats. *Toxicol. Sci.* 100:194-202.

Histopathology
There were no test substance-related changes in the thyroid gland, epididymides, testes, or kidney. Specifically, histologic examination of testes and epididymides revealed no alteration in the tissue structure, degree of spermatogenesis (testes), or number of spermatids. With regard to thyroid gland, there was no difference in height of follicular epithelium or amount or nature of colloid within the individual follicles. All histologic changes were considered to be incidental findings.

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is performed in accordance with the current US EPA OPPTS/OCSPP 890.1500 (2009) where the following deviations were noted. Some values of the control group were outside the guideline performance criteria range (mean body weight at time of weaning (PND 21), CV value for body weight at attainment of PPS, CV value for mean TSH level, and mean thyroid gland and kidney weights). However, CV values of mean body weight (PND 21) and thyroid and kidney weights; mean body weight at the attainment of PPS and the mean/CV value for the age of attainment of PPS; and mean TSH value were in the acceptable guideline performance criteria range. Thus, these deviations were not considered to affect the interpretation of the results. The study is therefore considered valid. A delay in the mean age at attainment of balanopreputial separation, lower reproductive organ weights (epididymides, seminal vesicle with coagulating gland, and ventral prostate), and a lower mean testosterone level were noted in the 1000 mg/kg bw/day group. These changes at the limit dose were considered to be a secondary consequence of overt toxicity, noted by 10.36 % lower mean body weights and 12.4 % reduced mean body weight gain during the dosing period in this group versus the control group. Thus, there was no evidence of any direct glyphosate-related androgenic or anti-androgenic effects, nor was there any evidence of direct glyphosate-related effects on pubertal development or thyroid function in the juvenile/ peripubertal male rat administered glyphosate up to the limit dose of 1000 mg/kg bw/day.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.8.3
Report author	[redacted]
Report year	2012
Report title	A Pubertal Development and Thyroid Function Assay of Glyphosate Administered Orally in Intact Juvenile/Peripubertal Female Rats
Report No	[redacted]-843007
Document No	Not reported
Guidelines followed in study	US EPA OPPTS/OCSPP 890.1450 (2009)
Deviations from current test guideline (OCSPP 890.1450, 2009)	The mean age of vaginal opening attainment in the control group (PND 36.4) was higher than the acceptable range of values in the performance criteria (PND 30.67 to PND 35.62). However, the coefficient of variation (CV) value (6.52) fell within the acceptable range (0.00 - 6.52), and thus, met the acceptance criteria. The weights of adrenal glands of control animals (adjusted and unadjusted: 33.3 and 33.2, respectively) were slightly lower than the acceptable range (38.34 - 48.84 mg). These deviations were not considered to affect the validity or final outcome of the study.

GLP/Officially recognised testing facilities	Yes
Comment on GLP	None
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary of the study according to OECD format

Executive summary

The objective of the study was to assess the potential effects of glyphosate on the endocrine system, by identifying effects on pubertal development and thyroid function in the juvenile/peripubertal female rat. For this purpose, 15 juvenile/peripubertal female Crl:CD(SD) Sprague Dawley rats per dose group were treated daily via oral gavage with glyphosate (in 0.5 % methylcellulose in deionized water) at doses of 0 (vehicle control), 100, 300, or the limit dose of 1000 mg/kg bw/day from postnatal day (PND) 22 to 42.

All females were observed twice daily for mortality and moribundity throughout the study. Clinical observations and body weights were recorded daily. All females were observed daily for vaginal opening. Once vaginal opening was observed, daily vaginal lavages were performed for each female to determine the stage of the estrous cycle. A complete necropsy was conducted on all rats euthanized in extremis or that survived to the scheduled euthanasia on PND 42. Adrenal glands, kidneys, liver, ovaries, pituitary gland, and thyroid were weighed and preserved at scheduled necropsy. Hormone (T4 and TSH) and clinical pathology evaluations (serum chemistry) were conducted on all surviving animals on PND 42. In addition, histopathological evaluation of the thyroid, kidney, ovary, and uterus was performed.

All treated females survived until terminal sacrifice. One female in the control group was found to have an impaired right forelimb on PND 27 and was sacrificed *in extremis*. Test substance-related rales were noted in a dose-related manner in the 300 and 1000 mg/kg bw/day dose groups. Rales were not noted in the control or the 100 mg/kg bw/day dose groups. Mean body weight and body weight change were unaffected by treatment. There were no treatment-related effects noted on the mean age of attainment of vaginal opening or body weight on the day of attainment. Mean estrous cycle lengths, estrous cyclicity, and age at the first occurrence of estrus were unaffected by treatment. There were no treatment-related changes in serum chemistry, organ weights or serum hormone levels (T4 and TSH). No test substance-related macroscopic or microscopic findings were noted at any dosage level compared to control.

There was no evidence of any glyphosate-related estrogenic or anti-estrogenic effect, nor was there any evidence of direct glyphosate-related effects on pubertal development or thyroid function in the juvenile/peripubertal female rat following administration of glyphosate at doses of 100, 300, or 1000 mg/kg bw/day.

I. MATERIALS AND METHODS

A. MATERIALS

Test material:

Identification:	Glyphosate acid
CAS No.:	1071-83-6
Description:	White powder

Lot/Batch No.:	GLP-1103-21149-T
Purity:	95.93 % glyphosate acid 85.14 % calculated glyphosate content
Stability of test compound:	Stable at room temperature
Vehicle:	Methylcellulose Source: Spectrum Chemical Manufacturing Corporation, New Brunswick, NJ, USA Lot/Batch No.: ZQ0344 CAS No.: 9004-67-5 Final concentration: 0.5 % in deionized water
Test animals:	
Species:	Rat
Strain:	Crl:CD(SD) Sprague Dawley
Source:	[redacted]
Age at start of dosing:	22 days
Sex:	Female
Weight at dosing:	41.4 - 51.3 g
Acclimation period:	Time-mated female Crl:CD(SD) Sprague Dawley rats (43 females) were received from Charles River on 23 August 2011. The females were used to obtain the juvenile females for the present study. Hence, animals of the present study were born at the testing facility. Weaning took place on PND 21. Study allocation took place on PND 22.
Diet/Food:	Harlan Laboratories basal diet (2016*CM* Teklad Global, 16 % Protein Rodent Diet; 11.0 ppm of total isoflavones (genistein + daidzein + glycitein), *ad libitum*
Water:	Reverse-osmosis filtered tap water, *ad libitum*
Housing:	Dams and littermates in plastic maternity cages with nesting material until weaning on PND 21. After weaning, juveniles were housed two to three females per cage throughout the study.
Environmental conditions:	Temperature: 21.4 - 22.1 °C Humidity: 41.2 - 58.9 % Air changes: 10/h Photocycle: 14 hours light/ 10 hours dark cycle

B. STUDY DESIGN AND METHODS

In life dates: 23 Aug 2011 delivery of pregnant rats; 28 Sep to 19 Oct 2011 test substance administration to female offspring

Animal assignment and treatment

Offspring of time-mated female rats were weaned and weighed on PND 21. Animals were assigned to study groups using a WTDMS™ computer program, which randomised the animals based on stratification of body weights in a block design. Littermates were not assigned to the same treatment group. The treatment groups included one vehicle control group and three glyphosate treatment groups at doses of 100, 300, and 1000 mg/kg bw/day.

All doses were administered once daily by oral gavage, from PND 22 through PND 42, in a volume of 5 mL/kg bw. Dosing was performed daily between 7:00 AM and 9:00 AM.

Table 5.8.3-28: A Pubertal Development and Thyroid Function Assay of Glyphosate Administered Orally in Intact Juvenile/Peripubertal Female Rats ([redacted] 2012): Study design of pubertal development and thyroid function assay with glyphosate, administered orally to female Sprague Dawley rats

Test group	Dose (mg/kg bw/day)[1]	No. of females	Dosing volume (mL/kg bw/day)
Control (vehicle)	0	15	5
Low	100	15	5
Mid	300	15	5
High	1000	15	5

[1] A correction factor of 85.14 % was used to account for the active substance.

Dose Preparation and Analysis
The vehicle was prepared approximately weekly for administration to the control group and for preparation of the test substance formulations; aliquots were prepared for daily dispensation to the control group and stored at room temperature. The vehicle was mixed throughout the preparation, sampling, and dose administration procedures. The test substance formulations were prepared approximately weekly as single formulations for each dosage level by mixing appropriate amounts of test substance with 0.5 % methylcellulose in deionized water, divided into aliquots for daily dispensation, and stored at room temperature. The test substance formulations were continuously stirred throughout the preparation, sampling, and dose administration procedures.

Analyses to demonstrate homogeneity, resuspension homogeneity for suspensions, and stability of the test substance formulations for up to 15 days of room temperature storage at concentrations of 1 and 200 mg/mL were conducted prior to the start of dose administration in a separate study ([redacted]-843004). During the present study, samples of dose formulations were analysed three times (on September 27, October 4, and October 11, 2011). Analysed concentrations ranged from 98.9 - 100 % of nominal for the low dose, 102 - 105 % of nominal for the mid-dose, and 104 - 112 % of nominal for the high dose. The analytical data indicated that the variation between nominal and actual dose to the animals was acceptable.

Mortality
All animals were examined twice daily, once in the morning and once in the afternoon, for mortality and moribundity.

Clinical observations
Clinical examinations were conducted on the day of randomization and daily (prior to test substance administration) through the day of scheduled necropsy. Animals were also observed for signs of toxicity approximately four hours following dose administration.

Body weight
Animals were weighed on the day of randomization, daily prior to test substance administration during the treatment period, and on the day of scheduled necropsy.

Food consumption
Food consumption was not evaluated.

Vaginal opening
Beginning on PND 22, all animals were examined daily for onset of vaginal opening. In addition, the appearance of a small "pin hole", a vaginal thread, and complete vaginal opening were recorded. The age and body weight on the day at which the vaginal lumen was first observed to open was recorded for each animal. If any animal within any group showed incomplete opening (persistent pin holes and/or threads) for greater than three days, a separate second analysis was conducted using the age at which incomplete

opening was first observed. Examination of the females was continued daily until vaginal opening was present or until euthanasia.

Estrous cyclicity
Beginning on the day of vaginal opening, up to and including the day of necropsy, daily vaginal lavages were performed. Slides were evaluated microscopically to determine the stage of the estrous cycle (proestrus [P], estrus [E], metestrus [M], diestrus [D]) of each female. The age at first vaginal estrus after vaginal opening was recorded. Females that had no E or P during the evaluation period were assigned an age of 43 days (last study day + 1 day). If a female had no E, but had a P during the evaluation period, the age at first estrus was considered the age on the day of P +1 day. The average cycle length was calculated and reported for complete estrous cycles (i.e. the total number of returns to M or D from E or P). Estrous cycle length was determined by counting the number of days from the first M or D in a cycle to the first M or D in a subsequent cycle.

At the end of the study, the overall pattern for each female was characterised as regularly cycling, irregularly cycling, not cycling, or insufficient data; based on predefined established definitions for these terms. For a "complete cycle", an animal must have exhibited at minimum an E from the previous cycle, followed by one cycle (D to E), and a D from the start of the next cycle. The "percent cycling" and "percent cycling regularly" was calculated.

Haematology and clinical chemistry
On PND 42 approximately 2 h post-dosing (approximately 01:00 PM), rats were removed one at a time from their home cages to a separate room for euthanasia by decapitation without anaesthesia so as not to induce stress-related responses or diurnal fluctuations, which may affect hormone measurements. Blood from the trunk of the animals was collected immediately into three serum separation tubes. One tube of serum samples was used for serum chemistry evaluation. The remaining two tubes of serum samples for each animal were used for total thyroxine (T4) and thyroid stimulating hormone (TSH) analyses. Samples were analysed fresh or stored frozen (≤ -20 °C).
The following clinical chemistry parameters were examined: calcium, chloride, phosphorus, potassium, sodium, albumin, creatinine, urea nitrogen, total cholesterol, globulin (calculated), albumin/globulin ratio (calculated), glucose, total bilirubin, total protein, triglycerides, bile acids, alkaline phosphatase (ALP), alanine aminotransferase (ALT, also SGPT), aspartate aminotransferase (AST, also SGOT), gamma glutamyltransferase (GGT).

T4 and TSH levels were analysed using an electrochemiluminescent immunoassay and (^{125}I)rTSH kit, respectively.

Sacrifice and pathology
On PND 42 approximately 2 h post-dosing (at approximately 01:00 PM), rats were removed one at a time from their home cages to a separate room for euthanasia by decapitation without anaesthesia so as not to induce stress-related responses or diurnal fluctuations which may affect hormone measurements. The necropsy was conducted in a randomized manner and included examination of the external surface, all orifices, the external surface of the brain and the abdominal, thoracic, and pelvic cavities, including viscera. Any tissues with gross lesions were saved in 10 % neutral-buffered formalin for possible future histopathologic examination. The following tissues were collected and weighed: ovaries (paired, without oviducts), uterus with cervix (both "wet" with luminal fluid and "blotted" following removal of luminal fluid), thyroid (weighed after fixation), adrenal glands (paired), pituitary, liver, and kidneys (paired). Additionally, the ovaries, uterus, thyroid and kidneys were fixed in 10 % buffered formalin (ovaries and uterus stored in 70 % ethanol prior to embedding) and subjected to histological processing and examination.

The thyroid sections (minimum of two sections) were subjectively evaluated for follicular epithelial height and colloid area and any abnormalities/lesions were noted. Five random sections from both ovaries were evaluated for follicular development and any abnormalities/lesions. The stage of the estrous cycle of a

female at the time of necropsy was taken into account in the final histological assessment.

Statistics
Organ weights, organ weight to necropsy body weight ratio (liver, kidneys, pituitary, and adrenal glands), daily body weights (including necropsy body weight), cumulative body weight gain, serum chemistries, serum hormones and vaginal opening data were each was tested for homogeneity of variance using Levene's test. For the purposes of this analysis, gamma glutamyltransferase (GGT) values under range were assigned a value of 0.1 (half the lower limit of quantitation) for statistical analysis and reporting. Except for GGT concentrations, homogeneity of variance was confirmed for each endpoint ($p > 0.01$); AST concentrations required log transformation to demonstrate homogeneity.

An ANOVA was conducted on the raw or log-transformed homogenous data. The statistical model contained a factor for treatment group and a blocking factor based on the time of necropsy. A two-sided Dunnett's test was conducted, regardless of the outcome of the ANOVA, looking for significant differences in the test substance-treated groups when compared with the control group. For the GGT data, a nonparametric Kruskal-Wallis test was used, ignoring the blocking factor, followed by Dunn's test, to compare each of the test substance-treated groups with the control group. The tests were two-sided at the 0.05 significance level, looking for significant differences from controls.

In addition, organ weights and vaginal opening data were subject to the following analyses: 1) Analysis of covariance (ANCOVA) with Dunnett's test. The model was as described above for ANOVA with the exception that PND 21 body weight was included as a covariate; 2) Linear trend test using the ANOVA model; and 3) Linear trend test using the ANCOVA model.

Chi-square analysis was used to determine significant difference between cycling status (cycling vs. not cycling) and percent of animals cycling regularly of the test substance-treated groups from the control group. Estrous cycle length and the day of first estrus were subjected to a parametric one-way ANOVA to determine intergroup differences. If the ANOVA revealed significant ($p < 0.05$) intergroup variance, Dunnett's test was used to compare the test substance-treated groups to the control group.

Histopathology findings presenting as a dichotomous response were analysed with pairwise Fisher's exact tests to compare each test substance-treated group with the control group. The tests were one-sided at the 0.05 significance level testing for an increase. Histopathology findings presented as a graded response were analysed with pairwise Mann-Whitney U tests to compare each treated group with the control. The tests were one-sided at the 0.05 significance level (testing for an increase). Tests were two-sided for graded responses presented on a grade 1-5 scale at 0.05 significance level testing for increased or decreased severity. Exact p-values were calculated for the Mann-Whitney U test.

II. RESULTS AND DISCUSSION

A. MORTALITY
All treated females survived until scheduled necropsy. Following dosing on PND 27, one control female was noted with impaired use of the right forelimb due to a possible mechanical injury. This female was subsequently euthanized *in extremis*.

B. CLINICAL OBSERVATIONS
Rales were noted for 4 and 13 females in the 300 and 1000 mg/kg bw/day dose group, respectively (see table below). They were observed approximately four hours following dose administration throughout the treatment period, and were considered treatment-related. Rales were neither observed in the control nor in the 100 mg/kg bw/day dose group. No other clinical signs were noted in the treatment groups compared to controls.

Table 5.8.3-29: A Pubertal Development and Thyroid Function Assay of Glyphosate

Administered Orally in Intact Juvenile/Peripubertal Female Rats ([redacted] 2012): Incidence of Clinical Observations

Observation	Dose Level (mg/kg bw/day)			
	Control	100	300	1000
Rales [1]	0 / 15	0 / 15	4 / 15	13 / 15

[1] Number animals with observation / number animals examined

C. BODY WEIGHT

No treatment-related effects on mean body weights or body weight changes were noted in the 100, 300, or 1000 mg/kg bw/day group when compared to the vehicle control group (see table below).

D. VAGINAL OPENING

Mean body weight and mean age at day of attainment of vaginal opening was not affected by treatment with 100, 300, or 1000 mg/kg bw/day glyphosate (see table below).

The mean age of vaginal opening attainment in the control group (PND 36.4) was higher than the acceptable range of values in the performance criteria (PND 30.67 to PND 35.62; US EPA OPPTS 890.1450). However, the coefficient of variation (CV) value (6.52) fell within the acceptable range (0.00 - 6.52), and thus, met the acceptance criteria. The increased mean age of vaginal opening of the control group was not considered to impact the validity or final outcome of the study.

E. ESTROUS CYCLICITY

Mean estrous cycle lengths in the 100, 300, and 1000 mg/kg bw/day treated groups (4.8, 5.0, and 5.0 days, respectively) were similar to control group values (5.0 days) (see table below). No statistically significant differences in the age at the first occurrence of estrus were observed when the glyphosate-treated groups were compared to the control group. The percentage of regularly cycling females in the 300 and 1000 mg/kg bw/day groups was significantly ($p < 0.01$ or $p < 0.05$) lower than the control group. However, a large number of females (up to ten per group) in the 300 and 1000 mg/kg bw/day groups had insufficient estrous cycle data (the animal did not display at least one complete estrous cycle but had at least one E and/or P and a partial cycle of five days or fewer, no E present on any days of estrous cycle determination and four or fewer days of data collected, or at least one E or P present and only one to four days of cycle data collection) that resulted in a limited number of females (five per group) available for evaluation of estrous cyclicity. These lower percentages did not occur in a dose-related manner and the percentage of females cycling in these groups was not statistically significantly different from the control group. Therefore, these lower values were not considered test substance-related.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Blood clinical chemistry

There were no treatment-related changes in serum chemistry parameters that were considered adverse (see table below). The following statistically significant differences from control were observed: decreased AST levels in all three dose groups, decreased potassium levels in the 100 and 300 mg/kg bw/day dose groups, increased chloride and ALP levels in the 1000 mg/kg bw/day dose group, and decreased phosphorus levels in the 100 mg/kg bw/day dose group when compared to concurrent control. The changes of the ALP and chloride values in the 1000 mg/kg bw/day dose group were considered test substance-related because the elevations were limited to the high dose group. However, they were considered of no biological relevance due to the absence of any histological correlate in the organs examined, including liver. In addition, the mean chloride value at 1000 mg/kg bw/day was within the range of historical control data of the testing laboratory for female Sprague Dawley rats at 6 - 8 weeks of age. The changes in AST involved a decrease of normal levels, which is not usually associated with toxicological effects, and therefore the change was considered spurious and unrelated to the test substance. The decreased potassium and phosphorus levels occurred without a dose response-relationship and were considered to be of no biological relevance. Mean

group potassium values, including the control group, were above the historical control data range of 3.97 - 5.94 mEq/L. However, this observation is considered to not influence the final outcome of the study.

Hormone Levels
There were no treatment-related alterations in thyroid hormone parameters at any dose level tested (see table below). The T4 levels in the control group and the corresponding CV were within the US EPA OPPTS 890.1450 performance criteria.

G. NECROPSY
Organ weights
There were no test substance-related changes in weights of the ovaries (paired, without oviducts), uterus, kidneys (paired), thyroid, liver, adrenal glands (paired), and pituitary (see table below). The organ weights of the control animals met the performance criteria outlined in US EPA OPPTS 890.1450, except for adrenal weights (adjusted and unadjusted: 33.3 and 33.2, respectively), which were slightly lower than the acceptable range (38.34 - 48.84 mg). The CVs for organ weights were all within the performance criteria.

Gross pathology
No treatment-related macroscopic findings were observed.

Histopathology
There were no treatment-related microscopic findings in the ovaries, uterus, kidneys, or thyroid gland (see table below). All histologic changes were considered to be incidental findings and consistent with the age and strain of rats used.

Table 5.8.3-30: A Pubertal Development and Thyroid Function Assay of Glyphosate Administered Orally in Intact Juvenile/Peripubertal Female Rats ([redacted] 2012): Body weight and vaginal opening (VO) - selected time points according to test guideline

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is performed in accordance with the current US EPA OPPTS/OCSPP 890.1450 (2009) where the following deviations were noted. The mean age of vaginal opening attainment in the control group was higher than the acceptable range of values in the performance criteria. However, the coefficient of variation value fell within the acceptable range, and thus, met the acceptance criteria. The weights of adrenal glands of control animals were slightly lower than the acceptable range. These deviations were not considered to impact the validity or final outcome of the study. The study is therefore considered valid. There was no evidence of any test substance-related estrogenic or anti-estrogenic effects, nor was there any evidence of test substance-related effects on pubertal development or thyroid function in the juvenile/peripubertal female rat following oral administration of glyphosate at dosage levels of 100, 300, and 1000 mg/kg bw/day.

Assessment and conclusion by RMS:

Data point:	CA 5.8.3
Report author	Hecker, M. *et al.*
Report year	2011
Report title	The OECD validation program of the H295R steroidogenesis assay: Phase 3. Final inter-laboratory validation study
Report No	DOI 10.1007/s11356-010-0396-x
Document No	Not reported
Guidelines followed in study	Not applicable (OECD Test Guideline (TG) was approved in July 2011 as OECD TG 456, after the work of the publication was completed).
Deviations from current test guideline (OCSPP 890.1550, 2009) (OECD 456, 2011)	None (key values provided in the publication are in line with current OECD TG 456).
Previous evaluation	Yes, accepted in EFSA peer review on endocrine disrupting properties (2017).
GLP/Officially recognised testing facilities	Not specified
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The purpose of this study was to validate a standardised steroidogenesis assay protocol to develop an OECD

draft test guideline. (Note: The OECD Test Guideline (TG) was approved in July 2011 as OECD TG 456.) Twenty-eight chemicals were selected as model substances to validate the H295R steroidogenesis assay, to identify potential effects of endocrine-disrupting substances on the production of testosterone (T) and 17β-estradiol (E2). These test substances were selected based on their known or suspected endocrine activity, or lack thereof, and included inhibitors and inducers of different potencies as well as positive and negative controls. They were selected and approved by the OECD Validation and Management Group for Non-Animal Testing (VMG NA). Glyphosate was one of the test substances evaluated. A total of seven laboratories from the US, Denmark, Germany, Japan, Hong Kong, and Canada participated in this validation study. Two of these participating laboratories evaluated glyphosate.

H295R cells were cultured under standard cell culture conditions for at least four or five passages prior to use in the assay. The cells were plated into 24-well cell culture plates at a density of approximately 200,000 to 300,000 cells/mL. Cells were allowed to acclimate for 24 hours prior to test substance exposure. Then, cells were exposed for 48 hours to seven concentrations of glyphosate using log intervals between 0.0001 and 100 µM of the test substance in triplicate. A concurrent quality control plate was included in each of the independent runs to demonstrate the correct assay's response to forskolin (a known inducer of testosterone and estradiol production) and prochloraz (a known inhibitor of testosterone and estradiol production). After the 48-hour exposure period, medium was collected from all wells and concentrations of hormones were measured using commercially available hormone detection kits (in one laboratory using enzyme linked immunoassay and liquid chromatography with mass spectroscopy [hormones were extracted with ethyl ether before analysis], in the other laboratory using radio immunoassay without previous extraction of the hormones). After media removal, cell viability was measured using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay or the Live/Dead® variability assay. All concentrations with cell viability ≤80 %, were excluded from the data analysis. One laboratory conducted one experiment without further replicates; the other laboratory conducted three independent experiments with the test substance glyphosate. All laboratories were required to demonstrate proficiency in performing the single procedures that are part of the H295R steroidogenesis assay protocol. For this purpose, predefined performance criteria had to be met. In addition, each test substance was tested for potential interference with the hormone detection system used before exposing cells in the main experiment. This was of particular relevance for antibody-based assays such as the enzyme linked immunoassay and the radioimmunoassay.

To examine the relative changes in hormone production, results were normalized to the mean vehicle control (VC) value, and results were expressed as percent change relative to the VC. Prior to conducting statistical analyses, the assumptions of data normality and variance of homogeneity were evaluated. Normality was evaluated using standard probability plots or the Shapiro–Wilk's test. If the data were normally distributed, differences between chemical treatments and vehicle controls were analysed using one-way analysis of variance (ANOVA) followed by a two-sided Dunnett's test. If data were not normally distributed, the Kruskal–Wallis test followed by the Mann–Whitney U test were used. Data analysis was conducted using pooled replicate experiments. Differences were considered significant at $p < 0.05$.

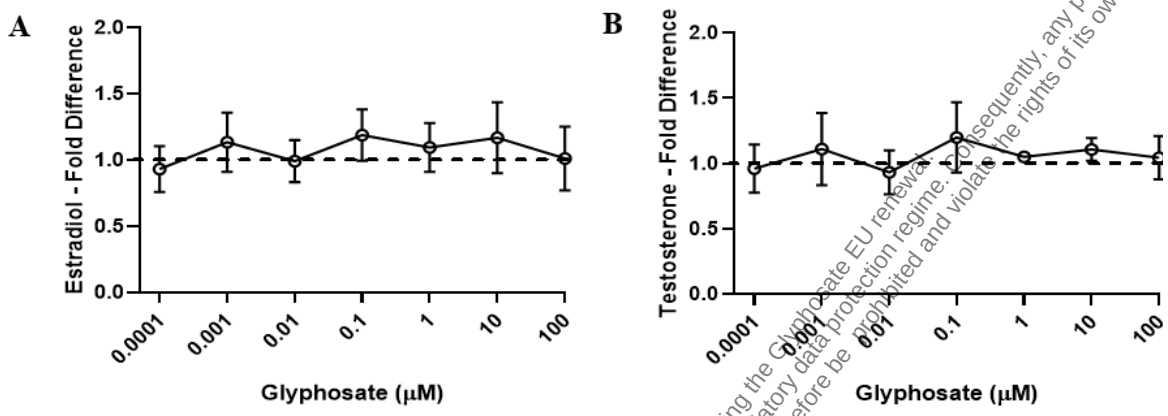
In the present H295R steroidogenesis assay validation study, glyphosate was tested negative for changes in T, as well as E2 production. None of the two laboratories could detect a change in hormone production when compared to the concurrent control (see figure below). The authors stated that test substances that tested negative for T and E2 effects *in vitro* (H295R assay), like glyphosate, did not cause any changes in serum T and E2 concentrations *in vivo*, too (Soso *et al.*, 2007[43]). This result is consistent with an article in the peer-reviewed literature using similar methodology in Leydig cells (Forgacs *et al.*, 2012[44]).

Figure 5.8.3-5: The OECD validation program of the H295R steroidogenesis assay: Phase 3. Final inter-

[43] Soso, A.B, Barcellos, L.J.G., Ranzani-Paiva, M.J. *et al.* (2007). Chronic exposure to sub-lethal concentrations of a glyphosate-based herbicide alters hormone profiles and affects reproduction of female Jundi'a (*Rhamdia quelen*). *Environ Toxicol Pharm*. 23:308-313.

[44] Forgacs A.L., Ding, Q., Jaremba, R.G., *et al.* (2012). BLTK1 murine Leydig cells: A novel steroidogenic model for evaluating the effects of reproductive and developmental toxicants. *Toxicol. Sci*. 127:391-402.

laboratory validation study (Hecker et al., 2011): Glyphosate did not affect production of 17β-estradiol (A) or testosterone (B) in the H295R steroidogenesis assay. Values are shown as mean fold-difference relative to the control ± standard error.



In conclusion, glyphosate was tested negative for changes in E2 and T production in the H295R steroidogenesis assay in two separate laboratories during OECD's Phase 3 validation.

CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
Key values provided in the publication are in line with current OECD 456 (2011). The study is therefore considered valid. This OECD inter-laboratory validation of the H295R steroidogenesis assay, which includes glyphosate as one of many test materials, demonstrates that glyphosate does not impact 17β-estradiol or testosterone production.

Assessment and conclusion by RMS:

2. Full summary

According to the ED criteria laid down in Regulation (EU) 2018/605, endocrine mediated adversity as well as activity and the biological link between those two must be apparent to identify a substance as an endocrine disruptor. Therefore, a comprehensive ED assessment was performed according to the guidance document *Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009* (ECHA-EFSA, 2018). For details please refer to the ED assessment report *Assessment on the endocrine disrupting properties of the active substance glyphosate in accordance with Commission Regulation (EU) 2018/605* ([redacted] 2020, CA 5.8.3/010).

Concerning the ED assessment of humans and mammals, potential effects of glyphosate on the HPT and HPG axis were addressed in several repeated dose toxicity studies of subacute to chronic exposure also considering different life stages (level 4 and 5 studies of the OECD conceptual framework). In addition, *in vitro* and *in silico* information are available and considered for the ED assessment of glyphosate. With regard to EATS-mediated adversity, a review of the available mammalian guideline studies in four species (dog, mouse, rabbit, rat), conducted with glyphosate over different exposure periods and considering different life stages (in rat), did not show carcinogenicity or any other EATS-mediated adverse effects based on a sufficient dataset as required in the ECHA/EFSA ED Guidance. Potential EATS-related activity was investigated in the male and female pubertal assay, where hormone measurements were performed, as well as the Uterotrophic and Hershberger Assay providing *in vivo* mechanistic data. Neither the described *in vivo* assays nor *in vitro* and *in silico* information provide any indication on EATS-related endocrine activity of glyphosate.

Hence, the ED criteria for glyphosate with regards to human health and mammals are not met, since neither EATS-mediated adversity nor endocrine activity has been observed.

With regards to non-target organisms, EATS-mediated adversity of glyphosate has not been observed in any of the ecotoxicological studies conducted with glyphosate in birds, fish, amphibians and invertebrates. Regarding the assessment of potential EAS-mediated adversity, only secondary effects as a consequence of systemic toxicity are observed. The effects are ranked as "sensitive to, but not diagnostic of EATS" modalities and "systemic toxicity". Potential EAS-mediated activity has been investigated within a Fish Short-Term Reproduction Assay and is therefore sufficiently investigated. No indication for EAS-related endocrine activity was observed.

T-mediated activity was investigated within an amphibian metamorphosis assay and is therefore sufficiently investigated. No effects on relevant parameters rated as "T-mediated" were found. This result is sufficient to conclude that T-mediated adversity is unlikely, as no T-related endocrine activity has been observed.

Hence, the ED criteria for glyphosate with regards to non-target organisms are therefore not met.

In conclusion, glyphosate does not induce EATS-mediated adversity and no EATS-related endocrine activity was observed *in silico, in vitro,* and *in vivo* for humans and mammals as well as for non-target organisms. This conclusion is in concordance with the current Peer review of the pesticide risk assessment of the potential endocrine disrupting properties of glyphosate (EFSA Journal 2017; 15(9): 4979) as well as

with the conclusion of EPA on the Endocrine Screening Program (EDSP) Tier l (US EPA, 2015).
Since glyphosate has not been shown to induce EATS-mediated adversity or endocrine activity, it is concluded that the ED criteria with regard to EATS-modalities in humans and mammals as well as non-target organisms are not met for glyphosate.

CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
Since glyphosate has not been shown to induce EATS-mediated adversity or endocrine activity, it is concluded that the ED criteria with regard to EATS-modalities in humans and mammals as well as non-target organisms are not met for glyphosate.
For details please refer to the ED assessment report *Assessment on the endocrine disrupting properties of the active substance glyphosate in accordance with Commission Regulation (EU) 2018/605*.

2. Full summary

(Q)SAR predictions were generated using selected publicly available and commercial models. Five QSAR

tools were applied for predictions of potential endocrine activity of glyphosate: OECD QSAR Toolbox, Vega, Endocrine Disruptome, Danish QSAR database and ToxCast COMPARA/CERAPP consensus models. The list of investigated receptors include: estrogen receptor (ER), androgen receptor (AR), thyroid receptor (TR), glycocorticoid receptor (GR), mineralocorticoid receptor (MR), liver X receptor (LXR), peroxisome proliferator-activated receptor (PPAR), retinoid X receptor (RXR), aryl hydrocarbon receptor (AhR), pregnane X receptor (PXR), and CYP3A4 receptor.
For details please refer to the (Q)SAR ED assessment report *(Q)SAR screening on endocrine disrupting potential of Glyphosate under the Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009*.

Table 5.8.3-36: (Q)SAR screening on endocrine disrupting potential of Glyphosate under the Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009 ([redacted], 2020): Outcome of the *in silico* screening for glyphosate

Modality	Summary outcome of *in silico* screening	Remarks
Estrogen	No indication	Estrogenic activity was predicted negative with all five applied models. Due to the high amount of data available on ER activity, the high quality of CERAPP Consensus predictions and glyphosate being part of the training set for ER binding tests, the assessment of ER activity of glyphosate is considered reliable.
Androgen	No indication	Androgenic activity was predicted negative with all five applied models. Due to the quality of CoMPARA consensus predictions in combination with other models (predicting no androgenic activity), the assessment of androgenic activity based on the available models is considered reliable. This is further strengthened, as glyphosate is part of the testing battery of the Danish QSAR DB and tested negative for antagonistic effect on the human androgen receptor *in vitro*.
Steroid	No indication	There are three results available for steroid receptors: glucocorticoid receptor (GR) and glucocorticoid receptor antagonism and mineralocorticoid receptor (MR). No steroid activity is predicted for all three receptors by the molecular docking method (Endocrine Disruptome).
Thyroid	No indication	TR binding activity is predicted to be low for glyphosate by the molecular docking method (Endocrine Disruptome). Two models available in the Danish QSAR database yield inconclusive and negative results. Both predictions are out of applicability domain and thus of low reliability.
Other	No indication	Overall, there is no indication of activity for endocrine activities other than estrogen, androgen, steroid and thyroid, however due to the general lack of models for the various receptors, the result should be considered with caution.

CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

Five QSAR tools were applied for predictions of potential endocrine activity of glyphosate: OECD QSAR Toolbox, Vega, Endocrine Disruptome, Danish QSAR database and OPERA ToxCast COMPARA/CERAPP consensus models.
For androgenic and estrogenic activity, the largest number of data and models is available. Specifically due to the available CONSENSUS models (CoMPARA/CERAPP) derived from the extensive high-throughput screening tests as conducted under the EDSP in combination with available literature derived predictions, the overall assessment of androgenic and estrogenic activities is considered reliable and was shown to be negative. This outcome is strengthened because glyphosate is part of the training set of ER binding tests showing negative results as well as tested negative for antagonistic effects on the human

androgen receptor *in vitro*.
For all other modalities, lower amount of data and models are available. Thus, the confidence in the screening assessments for thyroid, steroid or other modalities is lower. However, also here no indication for thyroid, steroid or other modalities activities were observed.
Overall, there is no indication that glyphosate has endocrine disrupting activity.
For details please refer to the (Q)SAR ED assessment report *(Q)SAR screening on endocrine disrupting potential of Glyphosate under the Guidance for the identification of endocrine disruptors in the context of Regulations (EU) No 528/2012 and (EC) No 1107/2009*.

Assessment and conclusion by RMS:

A literature search for the active substance glyphosate was performed in accordance to the provisions of the EFSA Guidance "Submission of scientific peer-reviewed open literature for the approval of pesticide active substances under Regulation (EC) [redacted] and reliable for this section and the summaries are thus presented below and are part of the general discussion at the beginning of the section.

Table 5.8.3-37: Publications on cellular effects of glyphosate

Annex Point	Study & Substance tested	Study type	Reliability and restriction comments	Result
CA 5.8.3/012	Gigante *et al.*, 2018 Glyphosate (Batch: not specified, Purity: not specified)	*in vitro:* granulosa cells of swine ovaries and adipose stromal cells (ASCs) from swine adipose tissue; parameters examined: cell proliferation; cell viability; steroid, O_2^- and NO production; FRAP assay; cell differentiation; expression of marker genes; and intracellular lipid accumulation	Test substance not characterized No positive control Only one dose tested in adipose stromal cells	Glyphosate decreased cell proliferation, cell viability, estrogen production and ferric reducing capacity and increased progesterone and NO production in granulosa cells when tested at 0.2 to 16 µg/mL. In none of the assays with granulosa cells a concentration-response relationship was established. Glyphosate treatment at 4 µg/mL decreased the viability of proliferating adipose stromal cells. Differentiated cell counts showed a significant inhibition of the adipogenic process by glyphosate.
CA 5.8.3/013	Vanlaeys *et al.*, 2018 Glyphosate (Batch: not specified), Purity: not specified)	*in vitro:* murine TM4 Sertoli cell line, parameters examined: cytotoxicity, glutathione transferase activity, and lipid accumulation	Test substance not characterized No positive controls	Glyphosate had no impact on cell viability after 24 hours of exposure to concentrations from 10 to 10,000 ppm. Glyphosate reduced succinate dehydrogenase to some extent over the entire concentration range from 10 to 10,000 ppm with no concentration-response relationship. It had no impact on glutathione transferase activity. Exposure of TM4 cells to glyphosate for 24 hours at 2,500 or 5,000 ppm induced an increase in cytoplasmic lipid droplets.
CA	Mesnage *et al.*,	*in vitro:* MCF-7, MDA-		Increased cell proliferation was

5.8.3/014	2017 Glyphosate PESTANAL® (Batch: not specified, Purity: ≥98.0 %)	MB-231 and T47D cell lines, parameters examined: estrogen receptor (ER)-mediated cell proliferation, ERE-luciferase reporter gene assay, gene expression profiling		observed in MCF-7 and T47D cells at 10,000 µg/L to 1,000,000 µg/L. Glyphosate stimulated ERE-mediated transcription of the luciferase reporter gene starting at a concentration of 1,000 µg/L. The analysis of gene ontology confirms that genes having their expression altered by treatment of MCF-7 cells with glyphosate were involved in cell cycle regulation, stimulation by steroid hormones and cell death through apoptosis. ONIOM binding energy assessment implies that binding of glyphosate to the ER is weak and unstable.
CA 5.8.3/015	Thongprakaisang *et al.*, 2013 Glyphosate (Batch: not specified, Purity: >98 %)	*in vitro:* T47D, T47D-KBluc, and MDA-MB231 cell lines; parameters examined: cell proliferation of hormone-dependent and - independent cell lines in with/without an ER antagonist; ERE-transcription activity with/without an ER antagonist; and expression of ERs	Results do not corroborate with in vivo Hershberger and Uterotrophic assays	Glyphosate induced cell proliferation in a hormone-dependent cancer cell line but not in a hormone-independent cancer cell line in the absence of estrogen (E2). In the presence of a potent ER antagonist the cell proliferation caused by glyphosate in a hormone-dependent cancer cell line was reduced. The interaction of glyphosate with the ER was confirmed by ERE activation with and without an ER antagonist. When cells were co-incubated with glyphosate and E2, glyphosate suppressed the E2-induced ERE activation suggesting that glyphosate behaves as an antagonist in the presence of an endogenous agonist. Glyphosate altered the expression of ERα and ERβ in human breast cancer cells.
CA 5.8.3/016 CA 5.8.3/017	Brennan *et al.*, 2016 Glyphosate (Batch: not specified, Purity: not specified)	*in vitro:* VM7Luc4E2 and VM7LucERβc9 cell lines, parameters examined: estrogen receptor (ERα/β)-mediated luciferase reporter gene assay	Test substance not characterized	Glyphosate did not show any estrogenic activity at a concentration of 10 µM in two cell lines or via the two human estrogen receptor (hER) subtypes, hERα and hERβ.
CA 5.8.3/018	Defarge *et al.*, 2016 Glyphosate IPA (Batch: not specified, Purity: not specified)	*in vitro:* JEG3 cell lines, parameters examined: aromatase activity, cytotoxicity (MTT, Toxilight bioassay)	Test substance not characterized	An effect on aromatase activity was not observed when cells were treated with glyphosate at non-toxic concentrations. At a higher glyphosate concentration (17.7 mM) a reduction of aromatase activity was seen at unphysiologic conditions and therefore, not considered relevant for human health.

8. Full summary

Executive Summary

The effect of glyphosate (GLY) at different doses (0.2, 4 and 16 µg/mL) was evaluated on granulosa cells growth (BrDU incorporation and ATP production), steroidogenesis (17-β estradiol and progesterone secretion) and redox status (superoxide and nitric oxide production and non-enzymatic scavenging activity). GLY has been shown to inhibit cell growth, 17-β estradiol and non-enzymatic scavenging activity and to increase progesterone and nitric oxide secretion ($P < 0.05$). In addition, GLY significantly decreased the viability of ASCs ($P < 0.001$), and inhibited their adipogenic differentiation. These data indicate that GLY alters the main features of granulosa cells and ASCs; thus suggesting that GLY could affect both reproductive function and adipose tissues homeostasis.

I. MATERIALS AND METHODS

A. MATERIALS

Test Material

Glyphosate was purchased from Sigma Chemical Co, St Louis, USA. The purity was not reported.

Isolation and culture of granulosa cells

Swine ovaries were collected at a local slaughterhouse, placed in PBS at 4 °C supplemented with penicillin (100 Ul/mL), streptomycin (100 Ul/mL) and amphotericin B (2.5 µg/mL) and transported to the laboratory within 1 hour. The samples were immersed for 1 minute in ethanol 70 % before processing. Cystic or hemorrhagic follicles were discarded and the granulosa cells were harvested by aspiration of the follicles in the later state of maturation. The granulosa cells were then centrifuged at 450xg for 10 minutes and the cell pellet obtained treated with ammonium chloride to remove red blood cells. The cell number was estimated after vital staining with trypan blue whereafter the cells were plated and cultured in a validated serum free system composed of DMEM/Ham's F12 medium supplemented with penicillin (100 µg/mL), amphotericin B (2,5 µg/mL), streptomycin (100 µg/mL), sodium selenite (5 ng/mL) and transferrin (5 µg/mL) (CM). CM medium maintains the characteristics of granulosa cells and avoids luteinization.

B. STUDY DESIGN

Cell proliferation

Cell proliferation is measured using the BrdU cell proliferation ELISA assay. The granulosa cells were plated into 96-well plates (10^4 cells/100 µL CM) and incubated overnight with glyphosate at 0, 0.2, 4 or16 µg/mL. At the end, plates were centrifuged for 10 minutes at 400×g, the supernatants discarded and the cells dried and fixed. The DNA was denatured before the addition of the anti-BrdU antibody, conjugated with horseradish peroxidase (POD). The POD substrate used was tetramethyl-benzidine (TMB). Absorbance at 450 nm of the blue color formed is proportional to the amount of newly synthesized DNA. To quantify the viable cell number, the absorbance of each sample was related to a standard curve prepared by culturing, in quintuplicate, granulosa cells at different plating densities for 48 hours. The curve was repeated in four different experiments. The cell number/well was estimated from the resulting linear regression equation and was used to correct experimental data. The assay detection limit was 10^3 cell/well and the variation coeffcient was less than 5 %.

Cell viability

Granulosa cell viability was assessed using the ATP-lite bioluminescent assay based on the reaction of ATP luciferase and luciferin. The light emitted is proportional to the ATP concentration in the cells. The test was validated by plating different viable cell numbers (from 2.5×10^3 to 4×10^5/100 µL) three times. The relationship between cell number and luminescence was linear ($r = 0.95$). 2×10^5 cells/100 µL CM were seeded in 96-well plates and treated with glyphosate at 0, 0.2, 4 or 16 µg/mL for 48 hours. Kit reagents were added according to the instructions and luminescence was measured.

Granulosa cell steroid production - Granulosa cells at 10^4/200 µL in CM supplemented with androstenedione at 28 ng/mL were seeded in 96-well plates and treated with glyphosate at 0.2, 4 or16 µg/mL. After 48 hours incubation, culture media were collected, frozen and stored at −20 °C until determination of progesterone (P4) and 17-β estradiol (E2) by a validated RIA. P4 assay sensitivity and ED_{50} were 0.24 and 1 nmol/L, respectively. E2 assay sensitivity and ED_{50} were 0.05 and 0.2 nmol/L. The intra- and inter-assay coefficients of variation were less than 12 % for both assays.

Granulosa cell superoxide (O_2^-) production

O_2^--production was measured using the WST-1 (4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2H-5-tetrazolium]-1,3-benzene disulfonate) test which is based on the cleavage of the water soluble tetrazolium salt, WST-1, to the water soluble formazan. A total of 10^4 cells/200 µL CM were seeded in 96-well plates and incubated with glyphosate at 0, 0.2, 4 or 16 µg/mL for 48 hours. During the last 4 hours of incubation, 20 µL of WST-1 was added to the cells, and the absorbance determined at 450 nm against 620 nm. The coefficients of variation were less than 3 %.

Granulosa cell nitric oxide (NO) production

10^5 viable cells/200 µL CM were seeded in 96-well plates and treated with glyphosate at 0.2, 4 or 16 µg/mL for 48 hours. At the end, plates were centrifuged for 10 minutes at 400×g, the supernatants were collected and NO levels assessed by measuring nitrite after incubation with Greiss reagent (1 % sulfanilamide, 5 % phosphoric acid and 0.1 % N-[naphtyl] ethylenediaminedihydrochloride). The absorbance was measured at 540 nm against 620 nm. A calibration curve ranging from 25 to 0.39 µM was prepared by diluting sodium nitrite in CM.

Non-enzymatic scavenging activity

The Ferric Reducing Activity of Plasma (FRAP) assay is a colorimetric method based on the ability of the antioxidant molecules present in a biological matrix to reduce ferric-tripiridyltriazine (Fe^{3+} TPTZ) to a ferrous form (Fe^{2+} TPTZ). 2×10^5 cells/200 µL CM were seeded in 96-well plates and treated with glyphosate at 0, 0.2, 4 or 16 µg/mL. At the end, the plates were centrifuged for 10 minutes at 400×g, the supernatants discarded and the cells lysed by adding, Triton 0.5 % + PMSF in PBS at 200 µL/well in an ice bath for 30 minutes. The test was performed on 40 µL of cell lysates added to Fe^{3+} TPTZ reagent. After 30 minutes incubation at 37 °C, absorbance of Fe^{2+} TPTZ was determined at 595 nm. The ferric reducing ability of cell lysates was calculated by plotting a standard curve of absorbance against $FeSO_4 .7H_2O$ standard solution.

Isolation and culture of adipose stromal cells (ASCs) from swine adipose tissue

Samples of about 5 g of subcutaneous abdominal adipose tissue were collected from pigs at a local slaughterhouse and placed in 20 mL of PBS supplemented with penicillin (100 Ul/mL), streptomycin (100 Ul / mL) and amphotericin B (2.5 µg/mL), transferred to Petri dishes in sterile conditions and shredded in fragments of about 3 mm^3. Thereafter, the adipose tissue fragments were distributed in 6-well plates, at a density of 10 fragments/well and then carefully covered with a minimal quantity (1 mL) of culture medium

(CM_{ASC}) to avoid floating. CM_{ASC} was composed of low glucose DMEM + GlutaMax, supplemented with 10 % FBS, penicillin (100 UI/mL), streptomycin (100 UI/mL) and amphotericin B (2.5 µg/mL). The plates were maintained at 37 °C in a humidified atmosphere at 5 % CO_2 and 19 % O_2. Every 48 hours CM_{ASC} was replaced. After 5 to 7 days, the adipose tissue fragments were removed from the culture plates and the remaining adherent cells, growing in monolayer, were cultured in fresh CM_{ASC} for 5 to 7 days, until 80 % confluence was reached. The ASCs were the trypsinized and cultured in 25 cm^2 flasks with 5 mL CM_{ASC}. The ASCs obtained were subsequently either used to evaluate the expression of adipogenesis-related marker genes or plated to study the effects of glyphosate at 4 µg/mL on cell viability and adipogenic differentiation.

Adipose stromal cells (ASCs) viability

Cell viability was evaluated using the MTT assay. ASCs were seeded in 96-well plates at 10^4 cells/well in 200 µL CM_{ASC} and incubated at 37 °C in humidified atmosphere at 5 % CO_2 and 19 % O_2 for 48 and 72 hours with glyphosate at 0 or 4 µg/mL. At the end of each incubation period, 20 µL of 5 mg/mL of MTT were added and incubated for 4 hours. Subsequently, media were discarded and 100 µL of lysis solution (SDS10 % in HCl 0.01 N) were added to the wells and left overnight at 37 °C. Absorbance was measured at 540 nm.

Adipose stromal cells (ASCs) adipogenic differentiation

ASCs were seeded in CM_{ASC} and incubated for 48 hours at 37 °C in a humidified atmosphere at 5 % CO_2 and 19 % O_2 to permit cell adhesion. Adipogenic differentiation was performed by exposing cells to 3 cycles of 4 days each, of the following treatments:

- 3 days with induction medium: CM_{ASC} supplemented with dexamethasone (DEX) at 1 µM, insulin (INS) at 1.7 µM, 3-iso-butyl-1-methylxanthine (IBMX) at 0.5 mM and indomethacin at 250 µM.
- 1 day with differentiation maintaining medium: CM_{ASC} supplemented with insulin (INS) at 1.7 µM.

Negative controls were performed using ASCs cultured in CM_{ASC}. Cell differentiation was evaluated by Oil Red O Staining to detect cytoplasmic lipid vacuoles as markers of adipogenesis.

Expression of adipogenic marker genes

In order to evaluate the expression of adipogenic marker genes crucial for the function of adipose tissue, PPARγ and Leptin total RNA was extracted from ASCs pellets (7×10^5 cells), subjected or not to adipogenic differentiation, using NucleoSpin RNA II. cDNA was then obtained by reverse transcription of 2 µg of the extracted RNA using the High-capacity cDNA reverse transcription kit. The expression of the genes was evaluated by PCR (Polymerase Chain Reaction) using the primers for PPARγ, leptin and GADPH. The occurrence of the amplification was verified by 2.5 % agarose gel electrophoresis in TAE buffer (Tris base, glacial acetic acid, EDTA 0,5 M, pH 8), where the correct length of the amplicons was verified by comparison with Gene Ruler™ 100 bp DNA LaddeR markers. DEPC treated water was used instead of cDNA as a negative control for all reactions. The DNA patterns were displayed under UV light and the images were captured with a PowerShot A610 Canon camera.

Solubilisation and quantification of Oil Red O production

To evaluate intracellular lipid accumulation, 20×10^4 ASCs were plated in 24 wells plates and subjected to a differentiation process with glyphosate at 0 or 4 µg/mL. After 12 days the cells were washed 3 times with PBS, fixed with 4 % formaldehyde for 1 hour and washed with 60 % isopropanol. The cells were then dried and stained with Oil Red O staining solution for 30 minutes. After multiple washings, Oil Red O was solubilized in each well with 60 % isopropanol for 2 hours and the absorbance measured at 540 nm. Absorbance was considered to be proportional to the amount of differentiated cells.

Adipose cell counting

5×10^4 MSCs were seeded on a cover slip in 6-well plates and subjected to the adipose differentiation process with glyphosate at 0 or 4 µg/mL. After 12 days, cover slips were fixed with formalin (4 %) and stained with Oil Red O. Then, cells were stained in Mayer haematoxylin for 3 minutes and images made by light microscopy (total magnification 10x) and quantified by counting the stained cells in 10 different fields.

Statistical analysis

The experiments were performed five times on granulosa cells and three times on ASCs and six replicate wells were used for the assessment of the effect of glyphosate. Every time the adipose tissue was collected from 3 pigs. Data are presented as the mean ± SEM. Statistical differences were calculated by ANOVA

using Statgraphics software. In the presence of a significant difference ($p < 0.05$), the means were subjected to Scheffè' F test for multiple comparisons.

II. RESULTS AND DISCUSSION

The effect of glyphosate on swine granulosa cells

Glyphosate statistically significantly decreased cell proliferation ($p < 0.001$) as evaluated by BrdU incorporation and cell viability ($p < 0.05$) as measured by ATP production without a concentration-response relationship. Granulosa cell steroidogenesis was affected by glyphosate. E2 secretion was statistically significantly inhibited ($p < 0.05$) whereas P4 secretion was statistically significantly increased ($p < 0.05$) both at all tested concentrations but without a concentration-response relationship. While O_2^--production was not statistically significantly modified by glyphosate at any of the concentrations tested, NO production was significantly stimulated ($p < 0.001$) at all the tested concentrations although with no statistically significant differences amongst them. Scavenging activity, represented by non-enzymatic antioxidant power, was significantly inhibited ($p < 0.05$) by glyphosate at all the concentrations tested but also without significant differences among them.

The effect of glyphosate on swine adipose stromal cells (ASCs)

The histological analysis of the isolated fragments obtained from pig fat showed typical characteristics of adipose tissue. In particular, adipocytes containing a single large lipid droplet with thin cytoplasm and flattened peripheral nucleus are surrounded by a microvasculature dispersed in the stromal tissue. After 3 to 4 days of *in vitro* culture of the fragmented explants, there was a migration of cells characterized by typical mesenchymal fibroblast-like morphology, which proliferated in adhesion to the bottom of the well. After 5 to 7 days from fragment removal, ASCs reached 80 % confluence in monolayer, maintaining their morphological characteristics. The proliferation of ASCs under basic culture conditions was statistically significantly increased ($p < 0.001$) (454 ± 12 vs 476 ± 7), while glyphosate treatment at 4 µg/mL significantly decreased ($p < 0.001$) the viability of proliferating ASCs both after 48 (432 ± 10) and 72 hours (451 ± 7). The expression of PPARγ and LEP, adipogenic markers was not observed in undifferentiated ASCs, but was detected following adipogenic differentiation. Adipogenic differentiation of ASCs was achieved, as shown by the appearance of red lipid droplets in the differentiated cell cytoplasm. Differentiated cell counts showed a significant inhibition ($p < 0.05$) of the adipogenic process by glyphosate at 4 µg/mL. These data were confirmed by spectrophotometric evaluation of solubilized Oil RedO.

Discussion

This study shows that glyphosate is able to significantly stimulate P4 production. This is a critical effect for granulosa cells because P4 is a hallmark of luteinization. Ovarian steroidogenesis is a key function for the survival of GCs, and is essential for follicular development and growth. To verify the potential effects of glyphosate on follicular physiology, the present study also analyzed the possible effect of glyphosate on granulosa cell proliferation and metabolic activity. The data show an inhibition of DNA replication activity and ATP production at all concentrations analyzed suggesting a disruption of follicular development in vivo. Since endothelial cell characteristics have been recently attributed to granulosa cells, it is interesting to evaluate the increased NO production in granulosa cells following glyphosate exposure. It can be hypothesized that glyphosate exerts direct pro-angiogenic effects on pigs GCs at all tested concentrations as a result of a significant increase in NO, which is a key molecule of this process. The stimulation of NO production can also be associated with an increase in oxidative stress which seems to be supported by the glyphosate-induced reduction of the non-enzymatic antioxidant power in GCs at all concentrations tested. Adipose stromal cells (ASCs) were isolated from abdominal subcutaneous fat tissue of pig and characterized. Their ability to differentiate into adipocytes under appropriate stimuli has been evaluated on the basis of the expression of PPARγ and leptin genes that was not detected in undifferentiated ASCs. These results were essential to define an adequate experimental model to investigate potential effects of glyphosate on the expression of these adipogenic markers. The inhibitory effect of glyphosate during induction of ASCs adipogenic differentiation suggests that this substance, once accumulated as a consequence of environmental exposure, can interfere with adipose tissue biology *in vivo*. Moreover, glyphosate was found to significantly decrease the viability of ASCs after 48 and 72 hours of exposure. Such evidence appears to be critical since it suggests a direct interference of glyphosate with adipose tissue function.

Study conclusion

In this *in vitro* study it is shown that glyphosate inhibits cell growth, 17-β estradiol production and non-enzymatic scavenging activity and increased progesterone production and nitric oxide secretion in granulosa cells. In addition, glyphosate significantly decreased the viability of adipose stromal cells (ASCs) and inhibited their adipogenic differentiation. These data are indicative of the interference of glyphosate with the main functional parameters of granulosa cells and ASCs and could affect both reproductive function and adipogenic processes *in vivo*.

III. CONCLUSIONS

9. Assessment and conclusion

Assessment and conclusion by applicant:

The effects of glyphosate on functional parameters of granulosa cells and adipose stromal cells from swine were investigated *in vitro*. In granulosa cells the effect of glyphosate was studied on cell proliferation, cell viability, steroid production, superoxide anion production, NO production and ferric reducing activity. In adipose stromal cells the effect of glyphosate was studied on cell viability, adipogenic differentiation, adipogenic marker genes (PPARγ and leptin), intracellular lipid accumulation and adipose cell count. Glyphosate was found to significantly decrease cell proliferation, cell viability, estrogen production and ferric reducing capacity and increase progesterone and NO production in granulosa cells when tested at concentrations ranging from 0.2 to 16 µg/mL. However, in none of the assays with granulosa cells a concentration-response relationship was established. Glyphosate treatment at 4 µg/mL significantly decreased ($p < 0.001$) the viability of proliferating adipose stromal cells after 48 and 72 hours. Differentiated cell counts showed a significant inhibition ($p < 0.05$) of the adipogenic process by glyphosate at 4 µg/mL. Since only one concentration of glyphosate was tested it was not possible to establish a concentration-response relationship. In this publication it is suggested that glyphosate interferes with the main functional parameters of the granulosa cell which could affect reproductive function. No effects on female reproductive function were reported in the rat in regulatory reproductive toxicology tests at doses beyond 2,000 mg/kg bw/day producing systemic glyphosate concentrations that are higher than those tested in this study.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate tested was not sufficiently characterized, no positive controls were included in the assays and only one dose level was used for the testing of adipose stromal cells.

2. Full summary

Executive Summary

Roundup and Glyphogan are glyphosate-based herbicides containing the same concentration of glyphosate

and confidential formulants. Formulants are declared as inert diluents but some are more toxic than glyphosate, such as the family of polyethoxylated alkylamines (POEA). In this study glyphosate alone, glyphosate-based herbicide formulations and POEA on the immature mouse Sertoli cell line (TM4) was tested, at concentrations ranging from environmental to agricultural-use levels.

I. MATERIALS AND METHODS

A. MATERIALS

Test Material
Glyphosate was purchased from Sigma-Aldrich, St Louis, USA. The purity was not reported.

Culture of TM4 Sertoli cells and treatments
The murine TM4 Sertoli cell line was obtained from the American Type Culture Collection (ATCC Manassas, USA). Cells were maintained in DMEM/HamF12 medium containing 0.2 % glutamine, 1.2 g/L $NaHCO_3$, 15mM Hepes, 5 % horse serum and 2.5 % foetal calf serum, 100 U/mL of antibiotics and fungizone (complemented DMEM/Ham F12 medium) at 37 °C (5 % CO2, 95 % air) during 24 hours to 80 % confluence in 24-well plates or in 6-well plates (for measurement of GST activity). Cells were then exposed to various concentrations of glyphosate.

B. STUDY DESIGN

Crystal violet cell viability assay
After incubation with glyphosate at different concentrations, culture supernatants were discarded and cells incubated in medium containing crystal violet solution (0.1 % w/v in PBS 0.01 M, pH 7.4) for 30 minutes at 20 °C with gentle rocking. Excess dye and non-adherent dead cells were removed through 3 washing steps with PBS. Diluted acetic acid solution (10 %) was then added to release the crystal violet taken up by cells, and the optical density reflecting living adherent cells was determined by absorption at 600 nm using a plate reader.

MTT cytotoxicity assay
This enzymatic test is based on the cleavage of MTT (tetrazolium dye, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) into a blue-colored product (formazan) by the mitochondrial enzyme succinate dehydrogenase. Activity of mitochondrial dehydrogenase enzymes indirectly measures activity of mitochondrial respiration and antioxidant defense systems. Culture medium was removed, and cells were washed once with PBS and then incubated with 500 µL MTT solution per well after each treatment. The plates were incubated for 3 hours at 37 °C. The reaction was stopped by placing the plates for 10 minutes at 4 °C followed by adding to each well 500 µL 0.04 N hydrochloric acid-containing isopropanol. The plates were then vigorously shaken for 40 min to solubilize the blue formazan crystals formed. Absorbance was measured by spectrophotometry at 570 nm.

Glutathione-S-transferase (GST) activity
For preparation of S9 fractions enriched in GST, the medium was removed, and cells were detached by treatment with trypsin-EDTA and washed twice with PBS at room temperature. Cells were then resuspended in 500 µL of 50 mM phosphate buffer at pH 7.2 containing 0.25 M sucrose and 1mM DTT. Then, they were homogenized and centrifuged at 9000g at 4 °C for 30 minutes. Supernatants corresponding to the S9 fraction were collected and stored at -80 °C. The protein concentration of each S9 fraction was determined using the Bradford assay. For the determination of GST activity 250 µg of S9 cell fraction was mixed with 10 µL of 100 mM reduced L-glutathione and 990 µL phosphate buffer (pH 6.5). The reaction was initiated by the addition of 10 µL of 100 mM 1-chloro-2,4-dinitrobenzene (CDNB) solution in 95 % ethanol. After incubation for 90 seconds at 37 °C absorbance was measured at 340 nm every 60 seconds for 3 minutes.

Lipid Sudan Black B staining
Sudan Black B stains lipids, including phospholipids and sterols. Culture medium was removed and cells were washed once with PBS. Cells were then incubated for 5 minutes at room temperature with 500 µL of

Sudan Black solution with gentle shaking. This solution was removed, and cells were washed 3 times or more with 70 % ethanol to remove excess stain and then at least 3 times with PBS. Then, intracellular Sudan Black B was extracted by incubation with DMSO for 30 minutes with gentle rocking and absorbance measured at 600 nm using a microplate reader.

Statistical analysis

The experiments were repeated at least in triplicate in different weeks on three independent cultures on each occasion (n=9). All data are presented as the mean ± standard error (SEM). Statistical differences from controls were determined by an ANOVA test. Results were statistically significantly different from controls when $p < 0.05$.

II. RESULTS AND DISCUSSION

Viability of TM4 cells

Glyphosate was found to have no impact on cell viability of TM4 cells after 24 hours of exposure at concentrations ranging from 10 to 10,000 ppm.

Mitochondrial succinate dehydrogenase activity

The measurement of succinate dehydrogenase (SD) activity was used to assess the effect of glyphosate on mitochondrial function and viability after 24 hours of exposure. Reduced SD activity was seen for glyphosate over the entire concentration range from 0.001 % (approx. 85 %) to 1 % (approx. 75 %) as derived from the graph.

Inhibition of glutathione-S-transferase (GST) activity

The effect of glyphosate on GST activity involved in the anti-xenobiotic defense system was evaluated. At an LC_{50} concentration glyphosate was found to have no impact on GST activity.

Lipid droplet accumulation

After staining with Sudan Black B exposure of TM4 cells to glyphosate for 24 hours at 2,500 or 5,000 ppm induces an increase in cytoplasmic lipid droplets as assessed microscopically.

Discussion

Measurements of cell viability, respiratory chain activity, detoxification system and lipid accumulation were undertaken in immature murine TM4 Sertoli cell line following 24 hours of exposure to glyphosate at concentrations ranging from environmental levels to agricultural use concentrations (1 %, 10,000 ppm). This study demonstrated that at sub-agricultural use levels (10-10,000 ppm) TM4 cell viability is not affected by glyphosate. Exposure of TM4 cells to glyphosate reduces mitochondrial succinate dehydrogenase (SD) activity at the lowest concentrations tested in TM4 cells, as compared with other cell types. The formulants present in commercial herbicides are known to increase glyphosate penetration into cells by membrane disruption and thus probably potentiate perturbation of mitochondrial permeability induced by glyphosate. This mechanism may explain the higher toxicity of formulations on mitochondrial activity. In this study, it was also demonstrated that 24 hours exposure of TM4 cells to glyphosate induced lipid droplet accumulation.

III. CONCLUSIONS

9. Assessment and conclusion

Assessment and conclusion by applicant:

In this study the effect of glyphosate on murine TM4 Sertoli cells was investigated *in vitro*. The endpoints were cytotoxicity, glutathione transferase activity and lipid accumulation. In contrast to the glyphosate-based formulations and co-formulants tested glyphosate was found to have no impact on cell viability after 24 hours of exposure at concentrations ranging from 10 ppm to 10,000 ppm. Glyphosate reduced succinate dehydrogenase to some extent over the entire concentration range from 10 (approx. 85 % of control) to 10,000 ppm (approx.75 % of control) with no dose-effect relationship and was found to have no impact on glutathione transferase activity. Exposure of TM4 cells to glyphosate for 24 hours at 2,500 or 5,000 ppm induces an increase in cytoplasmic lipid droplets. These concentrations are far beyond what is physiologically feasible *in vivo*.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate used is not sufficiently characterized and no positive controls were used in any of the assays conducted.

2. Full summary

Executive Summary

In this study, the estrogenic potential of glyphosate, commercial GBHs and polyethoxylated tallowamine adjuvants present as co-formulants in GBHs was evaluated. Glyphosate (≥10,000 µg/L or 59 µM) promoted proliferation of estrogen-dependent MCF-7 human breast cancer cells. Glyphosate also increased the expression of an estrogen response element-luciferase reporter gene (ERE-luc) in T47DKBluc cells, which was blocked by the estrogen antagonist ICI 182,780. Commercial GBH formulations or their adjuvants alone did not exhibit estrogenic effects in either assay. Transcriptomics analysis of MCF-7 cells treated with glyphosate revealed changes in gene expression reflective of hormone-induced cell proliferation but did not overlap with an ERα gene expression biomarker. Calculation of glyphosate binding energy to ERα predicts a weak and unstable interaction (-4.10 CAl mol-1) compared to estradiol (-25.79 CAl mol-1), which suggests that activation of this receptor by glyphosate is via a ligan- independent mechanism. Induction of ERE-luc expression by the PKA signaling activator IBMX shows that ERE-luc is responsive to ligand-independent activation, suggesting a possible mechanism of glyphosate-mediated activation.

I. MATERIALS AND METHODS

A. MATERIALS

Test Material

Glyphosate used was the PESTANAL® analytical standard (≥98.0 %) obtained from Sigma-Aldrich (UK). The batch of glyphosate (≥98.0 %) purchased from AccuStandard (New Haven, CT, USA) was tested exclusively in the ERE transcription luciferase reporter gene assay. Glyphosate-based formulations available on the market were Glyphogan (France, 39-43 % iso-propylamine salt of glyphosate, 13-18 % of POEA), Roundup Grand Travaux Plus (France, 450 g/L of glyphosate, 90 g/L of ethoxylated etheralkylamine), Roundup Original DI (Brazil, 445 g/L of glyphosate diammonium salt, 751 g/L of other ingredients) and Roundup Probio (UK, 441 g/L of the potassium salt of glyphosate, and other ingredients). POEA was purchased from ChemService (West Chester, PA, USA). The agricultural spray adjuvant was Gen-amin T200 (France, 60-80 % of POE-15).

Cell culture

MCF-7, MDA-MB-231 and T47D cell lines were obtained from Prof Joy Burchell (Research Oncology Department, King's College London). T47D-KBluc cells were purchased from the American Type Culture

Collection (ATCC, Teddington, UK) and harbour a stably integrated copy of a luciferase reporter gene under control of a promoter containing ERE. All cells were grown in a maintenance medium. Stock solutions of glyphosate, glyphosate-based herbicide formulations, POEA and Genamin T200 surfactant formulation were prepared in serum-free medium and adjusted to pH 7.2. Stock solutions of with estradiol, 3-isobutyl-1-methylxanthine (IBMX) and BPA were prepared by dissolution in ethanol. The solutions for testing were prepared by dilution of the stock solutions in test medium taking care that the solvent concentrations were always kept below 0.5 % for the cell assays and below 0.0005 % for transcriptome profiling. Cells were released from the flask substrate with trypsin and counted with a hemocytometer prior to seeding. A 24-hour recovery period was allowed for cell adherence in DMEM maintenance medium before cultures were subjected to the desired tests.

B. STUDY DESIGN

E-screen assay

The E-screen allows the determination of estrogenic effects by measuring ER-mediated cell proliferation in hormone responsive cells (MCF-7, MDA-MB-231, T47D). Cells were seeded into 48-well plates at a density of 20,000 cells per well in 250 µL maintenance medium. Following a 24-hour incubation to allow cell attachment, the medium was changed to the medium containing the test compounds. The test medium was refreshed after 3 days. Following another 3-day period of incubation, an MTT assay was performed. The MTT test allows the measurement of cytotoxic effects since the activity of mitochondrial dehydrogenase enzymes indirectly reflects cellular mitochondrial respiration. Cells were incubated with 250 µL of MTT solution for 2 hours. The test was terminated by lysing the cells with dimethyl sulfoxide (DMSO) and optical density was measured at 570 nm using the SPECTROstar Nano plate reader. The proliferative effect was expressed as a percentage of the control cell culture receiving no treatment.

ERE-luciferase reporter gene assay

The ERE-mediated transcription of a luciferase reporter gene was determined in T47D-KBluc cells using the Steady-Glo® luciferase assay system following the manufacturer's instructions. T47D-KBluc cells were seeded in 96-well plates at a density of 20,000 cells per well in 50 µL of maintenance medium and allowed to attach overnight. Prior to adding the test substance an initial 24-hour incubation was performed in the absence of test substance to improve residual estrogen clearance and assay sensitivity. After incubation, Steady-Glo® luciferase reagent was added. The plates were left to stand for 10 minutes in the dark at room temperature to allow cell lysis. Bioluminescence was measured using the Orion II microplate luminometer. ER-mediated gene activation was confirmed by ascertaining if the observed effects were subject to inhibition by addition of the estrogen antagonist ICI 182,780.

Microarray gene expression profiling

MCF-7 cells were seeded into 96-well plates with maintenance medium at a density of 20,000 cells per well. After steroid deprivation in hormone free medium, the cells were treated with test substance in triplicate in three independent experiments. RNA extraction was performed using the Agencourt RNAdvance Cell V2 kit according to the manufacturer's instructions. The samples were checked for RNA quality and quantified. Subsequently, technical replicates of samples, were pooled appropriately such that the final input amount of each biological replicate was 3 ng. Transcriptome gene expression profiles were determined using the Affymetrix Human Transcriptome 2.0 Array. Data were imported and normalized together in Omics Explorer 3.0 using the Robust Multi-array Average (RMA) sketch algorithm. These microarray data were submitted to Gene Expression Omnibus (NCBI) and are accessible through accession number GSE86472.

RNA-sequencing gene expression profiling

Gene expression profiling was performed by applying Illumina sequencing by synthesis technology. The RNA-seq data were submitted to Gene Expression Omnibus (NCBI) and are accessible through accession number GSE8770.

Statistical analysis

The ERE transcription luciferase reporter gene assay and the E-Screen assay were performed 4 and 6 times in triplicate, respectively. The concentrations required to elicit a 50 % response (AC_{50}) were determined using a nonlinear regression fit. For the transcriptome analysis, pair-wise comparisons were performed using a t-test controlling for batch effects in Omics Explorer 3.0. Affymetrix microarray and RNA-seq gene expression profiling were performed 3 times in triplicate. Data used for the functional analysis were selected at cut off p-values of <0.05 with fold change >1.2 to evaluate the ER activation signature. Gene and disease ontology were analyzed using the Thomson Reuters MetaCore Analytical Suite recognizing network objects (proteins, protein complexes or groups, peptides, RNA species, compounds among others). The p-values are determined by hypergeometric calculation and adjusted using the method of Benjamini and Hochberg.

II. RESULTS AND DISCUSSION

E-screen assay

The AC_{50} of 17β-estradiol and BPA in MCF-7 human breast cancer cells was 0.0013 µg/L and 46 µg/L, respectively. Glyphosate induced cell proliferation starting between 1,000 and 10,000 µg/L and peaking around 1,000,000 µg/L. Similar but less pronounced results were observed with the T47D cell line with cells retaining a response to glyphosate but not to Roundup Probio. No proliferative effects were observed in the ER-negative, hormone-independent MDA-MB-231 cell line, suggesting that the proliferative effects were mediated via the ER. Roundup Probio, tested in MCF-7 cells induced a non-statistically significant trend of cell proliferation.

ERE-luciferase reporter gene assay

Glyphosate stimulated ERE-mediated transcription of the luciferase reporter gene starting at a concentration of 1,000 µg/L. Roundup Probio did not show ER activity at a glyphosate equivalent concentration, which induced a cell proliferative effect when glyphosate is tested alone. This may be explained by the potentially higher toxicity of the glyphosate-based formulation, which could have resulted in cell death at the higher concentrations tested. Two other commercial formulations, Roundup Original DI and Roundup Grand Travaux Plus, also gave negative results. To evaluate whether the luciferase reporter gene stimulatory effects observed with glyphosate were mediated through the ER, experiments were performed with the addition of the potent ER antagonist ICI 182,780. This antagonist was effective at suppressing ER activation induced by 0.001 and 0.01 µg/L but not at 0.1 µg/L of 17β-estradiol. The addition of ICI 182,780 effectively blocked the stimulatory effects of glyphosate at 2,000-20,000 µg/L, confirming its agonist-like mode of action.

Microarray gene expression profiling

MCF-7 cells treated for 48 hours with glyphosate, Roundup Probio, POEA, or bisphenol A, and 17β-estradiol were subjected to full transcriptome profiling. The analysis of gene ontology confirms that genes having their expression altered by treatment of MCF-7 cells with 10,000 µg/L glyphosate were involved in cell cycle regulation, as well as in stimulation by steroid hormones. The transcriptome of glyphosate-treated cells was also reflective of cell death through apoptosis. Roundup ProBio was assessed at the glyphosate equivalent concentrations of 1 µg/L (environmental level), 100 µg/L and 1000 µg/L (showing a cell proliferative trend). The statistical analysis of differential expression showed that genes having their function altered by Roundup or POEA had low fold changes). No genes whose expression was increased or repressed by POEA showed fold changes higher than 2. The study of transcriptome profiles shows that POEA alone is unlikely to have estrogenic effects. This was confirmed in that none of the treatments exhibited statistically significant correlations to the ER biomarker

RNA-sequencing gene expression profiling

In order to confirm endocrine disturbances provoked by glyphosate, RNA extracted from MCF-7 cells treated with glyphosate (10,000 µg/L), estradiol (0.27 µg /L) or bisphenol A (80 µg/L) for 48 hours were subjected to a full RNA-Seq analysis using the Illumina sequencing platform. Although their gene expression profile were different, MCF-7 cells treated by these 3 chemicals presented alterations reflecting

a response to steroid hormones and a modulation of cell proliferation, although the significance of the overlapping genes and those in these pathways was lower for glyphosate than the other compounds. Overall, the RNA-seq method was more sensitive and identified 2-3 times more genes whose expression was significantly altered compared to the microarray approach. A total of 5102, 2939 and 1083 genes had their expression significantly disturbed by estradiol, BPA and glyphosate, respectively. Afterwards the ER gene expression biomarker was applied to see if ERα agonist effects could be detected after transcriptome profiling using RNA-Seq platforms. The results were similar to those obtained using the microarray data. Glyphosate failed to pass the threshold of significance for ERα activation. Although the RNA-seq platform was able to identify more statistically significant genes than microarrays, the genes altered differed between the two methods.

Molecular dynamics simulation and ONIOM binding energy calculations
The ability of glyphosate to bind to ERα was evaluated by molecular dynamics simulations and ONIOM calculations. Results from the molecular dynamics simulations of glyphosate-ER interactions reveal that glyphosate enters the active site with a large number of water molecules. The glyphosate phosphonate group interacts with ARG 394 by creating hydrogen bonds. It was noted that glyphosate is unlikely to interact with HIS 524, a residue having a pivotal role in maintaining protein structure in the biologically active agonist conformation. The results of the ONIOM binding energy assessment strongly imply that the binding of glyphosate at the active site of the receptor is weak and unstable, suggesting that glyphosate is unlikely to bind to ERα.

Discussion
The results of this study suggest that glyphosate is a weak activator of ERα in hormone-dependent hu-man breast cancer cells. The glyphosate intake necessary to reach a systemic concentration representative of the estrogenic effects shown in this study would only be encountered in cases of extreme exposures (incidental ingestion, mishandling). An evaluation of the glyphosate binding energy confirmed that this compound is unlikely to activate the ER. The presence of glyphosate-associated cytotoxic effects could explain the discrepancies between the results we obtained with the ERα biomarker and those from the cellular assays. It is thus plausible that glyphosate is activating ERα through a ligand-independent mechanism albeit at high concentrations. To determine any estrogenic potential of adjuvant co-formulants, a number of glyphosate-based formulations were tested and no estrogenic effects could be demonstrated. However, cytotoxicity was observed at glyphosate-equivalent concentrations lower than those required to elicit a proliferative response to glyphosate alone.

Study conclusion
This study has demonstrated that glyphosate activates ERα in breast cancer cells but only at relatively high concentrations, and that this activation happens through a ligand-independent pathway. These results suggest that humans exposed to glyphosate would not exhibit ER activation at typical exposure levels.

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant: The objective of this study was to evaluate the possible estrogenicity of glyphosate and glyphosate-based formulations and their adjuvants. The tests performed were the E-screen using different cell lines, the ERE-luciferase reporter gene assay, mmicroarray gene expression profiling and RNA-sequencing gene expression profiling. An increase in cell proliferation was observed in human breast cancer cells (MCF-7) at 10,000 µg/L and reached a maximum response at 1,000,000 µg/L. Similar but less pronounced results were observed with the T47D cell line. Glyphosate stimulated ERE-mediated transcription of the luciferase reporter gene starting at a concentration of 1,000 µg/L. The analysis of gene ontology confirms that genes having their expression altered by treatment of MCF-7 cells with glyphosate were involved in cell cycle regulation, stimulation by steroid hormones and cell death through apoptosis. ONIOM binding energy assessment strongly implies that the binding of glyphosate at the active site of the

estrogen receptor is weak and unstable, suggesting that glyphosate is unlikely to bind to ERα. This study has demonstrated that glyphosate activates ERα through a ligand-independent pathway only at high concentrations that are not encountered at typical exposure levels. This publication is considered relevant for glyphosate risk assessment and reliable without restrictions.

2. Full summary

Executive Summary

This study focuses on the effects of pure glyphosate on estrogen receptors (ERs) mediated transcriptional activity and their expressions. Glyphosate exerted proliferative effects only in human hormone-dependent breast cancer, T47D cells, but not in hormone-independent breast cancer, MDA-MB231 cells, at 10^{-12} to 10^{-6} M in estrogen withdrawal condition. The proliferative concentrations of glyphosate that induced the activation of estrogen response element (ERE) transcription activity were 5-13 fold of control in T47D-KBluc cells and this activation was inhibited by an estrogen antagonist, ICI 182780, indicating that the estrogenic activity of glyphosate was mediated via ERs. Furthermore, glyphosate also altered both ERα and β expression. These results indicated that low and environmentally relevant concentrations of glyphosate possessed estrogenic activity.

I. MATERIALS AND METHODS

A. MATERIALS

Test Material

Glyphosate (purity >98 %) was obtained from AccuStandard (New Haven, CT, USA).

Cell lines and culture conditions

A hormone-dependent human breast cancer cell line (T47D), a stably ERE-luc construct transfected hormone-dependent breast cancer cell line (T47D-KBluc) and a hormone-independent human breast cancer cell line (MDA-MB231) were obtained from the American Type Culture Collection (ATCC).

B. STUDY DESIGN

In vitro estrogen receptor activation-reporter assay

To study the estrogenicity and/or anti-estrogenicity of glyphosate, the T47D-KBluc cell line, stably transfected with a triplet ERE (estrogen response element)-promoter-luciferase reporter gene construct was used in this study. To minimize the effect of estrogen in the medium, 5 days prior to the start of the assay, cells were incubated in a non-phenol red RPMI modified medium with replacement of 10 % FBS by 10 %

dextran-charcoal treated FBS (CSS). One day prior to the assay, cells were seeded at 10^4 cells/100 µL/well and were allowed to attach overnight. The dosing medium was further modified by reduction to 5 % CSS and then replaced with 100 µL/well of dosing medium containing glyphosate at concentrations ranging from 10^{-12} to 10^{-6} M. Estradiol (E2) in the same range of concentrations was used as the positive control. Dosing medium without glyphosate was used as the negative control and wells without cells were used as the blank. After 24 hours of incubation, cells were washed with 100 µL PBS and harvested in 25 µL lysis buffer. The luciferase assay was performed by injecting 50 µL of reaction buffer and 50 µL of 1 mM D-luciferin and fluorescent intensity was measured by means of the microplate luminometer. Luciferase activity was quantified as relative light units (RLU).

Cell viability MTT assay

Cell growth and cell viability were tested using the 3-(4,5-dimetylthiazol, 2-yl)-2,5-diphenyltetrazolium bromide (MTT) reagent assay. Cells were seeded at 10^4 cells/100 µL/well in 96-well microtiter plates. For the E2 withdrawal condition, cells were cultured in 10 % CSS and a non-phenol red RPMI medium for 4 days before seeding. After 24 hours the cells were treated with E2 or glyphosate at concentrations ranging from 10^{-12} to 10^{-6} M. For E2 receptor antagonist conditions, E2- or glyphosate-treated cells were co-incubated with ICI 182780 at 1 and 10 nM. Cell sensitivity to a chemical was expressed as the % cell viability compared to control cells.

Cell number counting

T47D Cells were prepared in E2 withdrawal conditions 4 days before the start of the assay. Cells were placed in a 24 well culture plate with 10^4 cells/mL/well and incubated overnight. The medium was then replaced with 1 mL of treatment solution and incubated for 72 hours. Afterwards, the cells were washed with 1 mL PBS and then 100 µL of a trypsin–EDTA solution was added to detach. An aliquot of the cells was taken for counting using a counter analyzer.

Western blot analysis

Whole-cell extracts were prepared from cells treated for 6 and 24 hours with 10^{-12}, 10^{-9}, and 10^{-7} M glyphosate and non-treated control. The cells were lysed, incubated on ice and centrifuged. The supernatants were collected and either processed or stored at -80 °C until use. The protein concentration was measured using Bradford reagent and each lysate was aliquot for an equal amount of protein, 30 µg, before mixing with Laemmli loading buffer and then boiled at 95 °C for 5 minutes. The samples were resolved over 7.5 % polyacrylamide-SDS gels and transferred to a nitrocellulose membrane using a Mini Trans-Blot Electrophoretic Transfer Cell. The membrane was treated with blocking solution for one hour at room temperature and subsequently probed overnight with primary antibody (ERα, ERβ or β-actin) and then rinsed. HRP-conjugated secondary antibodies were added to the membrane for 2 hours and the membranes rinsed with TBS-T. Protein visualization was achieved by using enhanced chemiluminescence and the emitted light was captured on film. The signals on the films were quantified using densitometry.

Statistical analysis

Data are presented as the means ± SE. Statistical significance was determined using the Student's t-test. A two-tailed $p<0.05$ was evaluated as a statistically significant difference.

II. RESULTS AND DISCUSSION

T47D, hormone-dependent breast cancer cell growth

The hormone-dependent T47D and hormone-independent MDA-MB231 cell lines were studied both in completed medium and estrogen withdrawal medium to differentiate the effect of glyphosate from that of endogenous estrogen. Estrogen in a concentration range of 10^{-12} to 10^{-6} M was used as the positive control. Cell growth was assessed using the MTT cell viability assay. The results showed that T47D and MDA-MB231 cells exhibited different patterns of responses to glyphosate. In the absence of E2, glyphosate produced cell proliferation in T47D cells of approximately 15–30 %. This effect was about half of the E2 response which is the most potent agonist in hormone dependent ER-positive breast cancer cells. No effect

was observed on cell proliferation in MDA-MB231 cells both in the absence or presence of E2.

Cell proliferation via estrogen receptors
Due to the fact that the proliferative effect of glyphosate occurred only in T47D cells in the absence of E2, it was hypothesized that ER signaling may be involved in glyphosate-induced cell proliferation. Therefore, the effect of glyphosate on T47D cells was investigated in the presence of an ER antagonist, ICI 182780, to inhibit the estrogen receptor mediated response. The effective concentration of 1 nM of ICI 182780 was added to varying concentrations of glyphosate and E2 to observe its antagonistic activity. The results showed that ICI 182780 at 1 nM mitigated the proliferative effects of both glyphosate and E2. A higher concentration of ICI 182780 (10 nM) completely inhibited the growth promoting effects of glyphosate. These results suggest that glyphosate may produce the proliferative effect via the ER.

ERE-transcription activity via estrogen receptors
T47D-KBluc cells, stably transfected with a triplet ERE (estrogen response element)-promoter-luciferase reporter gene construct, were treated with the concentrations of glyphosate that produced cell proliferation. The results showed that glyphosate in a concentration range of 10^{-12} to 10^{-6} M induced ERE activation 5- to 13-fold of control and these effects were less than about half of that induced by E2. Glyphosate co-incubation with the ER antagonist, ICI 182780, exhibited a significant reduction in responses. ICI 182780 at 10 nM completely inhibited the ERE transcriptional activity of glyphosate. Since glyphosate was shown to induce cell proliferation and ERE activation via the ER, the potential effects of glyphosate on endogenous E2 signaling was investigated. Cells were co-incubated with glyphosate and E2 and the results revealed that glyphosate suppressed E2-induced ERE activation suggesting that glyphosate behaves as an ER antagonist in the presence of E2.

Expression of ERα and ERβ in human breast cancer cells
The expression of proteins involved in ERs including ERα and ERβ, was studied with the Western blot technique. After 6 hours of exposure, glyphosate increased the levels of both ERα and ERβ in a concentration-dependent manner while after 24 hours only ERα showed a significant induction at the highest glyphosate concentration tested (10^{-5} M). This result suggests that glyphosate alters the expression of both ERα and ERβ in human breast cancer cells.

Discussion
In this study, glyphosate was found to increase cell proliferation of a hormone dependent breast cancer T47D cell line at concentrations ranging from 10^{-12} to 10^{-6} M while this effect was not observed in a hormone independent breast cancer MDA-MB231 cell line. The results from the ERE luciferase assay confirmed ER activation because the responses seen could be blocked by the ER antagonist ICI 182780. Glyphosate induced rapid activation of ERβ while activation of ERα was slower but prolonged. It is suggested that glyphosate may behave like a weak xenoestrogen which can activate both subtypes of ER but with a different time course. Although the nature of the binding of glyphosate to the ER is still unknown, the ability of glyphosate to stimulate the ERE-gene transcription activity and upregulation of ERα protein expression suggests that glyphosate may exert the stimulatory effects via an ER-dependent mechanism.

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
The objective of this study was to investigate the possible estrogenic effect of glyphosate and its mode of action. The endpoints explored were the cell proliferation of hormone-dependent and hormone-independent cell lines with and without an ER antagonist, ERE-transcription activity with and without an ER antagonist, and expression of ERs. Glyphosate was found to produce cell proliferation in a hormone-dependent cancer cell line but not in a hormone-independent cancer cell line in the absence of E2. In the presence of a potent ER antagonist the cell proliferation caused by glyphosate in a hormone-dependent cancer cell line was reduced. The interaction of glyphosate with the ER was confirmed by

ERE activation with and without an ER antagonist. When cells were co-incubated with glyphosate and E2, glyphosate suppressed the E2-induced ERE activation suggesting that glyphosate behaves as an antagonist in the presence of an endogenous agonist. It was demonstrated that glyphosate alters the expression of both ERα and ERβ in human breast cancer cells.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the test results are not corroborated by *in vivo* regulatory ED toxicology studies such as the uterotrophic assay and the female pubertal assay (U.S. EPA Endocrine Disruptor Screening Program).

2. Full summary

Executive Summary

The study was based on an estrogen-responsive recombinant human breast cancer cell line (VM7Luc4E2) that was accepted by the US Environmental Protection Agency (USEPA) and Organisation for Economic Co-operation and Development (OECD) as a bioanalytical method to detect estrogen receptor (ER) agonists/antagonists. This cell line contains only 1 of the 2 known ER isoforms, ERα but not ERβ, and the

differential ligand selectivity of these ERs indicates that the currently accepted screening method only detects a subset of total estrogenic chemicals. To improve the estrogen screening bioassay, VM7Luc4E2 cells, which are derived from a human breast cancer cell line (MCF7 cells), were stably transfected with an ERβ expression plasmid and positive clones identified using ERβ-selective ligands. A highly responsive clone (VM7LucERβc9) was identified that exhibited greater sensitivity and responsiveness to ERβ-selective ligands than VM7Luc4E2 cells, and quantitative reverse-transcription polymerase chain reaction confirmed the presence of ERβ expression in these cells. Screening of pesticides and industrial chemicals identified chemicals that preferentially stimulated ERβ-dependent reporter gene expression. Together, these results demonstrate the utility of this dual-ER recombinant cell line for detecting a broader range of estrogenic chemicals than the current VM7Luc4E2 cell line. Additionally, screening with both cell lines allows identification of ERα- and ERβ-selective chemicals.

I. MATERIALS AND METHODS

A. MATERIALS

Test Material
Glyphosate (no data on purity or CAS number) (vehicle control: Dimethyl sulphoxide (DMSO, no data on purity); positive control: 17β-Estradiol (E2; no data on purity))

Cell lines and culture conditions
VM7Luc4E2 and VM7LucERβc9 cell lines were used in the studies with glyphosate. The VM7Luc4E2 cell line was developed by the authors and is used and accepted by USEPA and OECD for determination of ER agonists/antagonists. The VM7LucERβc9 was produced by stable transfection of the VM7LucERβc9 cells with ERβ/pcDNA3.1+Zeo. For routine maintenance, cells were grown in α-minimal essential medium containing 10% fetal bovine serum and additional 600 mg/L Zeocin for the VM7LucERβc9 cells.

B. STUDY DESIGN

Stable transfection
To produce the stable VM7LucERβ cell line, human ovarian carcinoma (VM7Luc4E2) cells containing a stably transfected estrogen-responsive luciferase plasmid were transfected with ERβ/pcDNA3.1+Zeo using FuGene6 transfection reagent according to the manufacturer's recommendation. After 24 h incubation in regular medium, the transfected cells were split 1 to 15 and replated into selective medium containing the antibiotic Zeocin (600 mg/L) which was replaced every 3 d with fresh Zeocin-containing medium. After approximately 3 weeks of growth, 28 individual cell colonies were isolated, their ERβ responsiveness was determined, and those clones exhibiting the greatest induction by ERβ-selective ligands (Br-ERβ-04 [31.6 nM] and genistein [10 nM]), were selected for further evaluation.

RNA isolation and RT-PCR
Cells in 10 cm plates (4 replicates per cell line) were grown in maintenance medium with the addition of Zeocin for the VM7LucERβc9 cells. Total RNA was isolated using RNeasy (Qiagen) according to the manufacturer's instructions (β-mercaptoethanol was added to the lysis buffer immediately before use, and cells were homogenized using QIAshredder homogenizer). Complementary DNA (cDNA) was generated from 2 mg RNA using a high-capacity cDNA Reverse Transcription kit (Applied Biosystems) with random primers followed by a 1:10 dilution with RNAse/DNAse-free water. Real-time quantitative polymerase chain reactions (20 mL) were performed with TaqMan Fast Universal PCR Master Mix and TaqMan Gene Expression assays (Applied Biosystems). The ERα and ERβ messenger RNA (mRNA) levels were quantitated, normalized to β-actin (internal control), and results presented relative to levels in VM7Luc4E2 cells (set to value of 1.0). Primers or probes for human ERβ (ESR2, Hs01100353_m1), human ERα (ESR1, Hs00174860_m1), and human b-actin (ACTB, Hs999999031_m1) were obtained from Applied Biosystems.

Incubation and luciferase analysis

VM7LucERβ cells were switched from maintenance medium to estrogen-stripped medium, containing 10% charcoal-stripped fetal bovine serum and incubated 3 d before plating into white, clear-bottomed 96-well tissue culture plates at a density of 750 000 cells/mL. Cells were allowed to attach for 24 h and then were incubated with carrier solvent DMSO (1% final solvent concentration) or 10 µM glyphosate for 24 h at 37°C with triplicate wells per chemical and controls. After incubation, cells were rinsed twice with phosphate-buffered saline, lysed with Promega cell lysis buffer, and shaken for 20 min at room temperature to allow complete cell lysis. Luciferase activity in each well was measured by a microplate luminometer. For comparative purposes, luciferase induction values were normalized to maximal luciferase induction obtained with 1 nM E2 in each plate (set at 100%). Values represented the mean ± standard deviation (SD) of triplicate incubations in the single screening analysis of the chemical compound.

Statistical analysis

Significant differences between results were determined using one-way analysis of variance (i.e., Student's t test, 2-tailed, type 2, $p<0.05$). Luciferase activity of control (solvent-treated) cells was substracted from that of treated cells to obtain final induced activity (relative light units [RLU]). Final RLU values less than 0 were set at 0 RLUs. Half-maximal concentrations induced (50% effective concentration [EC50]) or repressed (50% inhibitory concentration [IC50]) by chemical or extract were determined using SigmaPlot (Ver 12) by the concentration of chemical that induced exactly 50% of maximal E2-induced luciferase activity.

II. RESULTS AND DISCUSSION

Estrogenic effects of glyphosate

Glyphosate had no estrogenic effect in both VM7LucERβ and VM7LucERβ cells. The induction of luciferase activity was expressed as the mean ± SD of three replicate analyses of one exposure experiments. Values are presented as a percent of maximum E2 induction (set at 100%), and the mean result for glyphosate had been in the range of the solvent control. In the table below the solvent control, DMSO was set to 0% and E2 was set to 100%:

Compound	Activity [%] VM7Luc4E2	Activity [%] VM7LucERβc9
DMSO	0	0
Glyphosate	6 ± 2	2 ± 4
E2	100	100

III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:

Glyphosate did not show any estrogenic activity at a concentration of 10 µM in two cell lines or via the two human estrogen receptor (hER) subtypes, hERα and hERβ. Based on the OECD 455 guideline for the VM7 assay, relative activity for the test substance that is < 10% of the response of a maximally inducing concentration of E2 is considered to be negative. In addition, when the VM7Luc4E2 cell line was validated[45] (previously known as BG1 cell line) the threshold for positive agonist activity was set at 20% of the response of a maximally inducing dose of E2. Therefore, glyphosate is concluded to have no ERα, ERβ agonistic activities, in vitro.

The estrogenic effect of glyphosate has been investigated in VM7LucERβ and VM7LucERβ cells. In

[45] Interagency Coordinating Committee on the Validation of Alternative Methods. 2011. Independent Scientific Peer Review Panel Report: Evaluation of the LUMI-CELL® ER BG1Luc ER TA Test Method. Research Triangle Park, NC:National Institute of Environmental Health Sciences

the assay the induction of luciferase activity as a parameter for receptor activation was measured. The induction of luciferase activity by glyphosate was found to be in the range of the solvent control.

The publication on in vitro estrogen receptor agonistic activity of pesticides indicates that, even though it does not follow a defined guideline, the study is well documented and is scientifically sound. Therefore, the study is reliable with restriction and is relevant for risk assessment.

2. Full summary

Executive Summary

In this study endocrine disruption of co-formulants in six glyphosate-based herbicides were tested. All co-formulants and formulations were comparably cytotoxic well below the agricultural dilution of 1% (18–2000 times for co-formulants, 8–141 times for formulations), and not the declared active ingredient glyphosate alone. The endocrine-disrupting effects of all these compounds were measured on aromatase activity below the toxicity threshold. Aromatase activity was decreased both by the co-formulants alone (polyethoxylated tallow amine—POEA and alkyl polyglucoside—APG) and by the formulations, from concentrations 800 times lower than the agricultural dilutions; while glyphosate exerted an effect only at 1/3 of the agricultural dilution. It was demonstrated that endocrine disruption by glyphosate-based herbicides could not only be based on the active ingredient but also to co-formulants. These results could explain numerous *in vivo* results with glyphosate-based herbicides that were not seen with glyphosate alone.

I. MATERIALS AND METHODS

A. MATERIALS

Test Material

This study tested formulations, co-formulants and glyphosate alone. The focus of this assessment is on the glyphosate alone data. Glyphosate (isopropylamine salt of n-phosphonomethylglycine) (no data on purity, CAS number 1071-83-6) (vehicle control: not further specified, positive control: Formestan (4-hydroxyandrost-4-ene-3,17-dione; no data on purity))

Cell lines and culture conditions

JEG3 cells (human placental choriocarcinoma cells) used in these assays are well-characterized and validated as useful models to test toxicities of pesticides, corresponding to what is observed in fresh tissue or primary cells. They were reported to be partly less sensitive than primary cells and therefore do not overestimate cellular toxicity.

JEG3 cells were grown in phenol red-free Eagle's minimum essential medium (EMEM) containing 2 mM glutamine, 1% non-essential amino acid, 100 U/mL of antibiotics (a mixture of penicillin, streptomycin and fungizone), 10 mg/mL of liquid kanamycin and 10% fetal bovine serum. JEG3 cells were supplemented

with 1 mM sodium pyruvate. Cells were grown with this medium at 37°C (5% CO2, 95% air) during 48 h to 80% confluence, then washed and exposed 24 h with serum-free EMEM to glyphosate, glyphosate-based herbicide formulations and their co-formulants. Before treatment, all the glyphosate, glyphosate-based herbicide and co-formulants were diluted in serum-free medium and adjusted to a similar pH.

B. STUDY DESIGN

Cell treatment and cytotoxicity biomarkers

Confluent cells (80% of confluence) were washed with serum-free EMEM and then exposed to various concentrations of glyphosate, glyphosate-based herbicide and co-formulants in EMEM serum-free medium for 24 h. After treatments, cytotoxicity was determined by an MTT assay (optical density measured at 570 nm). The bioluminescent Toxilight bioassay (Lonza, Saint Beauzire, France) was applied for the membrane degradation assessment by intracellular adenylate kinase (AK) release in the medium that is described as a necrosis marker. Glyphosate was tested from 1 to 10000 mg/L.

Determination of aromatase activity

Aromatase activity was evaluated according to the tritiated water release assay. This method is based on the stereo-specific release of 1β-hydrogen from the androstenedione substrate, which forms tritiated water during aromatization.

JEG3 cells were exposed for 22 h at 37°C (5% CO2, 95% air) to 700 µL of non-toxic doses of different xenobiotics. Formestane, a well-known aromatase inhibitor, was used as a positive control. Then 50 µL of 200 nM [1β-3H] androstenedione was added, and incubation went on for 120 min more. The reaction was stopped by placing the plates at 4°C for 10 min. Cell fragments were removed by 5 min centrifugation at 2000 rpm at 4°C and by addition of 1 mL of chloroform to the 500 µL supernatant. After 5 min centrifugation at 4000 rpm at 4°C, 0.5 mL of charcoal/dextran (0.25%/0.025%) was added. The mixture was gently agitated, rested at 4°C for 10 min, and centrifuged at 4000 rpm for 10 min at 4°C. Supernatant fractions (500 µL) were harvested in 6 mL vials and 4 mL Ultima Gold LLT was added. The mixture was assessed for radioactivity by a double 5 min scintillation counting. Glyphosate was tested at non-toxic doses in the aromatase assay (16 mg/L).

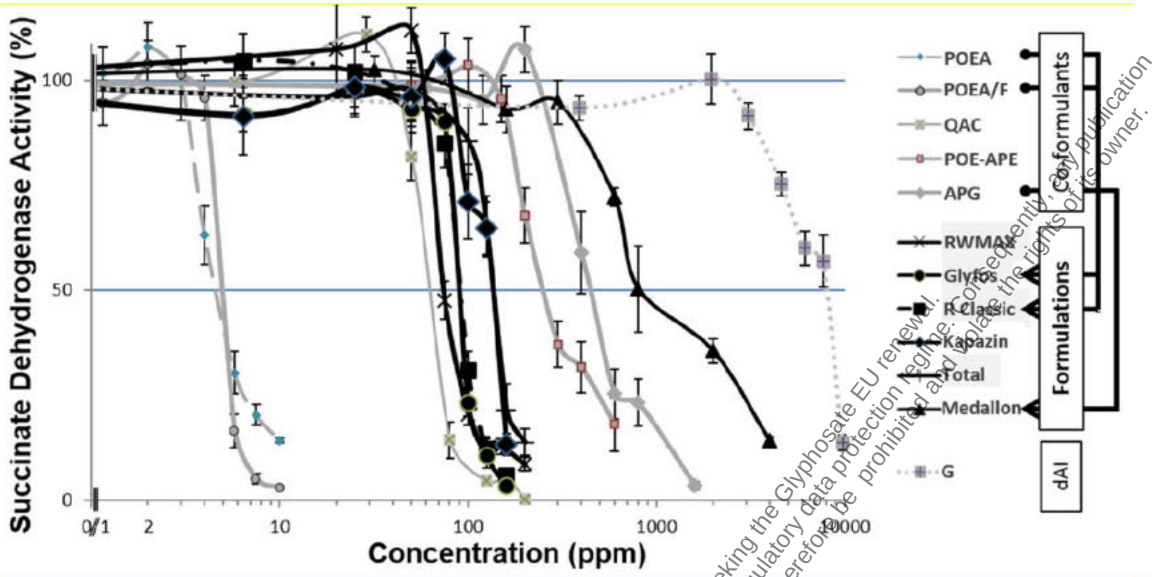
Statistical analysis

All results are means ± SEM. Three independent experiments were performed using triplicate cultures each. In MTT assays, LC50 values were the best-fitted value of a non-linear regression using asymmetric (5-parameters) equation with GraphPad Prism 5 (GraphPad software, La Jolla, CA, USA). Statistical differences were determined by a non-parametric Wilcoxon (Mann–Whitney) rank-sum test or, in case of more than two samples, a non-parametric Kruskal–Wallis test followed by a Dunn's post hoc test for multiple comparisons, using GraphPad Prism 5 (GraphPad software, La Jolla, CA, USA). Significant levels were reported with $p < 0.05$ (*), $p < 0.01$ (**) and $p < 0.001$ (***).

II. RESULTS AND DISCUSSION

Toxicity tests

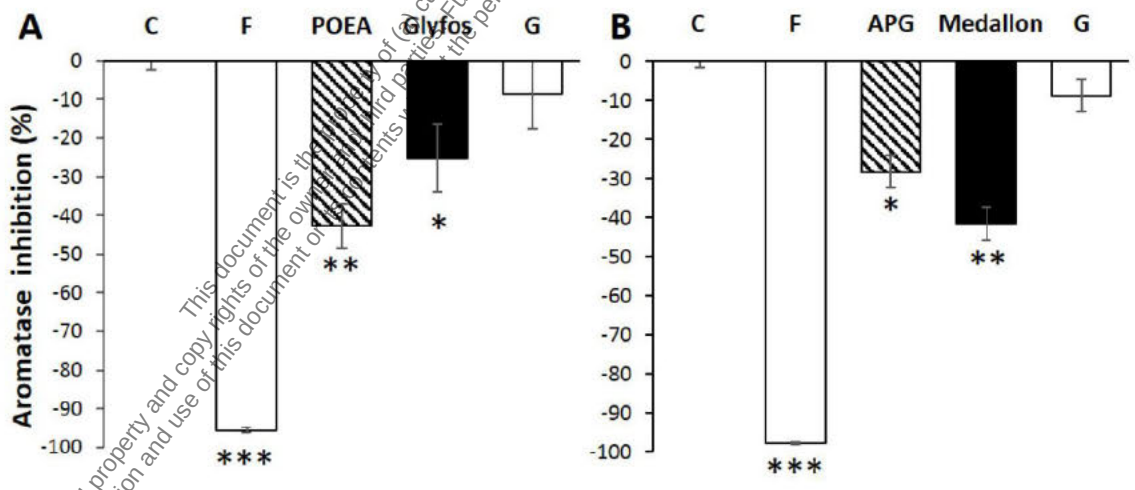
The lowest concentration exerting a significant toxic effect (LOEC) was considered to be the toxicity threshold. The highest concentration without significant cytotoxic effect (NOEC) was also reported. LC_{50}, NOEC, and LOEC values of 7878, 3100, and 4600 mg/L were determined for glyphosate. Glyphosate showed cytotoxic effects at high doses only, whereas the co-formulants or formulations were more toxic by a factor 10-1000 (see the following graph):



The adenylate kinase activity, which was determined as a marker for necrosis, was not influenced by glyphosate when compared to the negative control.

Aromatase activity

Glyphosate had no effect on the aromatase activity when tested at concentrations used in the formulations (16 – 146 mg/L). At very high doses of 3000 ppm a significant aromatase inhibition was observed by glyphosate (-51%; data not shown in article for 3000 ppm which is equivalent to 17.7 mM glyphosate). Nevertheless, according to the authors this is considered not relevant because of the high concentration used. In the following figure the effects of glyphosate (G) on the aromatase activity is exemplary shown (A: POEA, 2.5 ppm; Glyfos, 25 ppm; glyphosate, 16 ppm; B: APG, 120 ppm; Medallon, 300 ppm; glyphosate, 146 ppm):



III. CONCLUSIONS

3. Assessment and conclusion

Assessment and conclusion by applicant:
Toxicity in JEG3 cells as well as aromatase activity have been investigated. Cells were treated with glyphosate alone, formulations containing glyphosate as active ingredient and co-formulants alone. Glyphosate showed generally low cytotoxicity. An effect on aromatase activity was not observed when cells were treated with glyphosate at non-toxic concentrations. At a higher glyphosate concentration (17.7 mM) a reduction of aromatase activity was seen, which is in accordance with the authors not considered relevant at this high concentration in the test system used. Moreover, such a high concentration is not to be reached at physiologic conditions and therefore, not considered relevant for human health.

The publication on in vitro aromatase activity in human cells shows that, even though it does not follow a defined guideline, the study is well documented and is scientifically sound. Therefore, the study is reliable with restrictions and is relevant for risk assessment.

This publication is considered relevant for the risk assessment of glyphosate and reliable with restrictions because the glyphosate used was not sufficiently characterized and as a too high, non-physiological concentration had been considered for glyphosate exposure.		

Assessment and conclusion by RMS:

CA 5.9 Medical Data

CA 5.9.1 Medical surveillance on manufacturing plant personnel and monitoring studies

Monsanto Glyphosate Manufacturing Industrial Hygiene Monitoring Data, Luling, Louisiana, USA

Industrial hygiene air monitoring data for glyphosate with workers at the Monsanto Luling, Louisiana manufacturing facility are available for the years 1981-1998 and are presented below. No such data are available from a Monsanto European manufacturing facility. Based on the measured low exposures to glyphosate in the manufacturing setting (well below the ADI) and low toxicological concern, glyphosate specific medical monitoring is not considered necessary. These data are air concentration measurements which are conservatively applied as 100% bioavailable to calculations of mean and maximum daily exposures.

Table 5.8-38: Particulate exposures from glyphosate technical acid operations involving wetcake, e.g., supersack or container filling operations. Values are time weighted averages.

Improvements in manufacturing facility containment and ventilation systems over recent years further reduce the likelihood of operator exposures within glyphosate manufacturing facilities.

CA 5.9.2 Data collected on humans

Please refer to CA 5.9.3 and 5.9.4 were information available on direct observations and epidemiology is referenced.
Further references with regards to biomonitoring or other exposure information is provided at the end of the section under "Literature summaries". The full summaries of these publications are also provided at the end of the section under "Literature summaries".

CA 5.9.3 Direct observations

The summary in this section is based on well over 30 years of experience with numerous formulations of glyphosate in a wide range of situations. The extensive use of glyphosate has encouraged clinical assessment of various interventions and has resulted in reporting of alleged associations of symptoms with exposures to glyphosate products. The clinical toxicology of glyphosate and of glyphosate-surfactant formulations have been the subject of an extensive review (Bradberry et al 2004), and a review of cases with assessment of clinical prognostic factors was more recently published (Lee et al. 2008).

GENERAL:
Glyphosate does not inhibit cholinesterase, and has no cholinergic effect. Animals do not have the shikimic acid pathway; and no direct target-mediated action in mammalian systems has been clearly identified to date (Bradberry et al. 2004). While incidental exposure in glyphosate-surfactant herbicide mixtures is common, review of available case reports (AAPCC 2003-2011) indicates that the vast majority of reported non-suicidal exposures involve skin and/or eye irritation or irritation of the respiratory tract by inhalation of spray mist, and that systemic symptoms are rare following non-suicidal exposures to glyphosate products. Based upon human experience and animal data, even those systemic symptoms reported following incidental exposure appear unlikely to be causally related to exposure (Goldstein et al. 2002).

CLASSIFICATION OF EXPOSURES:
The following clinical effects are divided into those expected following minor and significant exposures for each category based upon expected severity of systemic symptoms. The factors which determine if the exposure is minor or significant include:

- The route of exposure. Dermal, eye and mist inhalation exposures to any commercially formulated glyphosate products of any dilution are minor exposures for purposes of the symptom descriptions below. Ingestions more than 50 ml (one mouthful if amount unknown) of a product with >10% glyphosate concentration may be significant.
- The concentration of the product. Glyphosate concentrations of less than 10% rarely if ever produce significant toxicity. Most serious illness has historically resulted from ingestion of the 41% (glyphosate IPA) concentrate. In the absence of extensive clinical experience for the 11-40% concentration range, any ingestion of greater than 50 ml of a glyphosate preparation having a greater than 10% concentration of glyphosate salts should be considered potentially significant for purposes of the symptom descriptions below.
- The intent of the exposure. Accidental ingestion rarely involves large quantities of concentrated formulations. Intentional ingestion cases may not present with a reliable history and may require observation if the amount ingested cannot be reliably determined.
- Clinical condition of the patient.
- Known or suspected co-ingestants (if any).
- Professional judgment.

ROUTE AND ORGAN SYSTEM SPECIFIC SYMPTOMS OF EXPOSURE:

DERMAL

MINOR EXPOSURES:

- Contact with skin may produce a dermatitis similar to that of detergents (Bradberry et al. 2004)
- It is expected that the severity of injury following skin exposure will be significantly decreased with a less concentrated product and with a reduced duration of contact.
- Phototoxic reactions (sunlight or ultraviolet (UV) light induced skin reactions) have been reported. This is believed due to an antimicrobial additive (benzisothiazolone) which is present in selected residential use (i.e. non- agricultural) products containing 10% glyphosate or less (Bradberry et al. 2004).
- Significant absorption through the skin does not occur (<0.2% for concentrates and <0.01% for dilute formulations; see section 5.9.9)
- Studies in farmers and farm family members during the machine spray application of glyphosate products indicates that farmer exposure is generally far below recommended maximal daily intakes and that urinary levels in children and spouses are largely non-detectable (limit of urinary detection 1 µg/L) (Acquavella et al. 2004). These studies do not provide a quantitative measure of dermal exposure, but are consistent with the primate data noted above.

SIGNIFICANT EXPOSURES:

- Skin exposures are not expected to cause systemic effects or serious cutaneous effects. Symptoms as noted in the minor exposure may occur.

OCULAR

MINOR EXPOSURES:

- A review of ocular exposures to US glyphosate-surfactant formulations (1513 exposures over a 5-year period), showed no permanent eye injury (Acquavella et al. 1999).
- Human eye exposures have generally resulted in temporary conjunctival irritation, clearing after irrigation or in 1-2 days and permanent eye damage is said to be “most unlikely” (Bradberry 2004).
- It is expected that the severity of injury following eye exposure will be significantly decreased with a less concentrated product or with a reduced contact time.

SIGNIFICANT EXPOSURES:

- Eye exposures are not expected to cause systemic effects or serious ocular injury (Acquavella et al. 1999; Bradberry et al. et al. 2004).

SYSTEMIC EXPOSURE- INGESTION OR INHALATION

NEUROLOGIC:

MINOR EXPOSURES:

- There is no clinical or experimental evidence that glyphosate or glyphosate-surfactant formulations cause neurological symptoms or injury after exposure by any route.

SIGNIFICANT EXPOSURES:

- There have been no reports of primary convulsions after ingestion.
- One author reports most patients present with a clear sensorium unless another substance, such as alcohol, has been co-ingested or severe hypoxemia has occurred (Tominack 1989); however "moderate disorders of consciousness" have been reported within 48 hours of suicidal ingestions of the concentrate (Sawada and Nagai 1987; Sawada et al. 1988). This has occurred in patients with significant systemic illness and is not believed to be the result of reduced organ perfusion (Bradberry et al. 2004) or perhaps other factors such as metabolic disturbance, but the possibility of a direct toxicological effect cannot be excluded (Bradberry et al. 2004).

- There are three isolated case report of Parkinson's disease developing in individuals with a history of glyphosate product exposure. In one case, Parkinson's disease of relatively acute onset was diagnosed 6 months following incidental dermal exposure to a glyphosate-surfactant product (Barbosa et al. 2001). It appears that the same case was reported as part of a case series by daCosta et at (2003) [Similar list of authors on both publications, case descriptions and ages match (52 years old at diagnosis vs 54 year old with a 2 year history of Parkinsons) and the T2- weighted Axial MRI images shown appear to be identical]. The second case (Wang et al. 2011) reports the development of Parkinson's of a 44 year old woman who had been employed in a glyphosate manufacturing facility. The third case described a woman who developed transient Parkinsonism that was reportedly reversed by the administration of atropine and pralidoxime. (Zheng et al 2018). In all instances, there is no evidence for causation other than a history of prior exposure. In the last case, it is notable that the patient recovered with the treatment for organophosphate exposure, which suggests a completely different etiology as glyphosate does not require treatment with anticholinergic agents. No other human or animal data support the contention that Parkinson's disease results from exposure to glyphosate, even following massive ingestion or prolonged exposure.

GASTROINTESTINAL:

MINOR EXPOSURES:

- Minor exposures are likely to be asymptomatic, but the patient may experience an unpleasant taste, tingling, mild self-limited nausea and vomiting.
- Self-limited diarrhoea may also occur, which is thought to be due to the surfactant.

SIGNIFICANT EXPOSURES:

- A burning sensation in the mouth and throat, salivation, oral erythema, sore throat, dysphonia, dysphagia, epigastric pain, nausea, spontaneous vomiting, abdominal pain and diarrhoea are common and may last up to a week.
- Serum amylase may be elevated; isoenzyme analysis done in a few cases identified a salivary gland origin (Tominack et al. 1989).
- In severe cases with large ingested doses, hematemesis, GI bleeding, melena and hematochezia may occur. Paralytic ileus has been reported as a rare event.
- Endoscopy has noted erosions of the pharynx and larynx, esophagitis and gastritis with mucosal oedema, erosions and haemorrhage. Transmural injury and perforation have not been noted on panendoscopy (Chang et al. 1999).
- In fatal cases, autopsy notes mucosal or transmural oedema and necrosis throughout the small bowel with erosion and haemorrhage; in the large bowel, mucosal oedema and focal haemorrhage was noted (Tominack et al. 1989).
- Clinical, autopsy and experimental evidence ([redacted] 1987) indicate a potential for gastrointestinal damage from glyphosate components of glyphosate formulations, but the frequency of severe injury appears to be low and early endoscopy is probably not indicated (see below).

CARDIOVASCULAR:

MINOR EXPOSURES:

- Dermal, eye and mist inhalation exposures to any commercially formulated glyphosate products of any dilution are minor exposures. Cardiovascular effects are not expected from minor exposures. A recent case report describes a patient who presented with syncope and a wide-complex tachycardia where the authors claim that there is a prolonged QTc while measuring a wide complex beat. This is not how a QT interval is determined, it should be derived from the measurement of a narrow complex as a prolonged QRS interval actually makes it impossible to determine the QTc. The patient, when pressed repeatedly about pesticide exposure, said that she had spilled a small amount of formulated glyphosate on her hand the previous evening. The authors attribute her syncope and arrythmia to this minor exposure. Since significant absorption through the skin does not occur (<0.2% for concentrates and <0.01% for dilute formulations; see section 5.9.9), it is inaccurate to claim that a small dermal

exposure can trigger a malignant arrhythmia, furthermore, glyphosate is not cardiotoxic and this patient appears to have early and late afterdepolarisations on her EKG, suggestive of a channelopathy.(Brunetti et al, 2020)

SIGNIFICANT EXPOSURES:

- Hypotension is common after ingestions of a mouthful or more of the concentrated product (not the diluted forms) and usually responds to IV fluids and pressor amines. Shock as manifested by oliguria, anuria and hypotension which was unresponsive to fluids and pressors, ultimately resulting in death, has been reported. (Tominack et al. 1989, Bradberry et al. 2004). Transient hypertension may be noted.

UPPER RESPIRATORY:

MINOR EXPOSURES:

- Dermal, eye and minor ingestions of dilute solution exposures to any commercially formulated glyphosate products of any dilution are minor exposures. Significant upper respiratory effects are not expected from minor exposures, but minor irritation or discomfort may occur (Bradberry et al. 2004).

SIGNIFICANT EXPOSURES:

- Significant systemic exposures are not anticipated to occur via the inhalational route, see minor exposures within this subheading.

LOWER RESPIRATORY:

MINOR EXPOSURES:

- Because of the non-volatile nature of glyphosate and the surfactant, there are no vapour exposures possible. The spray equipment commonly used with the product produces particles that are non-respirable.

SIGNIFICANT EXPOSURES:

- Tachypnea, dyspnea, cough and bronchospasm including cyanosis have been seen in severe ingestions (more than a mouthful of concentrated product). These effects appear to be the result of systemic toxicity.
- Aspiration pneumonia, pulmonary oedema and respiratory failure have been seen although the exact role of aspiration has not been fully investigated.
- An isolated case report suggests the development of acute pneumonitis in a worker following his performing maintenance on non-operating spray equipment used to apply a glyphosate-surfactant formulation (Pushnoy et al. 1998). However, the registrants do not believe that a credible mechanism of exposure was documented in this case, and the occurrence of pneumonitis in this individual was more likely coincidental in nature (Goldstein et al. 1999).
- There is also a case report out of Germany in which a glyphosate-surfactant product (tallowamine or "POEA" based) was applied by knapsack spayer in a 0.5ha forestry application at the registered application rate at 25° C for approximately 3 hours. About 7 hours after application he developed chest pain with rapidly increasing severe respiratory distress and fever up to approximately 38° C. On hospital admission, radiographic changes of lungs could be demonstrated. To further assess possible causes, bronchoscopy and closed lung biopsy was performed. Histopathology revealed "toxic inflammation of the lungs" (significantly different than bacterial infection). After 7-days of drug treatments, changes in lung reversed. Six months after the incident the patient still experienced moderate respiratory complaints on exertion. In the X-ray findings lungs showed improved results, but still detectable changes. While it is possible to differentiate acute bacterial infections on histopathology (microorganisms and polymorphonuclear leucocytic inflammatory changes should be visible), characteristics of viral, mycoplasmal, or autoimmune (vasculitic, Wegoner's granulomatosis) induced pneumonitis or Bronchiolitis Obliterans with Organizing Pneumonia (BOOP, which closely mirrors the limited case information available) are not clinically distinguishable from "toxic" etiologies. Many cases occur, most being idiopathic (no identifiable cause). Agricultural aerosols are far larger than 10 microns (generally 200 microns or so in size) and

not respirable to lung, and POEA is not volatile. Contrary to this isolated case, backpack applications of glyphosate-surfactant products occur regularly in forestry and in agriculture in the developing world, without known occurrence of serious lower respiratory disease.

RENAL:

MINOR EXPOSURES:

- Dermal, eye, mist inhalation and minor ingestions of dilute solution exposures to any commercially formulated glyphosate products of any dilution are minor exposures. Renal effects are not expected from minor exposures.

SIGNIFICANT EXPOSURES:

- Hypotension and hypovolemic shock may result in oliguria and anuria, following severe ingestions (Bradberry et al. 2004). Abrupt rises in BUN and serum creatinine may be seen.

METABOLIC:

MINOR EXPOSURES:

- Dermal, eye, mist inhalation and minor ingestions of dilute solution exposures to any commercially formulated glyphosate products of any dilution should be considered minor exposures. Metabolic effects are not expected following minor exposures.

SIGNIFICANT EXPOSURES:

- Mild fever may be noted even in the absence of infection (Bradberry et al. 2004)
- Metabolic acidosis is often seen in a severely poisoned patient (Bradberry et al. 2004) and the acidosis may fail to respond to bicarbonate therapy. Although the exact cause of the acidosis is unknown, a lactic acidosis is suspected.

HEMATOLOGIC:

MINOR EXPOSURES:

- Dermal, eye, mist inhalation and minor ingestions of dilute solution exposures to any commercially formulated glyphosate products of any dilution should be considered minor exposures. Haematological effects are not expected from minor exposures.

SIGNIFICANT EXPOSURES:

- Leukocytosis without evidence of bacterial infection has been noted in peripheral blood after ingestion of the concentrate (Bradberry et al. 2004).
- Hemoconcentration has been seen as a result of intravascular volume depletion (possibly indicating severe capillary fluid leakage) (Tominack et al. 1989).
- No primary toxic effects on bone marrow or formed elements have been seen to date.

HEPATIC:

MINOR EXPOSURES:

- Dermal, eye, mist inhalation and minor ingestions of dilute solution exposures to any commercially formulated glyphosate products of any dilution should be considered minor exposures. Hepatic effects are not expected from minor exposures.

SIGNIFICANT EXPOSURES:

- No direct hepatotoxic effects have been noted; however, minor elevations in transaminases and bilirubin are reported (Tominack et al. 1989; Bradberry et al. 2004).
- A 2018 case report describes a patient who developed fulminant hepatic failure after opening a bottle of formulated glyphosate with his mouth and accidentally ingesting a mouthful of the product. There is not a mechanism by which a small ingestion would cause fulminant hepatic failure nor do any GLP studies demonstrate hepatotoxicity; (Khot et al. 2018)

ELECTROLYTES:

MINOR EXPOSURES:

- Severe or prolonged vomiting and diarrhoea may induce fluid and electrolyte imbalance. This degree of illness is not generally expected from a minor exposure.

SIGNIFICANT EXPOSURES:

- Electrolytes (Na, K, Cl and Ca) in the absence of renal failure generally remain normal. Severe or prolonged vomiting and diarrhoea may induce fluid and electrolyte imbalance.
- POTASSIUM SALTS: While potentially toxic ingestions of all glyphosate products may result in fluid and electrolyte disturbances, particular attention to potassium may be important following ingestion of the potassium salt products. Close monitoring of serum potassium levels and/or electro-cardiographic monitoring (for peaked T-waves or rhythm disturbances) is recommended following significant ingestion of potassium salt products, particularly for high-risk individuals. Individuals with the following may be at elevated risk following acute potassium exposure: known hyperkalemia, renal failure / renal dysfunction, use of potassium sparing diuretics, hypoaldosteronism, co-ingestion of other K+ containing materials, underlying heart disease, use of digoxin, digitoxin, oabain, or exposure to other cardiac glycosides. The quantity of potassium ingested from a glyphosate potassium salt product can be estimated from the weight percent of glyphosate potassium as:

  Percent K+ salt x 5.3 = mEq potassium per 100 cc of product

- Several case reports do indicate that with large ingestions of glyphosate-potassium salt concentrate solutions, clinically significant hyperkalemia may occur. Bando et al (2001) report a 65 year old female who ingested a glyphosate-potassium salt (350 ml Roundup Maxload missing from container, in addition to 250 ml of another glyphosate formulation which was not a potassium salt- but amount actually ingested unclear) in an attempt at suicide. On admission, serum potassium level was 9.3mEq/L (typical normal value < 5) with electrocardiographic changes consistent with hyperkalemia. The patient did have a concomitant acidosis (pH 7.272) which may account for some portion of the elevation in potassium (acidosis displaces intracellular potassium). The patient responded to medical management and survived.
- Kamijo et al (2012) report a 69 year old female who ingested approximately 500 ml of the same product. On arrival in the hospital, the patient had hyperkalemia (10.7 mEq/l), pulseless ventricular tachycardia, and a severe metabolic acidosis (pH 7.005, will elevate potassium.) The patient required aggressive cardiopulmonary resuscitation and hemodialysis but did recover.
- Monsanto is aware of one additional inquiry (unpublished) of a similar ingestion with a dramatically elevated potassium level in which the patient was moribund when medical care was instituted. The patient could not be resuscitated. Because serum potassium levels rise rapidly following death (due to redistribution of intracellular potassium) , it is not possible to know how much of the observed hyperkalemia was the result of the ingestion versus profound acidosis and post-mortem redistribution (which is partially due to acidosis).
- It should be noted that the issue of hyperkalemia is limited to cases involving the suicidal ingestion of glyphosate-potassium concentrates. Potassium is a normal component of the human diet, and potassium intake attributable to occupational glyphosate-surfactant herbicide exposure will be negligible compared to typical dietary intake. While the concentrate formulations may contain up to approximately 250 mEq of potassium per 100 ml, product diluted for use (1% glyphosate concentration) will contain about 6 mEq potassium per 100 ml. By way of reference, a medium size banana contains about 10 mEq (425 mg) of potassium.
- Finally, it should be noted that the apparently very large (>150 ml) ingestions of glyphosate-surfactant concentrates observed in these cases are well within the range isopropylamine salt products reported to produce fatalities, and that elevations in potassium concentrations are reported (probably due to acidosis) following ingestions of glyphosate IPA salt products. While the cases do suggest that potassium salt products likely contribute to the risk of hyperkalemia, it is not clear at this time that the use of postassium salts will increase the overall clinical severity and/or mortality associated with

glyphosate concentrate product ingestions.

SPECIFIC DIAGNOSTIC TESTING AND PROGNOSTIC CONSIDERATIONS

Serum or other body fluid measurements of glyphosate are generally not available in a time frame useful for acute clinical diagnosis. As the management of symptoms associated with glyphosate-surfactant product ingestion is symptom-driven in any event, the lack of rapidly available concentrations of glyphosate will generally not impair clinical care. Levels may be helpful in addressing forensic issues following clinical recovery or in the event of a fatality of unclear cause.

Attention should be paid to electrolyte concentrations in individuals with significant ingestion exposures, particularly to glyphosate-potassium concentrate solutions.

Respiratory distress requiring intubation, pulmonary oedema, shock (systolic BP < 90 mmHg), altered consciousness, abnormal chest X-ray, ingestion of over 200 cc concentrate (41%), or renal failure necessitating dialysis have been associated with a higher risk of poor clinical outcomes including mortality (Lee 2008). These authors also developed a prognostic index based upon these factors. The use of prognostic criteria does not appear to add significantly to patient care. As symptom onset may be delayed, early use of such prognostic indicators may lead to an under-estimate of clinical severity.

National Chemical Emergency Centre (NCEC)

Reports from the National Chemical Emergency Centre (NCEC) in EU on any emergency calls received during the timeframe of 2017-2019 are submitted under CA 5.9/012 and CA 5.9/013.

A list of case reports is added in Appendix 1 of this document and available in the literature search report (CA 9-01).

CA 5.9.4 Epidemiological studies

The epidemiological publications found relevant and reliable were discussed in detail in section CA 5.5 and summaries of these publications were also prepared and provide in CA 5.5 (CA 5.5/030, CA 5.5/033, CA 5.5/035, CA 5.5/036, CA 5.5/037).

CA 5.9.5 Diagnosis of poisoning (determination of active substance, metabolites), specific signs of poisoning, clinical tests

Any relevant information on poisoning is provided in CA 5.9.7.

CA 5.9.6 Proposed treatment: first aid measures, antidotes, medical treatment

First aid measures

SKIN EXPOSURE:

- Remove all contaminated clothing and flood the skin surface with water.
- Wash the exposed skin twice with soap and water.
- A close examination of the skin may be required if pain or irritation exist after decontamination.
- All clothing that are contaminated should be laundered before they are worn again

EYE EXPOSURE:

- Remove contact lens from the affected eye(s) if appropriate.
- Exposed eyes should be irrigated with copious amounts of water or saline for at least 15 minutes. Pour the water from a cup or glass held 3 inches from the eye.
- A close examination of the eyes may be needed if pain or irritation persists after 15 minutes of irrigation with water or saline. If symptoms persist, seek medical evaluation, preferably with an eye specialist.

INGESTION EXPOSURE:

- DILUTE PREPARATIONS (Glyphosate <10%): An ingestion of a dilute preparation of glyphosate (<10%) probably does not require treatment other than dilution with milk or water, and symptomatic care. Further gastrointestinal decontamination is not needed, even if spontaneous emesis has not occurred.
- Concentrated (> 10%) preparations: Irrigate and dilute: irrigate the mouth with water. Immediate therapy should include dilution with milk or water if the patient is able to swallow. Do not exceed 5 ml/kg in a child or 250 ml in an adult.

INHALATION EXPOSURE:

- No pulmonary treatment is necessary for occasional, accidental breathing of mist.
- Severe, acute pulmonary injury has not been reported following inhalation exposure. Individuals with respiratory distress from any cause should be relocated (if medically stable) to fresh air and receive supplemental oxygen if available.
- In the event of respiratory failure or lack of respiration, administer artificial respiration (or if pulse not detectable, cardiopulmonary resuscitation).

Therapeutic regimes

The registrants believe that the following represent general best practices for medical management of serious ingestions of glyphosate-surfactant products.

1. Establish respiration and assure adequacy of ventilation.

2. Eye exposure:
   A) Remove contact lens from the affected eye(s) if appropriate.
   B) Exposed eyes should be irrigated with copious amounts of water or saline for at least 15 minutes. Pour the water from a cup or glass held 3 inches from the eye.
   C) A close examination of the eyes may be needed if pain or irritation persists after 15 minutes of irrigation with water or saline. If symptoms persist, seek medical evaluation, preferably by an eye specialist.

3. Ingestion exposure:
   A) Irrigate and dilute: irrigate the mouth with water. Immediate therapy should include dilution with milk or water if the patient is able to swallow. Do not exceed 5 ml/kg in a child or 250 ml in an adult.
   B) patient disposition:
   Concentrated preparations (Glyphosate 41% or greater):
      1) Any person ingesting greater than a large mouthful (50 ml in an adult, 0.5 ml/kg in a child) of a 41 % or greater glyphosate concentrate product should be admitted to a hospital and observed for 24 hours.
      2) Any adult ingesting greater than 100 ml of a 41% or greater glyphosate concentrate product (>1.4 ml/kg in a child) should be admitted to the intensive care unit.
      3) Any suicide attempt by person ingesting a concentrated product should be evaluated for psychological status and should be admitted if necessary for observation with suicide precautions.

Concentrated preparations (Glyphosate 10%-40%):

An ingestion of concentrated glyphosate (10%-40%) will usually result in spontaneous emesis. There is limited experience with glyphosate formulations in this concentration range. In view of this limited information, the registrants currently recommend managing these ingestions in a manner similar to the management of the 41% concentrate.

4. Prevention of absorption *(This lists various methods for "Prevention of Absorption". These should NOT be construed as being in order of preference. Consult with Poison Center or medical personnel to determine the need for and preferred method for decontamination. In many instances, no intervention is required.):*

A) Gastric aspiration: If no significant spontaneous vomiting has occurred gastric aspiration may be considered. If performed soon after ingestion, gastric emptying by aspirating liquid gastric content with a lavage or standard NG tube may possibly remove some of the ingested glyphosate. The intent is to remove unabsorbed liquid by aspiration not to use lavage fluid. As absorption of liquids is likely to be relatively rapid, gastric aspiration after 1 to 2 hours is unlikely to be effective.

B) Emesis: Emesis is controversial at this time. Glyphosate/surfactant products are irritants. The registrants do not recommend the routine use of syrup of ipecac for glyphosate/ surfactant ingestions because of the risk of exacerbating the irritant effects on the GI tract.

C) Activated charcoal: There are no data to support or refute the use of activated charcoal in glyphosate/surfactant product ingestions. Low molecular weight, amphoteric compounds and detergents do not always bind well to activated charcoal. In the event of a mixed ingestion, activated charcoal may be advisable.

5. Assessment of gastro-intestinal injury:

Injury to the upper gastrointestinal tract may occur following ingestion of glyphosate concentrates. A study of upper gastrointestinal endoscopy following glyphosate–surfactant ingestions suggested that Zarger grade 2 lesions (erosions) were associated with longer hospital stay and with a higher incidence of serious complications (Chang 1999). However, no major esophageal or gastrointestinal injury was observed, and strictures have not been reported following uncomplicated glyphosate-surfactant ingestion.

Because no serious gastrointestinal injury is reported, and because the need for hospitalization and/or treatment of complications can be determined without endoscopic evaluation, the registrants recommend that endoscopy be reserved for patients with co-ingestions suggesting a need for endoscopy or for patients with signs and symptoms suggestive of more serious injury (serious oral burns, inability to handle secretions, clinical obstruction) regardless of clinical history.

6. Monitor blood pressure:

Monitor the patient closely for signs of hemodynamic instability.

7. Hypotension:

If the patient is hypotensive, administer IV fluid boluses and place in Trendelenburg position. If the patient is unresponsive to these measures, administer a vasopressor (dopamine, epinephrine, norepinephrine, phenylephrine.) if needed.

8. Monitor blood gases and obtain chest radiograph:

Consider the use of repeat blood gases and a peripheral pulse oximeter to monitor hypoxemia. Observe closely for sign of acidosis.

9. Pulmonary oedema:

Closely monitor arterial blood gases. If PO2 cannot be maintained above 50 mm Hg with inspiration of 60% oxygen by face mask or mechanical ventilation, then positive end expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) may be needed. Avoid a positive

fluid balance by careful administration of crystalloid solutions. Monitor fluid status through a central venous line or Swan Ganz catheter as needed.

10. Acidosis:
Correction of acidosis should be guided by blood gases, electrolytes and clinical judgment. Attention should be directed to volume status and correction of poor perfusion in mild cases. Sodium bicarbonate may be used to correct the acidosis in severe cases.

11. Hyperkalemia (from ingestion of Potassium salt formulations):
For moderate hyperkalemia (K+ of 6.0-7.0 mEq/L), administer sodium polystyrene sulfonate For more severe hyperkalemia (K+ > 7 mEq/L) or serious complications of hyperkalemia, correct metabolic or respiratory acidosis if present to allow potassium to enter the intracellular space. Additional management may include a glucose/insulin drip, intravenous sodium bicarbonate or calcium, and dialysis to remove excess potassium.

12. Monitor renal function closely:
Assure adequate urine output. Catheterize severely ill patients. Hemodialysis may be needed in the event of renal failure or electrolyte disturbances.

11. Enhanced elimination:
A) Forced diuresis: Glyphosate is excreted very well by the kidneys. Adequate urine flow will ensure the rapid elimination of glyphosate. Although elimination may perhaps be enhanced by forced diuresis, there is no clinical evidence that this is necessary, and fluid overload may precipitate pulmonary oedema.
B) Hemodialysis: Hemodialysis may be useful to correct fluid, electrolyte and metabolic disturbances in the patient with renal failure. The institution of hemodialysis solely to enhance the removal of glyphosate or other product components is not of proven benefit. Nevertheless, it is reasonable to consider the initiation of hemodialysis in the significantly ill patient who fails to respond to routine supportive management.

12. Serious exposure via inhalation is not expected:
Inhalation exposures are not expected due to the aerodynamics of droplet size from sprayers and because the product is not volatile. Monitor the patient for signs of respiratory compromise. Create an artificial airway if necessary. Check adequacy of tidal volume. Monitor the patient for respiratory distress; if a cough or dyspnea develop, evaluate the patient for respiratory irritation, bronchitis and/or pneumonia, but these are not expected.

13. Serious exposure via skin is not expected:
Significant skin exposures are not expected; however, the patient should be treated empirically if a dermal exposure is suspected. Remove all contaminated clothing and flood the skin surface with water. Wash the exposed skin twice with soap and water. A close examination of the skin may be required if pain or irritation exist after decontamination. All contaminated clothing should be laundered before wearing.

14. Laboratory:
Monitor electrolytes, especially if the patient is experiencing vomiting and diarrhea.15 Patients ingesting concentrated products based on the potassium salt of glyphosate may ingest large amounts of potassium (see calculations above). Observe serum potassium and/or electrocardiogram carefully. Patients experiencing pulmonary symptoms or having chest radiograph changes should have arterial blood gas monitoring. A peripheral pulse oximeter and a Swan Ganz catheter may be needed.

CA 5.9.7 Expected effects of poisoning

Expected effects and duration of poisoning as a function of varying time periods between exposure or ingestion and commencement of treatment

The outcome of eye, dermal, and inhalational exposures, which are not expected to result in serious injury in any event, will not be significantly altered by delays in medical management. Similarly, minor oral exposures are symptomatically managed and unlikely to result in severe gastrointestinal symptoms. Medical management with intravenous fluids may provide some symptomatic relief in the event of dehydration, but recovery is anticipated in any event.

For serious ingestions having major electrolyte disturbances or life threatening alterations of cardiovascular performance, medical intervention may be life saving. Fortunately, as noted above, the onset of serious symptoms following ingestion is generally delayed by at least several hours, allowing for medical transport in all but the most remote or extreme circumstances. The availability (or lack) of acute field management does not appear likely to impact severity of survival of most serious ingestions.

Expected effects and duration of poisoning as a function of the type, level and duration of exposure or ingestion

Dermal exposure:

Skin irritation following exposure to glyphosate-only or glyphosate-surfactant materials is generally limited to topical irritation which will resolve within 3 days to 1 week following exposure. If exposure is aggravated by occluded conditions or physical abrasion, more severe skin injury with open skin injury may rarely result and may take longer to fully resolve.

Eye exposure:

Irritant symptoms generally resolve within 3-7 days of exposure. Most irritation is minor, but exposure to concentrate or the occurrence of a foreign body or of abrasions (from rubbing the eye) may result in corneal abrasion requiring topical antimicrobial therapy, often given in conjunction with topical corticosteroids and temporary eye patching to provide symptomatic relief. As noted above, a large study of (U.S.) ocular exposures to glyphosate-surfactant products demonstrated no long term eye injury.

Inhalation exposure:

Glyphosate-surfactant products generally do not contain readily volatile ingredients and thus inhalation exposure is limited to inhalation of agricultural droplets, which will deposit primarily in the upper airway. Resulting irritant symptoms will generally resolve within hours to a few days following exposure.

Ingestion:

Following minor or incidental ingestions, or ingestion of fully diluted formulations, gastrointestinal upset with nausea, vomiting, and diarrhoea may occur. Nausea and vomiting usually resolve within a few hours of ingestion. Diarrhoea may last for several days but is generally not severe. Following a major ingestion, the onset of systemic symptoms may be delayed by several hours. Fatalities due to cardiovascular failure are generally delayed by 12 – 36 hours. For serious but non-fatal cases, primary clinical injury generally is manifest within 72 hours but secondary complications such as infection or respiratory distress syndrome may supervene. The majority of serious but surviving cases will be fully recovered within 7-10 days of ingestion. Individuals with complicated hospital courses can require a more extended and highly variable time to recover.

1. Full summary of the study according to OECD format

The study aimed to characterise occupational exposures to glyphosate among amenity horticulturists through the collection and analysis of urine samples following pesticide application. The impact of work practices on personal exposure, as well as suitability of collecting multiple spot urine samples as a sampling strategy for the assessment of occupational exposure for glyphosate were also examined.

Materials and methods

Site description and study population - The monitoring campaign took place from September 2016 to September 2017. In this study 3 similar exposure groups (SEGs) were considered for glyphosate applications: (1) manual knapsack (Roundup Biactive XL, 360 g/L; Clinic Ace, 360 g/L; Roundup Biactive, 360 g/L; Pistol, 250 g/L; Roundup XL, 360 g/L), (2) pressurized handheld lance (Roundup Biactive XL, 360 g/L; Pistol, 250 g/L; Glyfos, 360 g/L; Rambo, 360 g/L; Roundup Gold, 450 g/L), (3) controlled droplet applicator (Nomix Dual, 120 g/L; Roundup XL, 360 g/L). Recruitment was completed in coordination with the OPW Health and Safety Unit. The lead researcher explained the project background and objectives and circulated project information leaflets to potential study participants. Participation in the study was voluntary. After having given informed consent the participants completed a self-administered questionnaire providing relevant personal and work related details, as well as information on their use of pesticides outside of work and dietary habits. Biomonitoring protocols were developed based on established protocols. Project ethical approval was received from the National University of Ireland, Galway Research Ethics Committee.

Urine collection - Biomonitoring exposure assessments took only place on the days workers were using glyphosate based pesticide products. The researcher observed all work tasks on site, and collected information such as SEG, personal protective equipment (PPE) worn, climatic conditions, and any activities or work duties performed between samples and the duration of these activities. Individual full urinary void spot samples were collected over the exposure assessment period. The void spot samples were kept and analysed separately. Time and date were mentioned on each sample container which was stored in a cooler box until collection by the researcher the morning following each task. A minimum of 3 spot urine samples were provided: a pre-task sample, a post-task sample taken within one hour of task completion and a sample taken on the following morning after the first morning void. Participants were also given the option to provide urine samples for all additional voids over the exposure assessment period (pre-task to the following first morning void sample). Participants provided more than the minimum required 3 spot samples for 59% (17) of the tasks sampled ranging between 3 and 7 samples per task. Of the spot urine

samples provided, a peak urinary sample was identified for each task and defined as the highest urinary glyphosate concentration measured during the sampling period. Following sample collection, the researcher measured and recorded the volume of each urinary spot sample. A 20 mL aliquot of the well mixed spot urine sample was then transferred into a 20 mL Sterilin™ pot and labelled with a unique identifier number, date and time. Care was taken to avoid any contamination. All samples were stored at −18°C within 24 hours pending analysis.

Analysis of glyphosate in urine samples - Glyphosate was extracted from diluted urine samples (200 µL urine added to 800 µL deionised water) using anion exchange solid phase extraction (SPE) with 10% formic acid in methanol as the eluent. The eluent was evaporated under a stream of nitrogen and reconstituted in 100 µL of 0.1% formic acid for quantitative analysis by LC-MS/MS. Chromatographic separation was achieved on a Zorbax XDB-C8, 150×4.6 mm, 5 µm (Agilent, Stockport, UK) column with 0.1% formic acid and acetonitrile with a gradient elution as the mobile phase. The method was linear over the range of 0–20 µg/L and the limit of quantification (LOQ) was 0.5 µg/L. Creatinine was determined in all urine samples with a Pentra C400 clinical analyser using the alkaline picrate method.

Statistical analysis - Prior to analysis, all glyphosate concentration levels below the LOQ were imputed, using SAS v 9.4. Differences in urinary glyphosate concentrations between the pre-task samples versus the post-task and the peak urinary samples were both analysed using paired Student t-tests. Determinants of exposure on glyphosate urine concentrations were evaluated using Pearson's correlation coefficients and linear regression. A multivariate mixed effect model was elaborated to compare the glyphosate concentrations between post-task and following first morning void samples. In these models, worker identity was entered as a random effect to account for the presence of correlations between repeated measurements from the same individuals.

Results

Descriptive *and summary statistics of demographic and task characteristics* - 18 male and 2 female amenity horticultural workers applying pesticides as part of their work duties consented to participate in the study. Urine samples were collected for 29 work tasks involving glyphosate based pesticides. The concentration of glyphosate in 14 (48%) of the pre-task samples could have been influenced by work tasks performed in the days prior to this study and by starting the work task before giving the pre-task sample. For 6 (21%) of the pre-task samples, workers reported performing work tasks involving handling of glyphosate based products on the previous day to the measurement period. Similarly, for 10 (35%) of the pre-task samples (including 2 who were also involved with spraying the previous day), workers reported collecting, checking or handling potentially contaminated spraying equipment or other work equipment prior to providing the first sample (pre-task sample). A large proportion of workers reported using pesticides outside of their job (90%), corresponding to 27 (93%) of the 29 tasks included in this study. However, none reported using glyphosate based pesticides at home on the days before the sampling. The majority of the workers (60%) reported using pesticides at work for 6–7 months per year. 100% of the workers wore gloves, 90% a Tyvec suit and 97% RPE.

Urinary glyphosate concentrations - 125 spot urinary samples were collected and analysed for 29 work tasks. Participants provided between 3 and 7 individual spot samples per exposure assessment period. Participants giving more than 3 spot urine samples over the exposure assessment period (n=17) allowed for a more accurate estimation of the urinary concentrations over time. There was no statistically significant difference in the average log transformed peak urinary concentrations where only the minimum of 3 samples were provided versus those tasks where multiple samples were provided (Student t-test; $p = 0.14$). For 13 (45%) of the 29 tasks, the peak concentrations were identified within the samples that were collected in addition to the minimum required (pre-task, post-task and following first morning void) samples. Another 31% of the peak samples were identified in post-task samples, whereas 24% comprised of following first morning void samples. The geometric mean of the glyphosate concentrations measured in urine samples of the combined glyphosate SEGs were 0.68 µg/L for pre-task samples, 1.17 µg/L for post-task samples and 0.83 µg/L for following morning void samples. The geometric mean of the peak samples was 1.9 µg/L. Glyphosate concentrations were less than the LOQ in 34 (27%) urinary samples, of which 11 (38%) were

pre-task samples and a further 11 (38%) were following first morning void samples. Two (7%) of the 29 work tasks had peak samples with urinary glyphosate concentrations below the LOQ, both belonging to the manual knapsack SEG.

Conclusion

This study provides information on occupational exposures to glyphosate among amenity horticulturalists and suggests that the collection and analysis of urine samples given up to 3 hours after task completion can be a suitable sampling strategy for estimating potential occupational exposures to glyphosate. The findings suggest that amenity horticulturists, largely complying with workplace exposure controls, have low levels of glyphosate exposures.

1. Assessment and conclusion

Assessment and conclusion by applicant:

In this study the exposure of amenity horticulturalists to glyphosate was assessed. Three similar exposure groups (SEGs) were considered for the application of various glyphosate based herbicides: one using a manual knapsack, one using a pressurized handheld lance and one using a controlled droplet applicator. Urine samples were taken pre-task, post-task and the morning after the task and analysed for glyphosate using and LC-MS/MS method with an LOQ of 0.5 µg/L. Glyphosate concentrations were found to be less than the LOQ in 27% of the urinary samples, of which 38% were pre-task samples and 38% were following morning void samples. Two of the 29 work tasks had peak samples with urinary glyphosate concentrations below the LOQ, both belonging to the manual knapsack SEG. The geometric means of the glyphosate concentrations measured in urine samples of the combined glyphosate SEGs were 0.68 µg/L for pre-task samples, 1.17 µg/L for post-task samples and 0.83 µg/L for following morning void samples. 100% of the workers wore gloves, 90% a Tyvec suit and 97% RPE.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because more detail could have been provided on the validation of the analytical method. Also the number of participants per exposure scenario was rather limited.

2. Full summary of the study according to OECD format

This study aimed to estimate the human half-life of glyphosate from human urine samples collected from amenity horticulture workers using glyphosate based pesticide products.

Materials and methods

Site description and study population - An occupational urinary biomonitoring study for glyphosate was carried out from September 2016 to September 2017. Sample collection took place at the Irish

Commissioner for Public Works (OPW) field sites. The tasks completed by the workers sampled were subdivided into three similar exposure groups (SEGs) based on the application method used by the workers to apply glyphosate based pesticide products: manual knapsacks, pressurized applicators and controlled droplet applicators, all of which involved the use of a handheld lance.

Urine collection - Full void urinary spot samples were collected from the participants for 29 work tasks and collected and analysed separately. A minimum of 3 urine samples were collected from each participant: one pre-task sample, one post-task sample and the first morning void sample obtained the day after completing the work task (following first morning void). Participants had an option to provide individual spot urine samples for all urinary voids from the start of the pesticide task to the following first morning void. A pre-labelled sample container was given to every participant for each void and they were asked to write the time and date on the container label. The volume of each urine sample was recorded and the sample was well mixed before taking a 20 mL aliquot to be transferred into a Sterilin™ pot, labelled with a unique identifier number, date and time. Care was taken to avoid any contamination. All samples were stored frozen at -18°C within 24 hours of collection pending analysis.

Urine sample analysis - Glyphosate was extracted from diluted urine samples (200 µl added to 800 µL deionized water) using anion exchange solid phase extraction (SPE) using 10% formic acid in methanol as an eluent. Quantitative analysis was performed by liquid chromatography tandem mass spectrometry (LC-MS/MS). Chromatographic separation was achieved on a Zorbax XDB-C8, 150×4.6 mm, 5 µm column with 0.1% formic acid and acetonitrile with a gradient elution as the mobile phase. The analytical method was linear over the range 0–20 µg L^{-1} and intra- and inter-assay coefficient of variations (CVs) of 3.54% (n = 10) and 9.96% (n = 40, over 4 runs) were achieved. The analytical limit of quantification (LOQ) was 0.5 µg L^{-1}. Creatinine analysis was performed on all urine samples with a Pentra 400 clinical analyser using the alkaline picrate method.

Estimation of the half-life time of glyphosate - To explore the elimination rate and to estimate the potential human biological half-life of glyphosate, only work tasks with at least two spot urine samples collected after the peak exposure were included for excretion profile analysis. The peak urinary exposure value was defined as the highest urinary glyphosate concentration measured in a spot sample after application per task. The elimination time and the estimation of the half-life of glyphosate was assessed using three different measurement metrics: unadjusted glyphosate concentrations (µg/L), creatinine corrected concentrations (µmol/mol creatinine) and Urinary Excretion Rates (UER). The UER (µg/hr) was calculated by taking the glyphosate concentration of the spot urine sample and multiplying it by the volume of the void and dividing it by the time that elapsed between this urine void and the last urine void.

Statistical analysis - All statistical analyses were performed on Microsoft Excel and Stata Software. Glyphosate concentrations were log transformed as the data showed a log normal distribution. The period of peak sample collection was taken as the start time (t = 0) and the time period from the sample collection time (t = 0) to each proceeding sample was calculated. The slope of the glyphosate urine concentration by the time duration (time passed from the start time) was calculated for each task. Linear interpolation using regression analysis was also performed for each of the included tasks. The mean values, as well as the 95% confidence interval of the half-lives were calculated to estimate the half-life range for each measurement metric.

Results

Urine samples from 7 participants performing 8 work tasks involving glyphosate based products were analysed. Data from 6 males and one female worker is included in this study. One male participated twice on two consecutive days. The age range was from 32 to 60 years, with an arithmetic mean (AM) of 48 years. Workers carried out work tasks that involved the application of glyphosate based pesticide products within one of the SEGs, which lasted between approximately 1 and 6 hours daily. The total sampling time duration of the selected 8 work tasks included in the data analysis, ranged from approximately 19 to 26 hours. In total, 28 individual spot urine samples were analysed for the 8 work tasks included in this study

(3 to 4 spot urine samples per sample set). Each sample set was analysed to evaluate the relationships between the measured urinary glyphosate concentrations (µg/L, µmol/mol creatinine or UER) and the duration. The duration started from the peak concentration sample (start time) to each of the subsequent samples. Correlations and linear regression analysis were performed for each sample set. Four sample sets were excluded from the analysis: two creatinine corrected samples sets (µmol/mol creatinine) and two UER calculated sample sets. One creatinine corrected sample set was excluded due to low creatinine levels (< 3 mmol/L) in individual spot urine samples and another because there was no association between concentrations and duration of sampling. This lack of association could relate to a number of factors like gender, diet and hydration.

Each of the sample sets showed a moderate to strong relationship between concentration and duration for all samples (R^2 = 0.42–1.00), with an estimated half-life ranging approximately from 1.5 to 10 hours for unadjusted values or from 4.75 to 20 hours for creatinine corrected values. When the results were restricted to sample sets which showed very strong relationships (R^2 > 0.90), the estimated half-life average (range) was 4.5 (1.5 - 7) hours and 7.5 (4.75 – 9.25) hours for unadjusted and creatinine corrected values, respectively. UER calculated samples showed moderate to strong relationship (R^2 = 0.60–0.95), with an estimated half-life average (range) of 7.25 (3 and 9.50) hours. The average glyphosate half-life including all measuring metrics was approximately 5.5 to 10 hours. The average and range of the half-life on sample sets (numbers 2, 12, 19 and 30) that had all three measuring metrics included was calculated. Sensitivity analysis on the four sample sets, common across all measuring metrics, had an estimated half-life average (range) of approximately 6.5 (4–10), 11.75 (7.25 - 20), and 6.5 (3–7.75) hours for the unadjusted glyphosate concentrations, creatinine corrected concentrations and urinary excretion rate. The limitations of this study are the lack of standardization (pesticide products used, quantity of pesticides applied per task, different application methods and different sampling times). The small sample size prevented the use of more elaborate statistical tests to identify differences due to sex or age. The pharmacokinetic analysis revealed first order kinetics but due to the collection of urine samples over a limited period of time (19-26 hours) multi-phasic kinetics may not have been identified.

Conclusion

The results from this study provide new information on the elimination rate and estimated human biological half-life of glyphosate based on the analysis of urine samples collected during an exposure assessment study. This information can be helpful in the design of sampling strategies, as well as assisting in the interpretation of results for human biomonitoring studies involving glyphosate. The data could also contribute to the development or refinement of Physiologically Based PharmacoKinetic (PBPK) models for glyphosate.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Analytical data for glyphosate obtained from spot urine samples collected during a glyphosate exposure study (Connolly et al., International journal of Hygiene and Environmental Health (2018), Vol. 221, 1012-1022) were used to estimate the human biological half-life of glyphosate. To that end only work tasks with at least two spot urine samples collected after the peak exposure were included for excretion profile analysis. Glyphosate concentrations were log transformed and the slope of the glyphosate urine concentration by the time duration (time passed from the start time) was calculated for each task. When the results were restricted to sample sets which showed very strong relationships (R^2 > 0.90), the estimated half-life average (range) was 4.5 (1.5 - 7) hours and 7.5 (4.75 - 9.25) hours for unadjusted and creatinine corrected values, respectively. UER calculated samples showed moderate to strong relationship (R^2 = 0.60–0.95), with an estimated half-life average (range) of 7.25 (3 and 9.50) hours. This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions in view of the limitations of the study such as the lack of standardization (pesticide products used, quantity of pesticides applied per task, different application methods and different sampling times). The

small sample size prevented the use of more elaborate statistical tests to identify differences due to sex or age. The pharmacokinetic analysis revealed first order kinetics but due to the collection of urine samples over a limited period of time (19-26 hours) multi-phasic kinetics may not have been identified.

2. Full summary of the study according to OECD format

This study aims to measure occupational exposures to amenity horticuturalists using pesticides containing the active substances, e.g. glyphosate by urinary biomonitoring. A total of 40 work tasks involving glyphosate were surveyed over the period of June – October 2015. Pesticide concentrations were measured in urine samples collected pre and post work tasks using liquid chromatography tandem mass spectrometry. Pesticide urinary concentrations were higher than those reported for environmental exposures and comparable to those reported in some agricultural studies. Log-transformed pesticide concentrations were statistically significantly higher in post-work samples compared to those in pre-work samples. Urinary pesticide concentrations in post-work samples had a geometric mean / geometric standard deviation of 0.66 / 1.11 $\mu g\ L^{-1}$. Linear regression revealed a statistically significant positive association to exist between the time-interval between samples and the log-transformed adjusted (i.e. post-minus pre-task) pesticide urinary concentrations ($\beta = 0.0039$; $p < 0.0001$).

Materials and Methods

Site description and study population - This study was conducted over the period of June – October 2015

in the Republic of Ireland, at field sites managed by the Office of Public Works (OPW). A walk through survey was performed by the researcher at the selected OPW sites including national parks, ornamental gardens and historic monuments, to collect information on the frequency of use of pesticides containing glyphosate and spraying methods used. In this study 3 similar exposure groups were considered for glyphosate applications: glyphosate with a manual knapsack (8 participants using Roundup Biactive XL, 360 g/L; Pistol, 250 g/L; Destrol Amenity, 250 g/L; Glyfos, 360 g/L; Rambo 360, 360 g/L), glyphosate with a controlled droplet applicator (4 participants using Nomix Dual, 120 g/L), and glyphosate with a pressurized handheld lance (5 participants using Roundup Biactive XL, 360 g/L; Pistol, 250 g/L; Glyfo, 360 g/L; Rambo 360, 360 g/L). Amenity horticulturists (age ranging from 33–66 years) who used glyphosate and worked with the OPW at the designated sites, were invited to participate in the study. Participation in the study was voluntary and recruitment was done in coordination with the OPW Health and Safety Unit. Prior to the commencement of the study, the workers were informed of the sampling protocols and methods and completed a self-administered questionnaire to collect information on the participants including their work activities, out-of-work use of pesticides, dietary habits and smoking status.

Biological Monitoring

Urine collection - On the day workers participated in the study, they were asked to provide a pre-work and a post-work sample of up to 50 mL each. The post-work sample was taken within one hour after completion of the task. The samples were stored at -18°C until laboratory analysis. The sampling time in this study was defined as the time interval between the pre- and post-sample collection. Following information was collected for each task: sampling time, application method, pesticide used, personal protective equipment (PPE) used and climatic conditions. Any changes in PPE, change in weather conditions, breaks taken and problems were also recorded.

Urine sample analysis - Glyphosate standard and glyphosate internal standard (2-$^{13}C^{15}N$-glyphosate) were purchased commercially. 500 µL of urine sample was diluted with 500 µL of deionised water for the analysis of glyphosate. The prepared samples were spiked with 10 µL of internal standard (500 µg/L). Glyphosate was extracted from urine by solid phase extraction (SPE) with subsequent analysis by liquid chromatography tandem mass spectrometry (LC–MS/MS) using a Zorbax SB-C3 150 × 4.6 mm, 5 µm column equipped with a C18 guard column. Mass spectrometry analysis was performed in negative MRM mode. The method was linear over the calibration range 0–20 µg/L. The intra and inter assay coefficients of variation were 3.54% (n = 10) and 9.96% (n = 40, over 4 runs) for glyphosate. The limit of detection (LOD) for glyphosate was set at 0.5 µg/L. Creatinine analysis was performed on all urine samples. Statistical analysis for this study was performed using STATA software. Urinary glyphosate concentrations are expressed as geometric means (GM) and geometric standard deviations (GSD) along with arithmetic mean (AM), minimum and maximum levels.

Results

Demographic and working characteristics - The study population consisted of 18 horticulture amenity gardeners (17 men and one woman), who applied pesticides as part of their work. One participant stated that he was a smoker. In 58% of the tasks sampled, a pesticide task had also been completed on the previous day. Of the 40 tasks analysed in this study, 93% of the workers applied glyphosate by spraying with 53% being involved with mixing and loading. The vast majority of the workers wore PPE for each task: 94% wore gloves, 83% respiratory protective equipment (RPE), and 67% Tyvek suits. 89% of the workers reused their PPE and 78% of the workers did not take breaks during the task. The average duration of exposure to glyphosate (from pre-work to post-work sampling time) was 110 minutes for application with a manual knapsack, 235 minutes for application with a large droplet applicator, and 219 minutes for application with a pressurized lance applicator.

Urinary glyphosate concentrations - A total of 80 samples were collected in this study, 40 pre-work and 40 post-work samples. 58% (23 samples) of the pre-work samples and 43% (17 samples) of the post-work samples had glyphosate concentrations below the LOD. For the combined exposure groups the geometric

mean was 0.42 µg/L for the pre-work samples and 0.66 µg/L for the post-work samples. The geometric means of the glyphosate urinary concentrations of the knapsack and pressurized lance applicators were comparable (0.62 µg/L and 0.57 µg/L, respectively) whereas the geometric mean of the post-work samples of the controlled droplet applicators was higher (1.00 µg/L) although not statistically significantly different from the other exposure groups. The urinary glyphosate concentrations (both simple and corrected for creatinine values) of the pre- and post-work samples were statistically significantly different. When the effects of the time between the collection of the pre- and post-work samples on the urinary concentrations were considered, a positive statistically significant association was observed. Similar results were found with the creatinine corrected values Similar but somewhat less pronounced associations were observed for the controlled droplet applicator and pressurized lance groups, but not for measurements performed during spraying with the manual knapsack. Pesticide urinary concentrations from workers who took breaks during the task were significantly higher by a factor 1.7 on average, compared to those from workers who did not take breaks. Trends were similar when analysis was repeated using the creatinine corrected values. Similarly, median exposure durations were statistically significantly longer for the measurements where workers took breaks compared to those who did not (273 versus 105 minutes), as well as those samples that had pesticide concentrations above the LOD compared to those with concentrations below the LOD (170 versus 98 mins).

Discussion

Studies quantifying occupational exposure to pesticides in amenity horticulture are very sparse. The sensitivity of the analytical method used for glyphosate (LOD of 0.5 µg/L) was comparable to those previously reported. The study results suggest that amenity workers have elevated urinary pesticide levels for glyphosate, above what would be expected from dietary exposures. In 43% of the post-work samples, pesticide concentrations were lower than the LOD. Although very low, the pesticide concentrations in almost all of the post-work samples were higher than those in the pre-work samples. Although no human biomonitoring data are available for the Irish population, the arithmetic mean of the urinary concentrations in the post-work samples (1.35 µg/L) is higher than the mean of 0.21 µg/L reported in an European environmental exposure study. Similarly, both mean and maximum values reported in the current study (1.35 µg/L and 10.66 µg/L, respectively) are also higher than the maximum urinary glyphosate concentrations (0.41 µg/L) reported for German adults with non-occupational exposures to glyphosate. Compared to previous studies among working populations, glyphosate urinary concentrations are comparable to those reported on agricultural exposures and slightly lower but within the range of urinary concentrations reported in studies among farm families in Iowa and farmers in Minnesota and South Carolina. The mean urinary glyphosate concentrations were comparable across all exposure groups although the exposure data from the controlled droplet applicator group appeared to be somewhat more variable than those from the other groups. The observed variation in exposure within this group may reflect inconsistent use of PPE and complacent work practices. Protective coveralls were only worn for 29% of the tasks in this group compared to at least 50% in the other groups.

Previous studies have associated higher pesticide exposures with the mixing and loading of pesticide concentrate. In this study, the majority of the participants performed mixing and loading of the pesticide concentrate as part of the overall task assessed with the exception of the controlled droplet applicators who used a pre-mixed solution. It was therefore not possible to evaluate pesticide exposure during the mixing and loading of the pesticide concentrate. A strong association was found between urinary glyphosate concentrations and exposure duration. The duration of exposure for work involving spraying with the manual knapsack and controlled droplet applicator groups ranged from 5 to 115 min and 33–195 min, respectively. No association between urinary pesticide levels and exposure duration was found for manual knapsack applicators. These study results show that there is a potential for exposure during tasks in horticulture and amenity gardening that typically involve small volumes of pesticides, ranging from 100 mL to 2 L, which warrants further investigation. 89% of the workers reused PPE such as coveralls, gloves, disposable face masks and this may have contributed to the level of exposure. Higher levels of urinary pesticide levels were found among workers who took breaks during the task. Workers who encountered problems during pesticide application such as adjusting the nozzle, leaks or spills, change in climatic

conditions or issues with PPE, had higher average urinary concentrations of glyphosate. The sampling strategy adopted in this study (spot sampling pre- and post-work), most likely underestimates the exposure potential. A larger study incorporating 24–72 h urine samples would provide more reliable estimates of exposure and allow comparison with ESFA's designated ADIs and AEOLs.

Conclusions

The results from this study provide evidence of occupational exposure to glyphosate among amenity horticultural workers. The measured levels of urinary concentrations are comparable to those reported for agricultural workers. Urinary concentrations appeared to be dependent on the duration of exposure and the levels measured were higher among workers who took breaks or performed longer tasks, such as the use of controlled droplet applicators. Further research is currently underway to investigate 24 h exposures, evaluate dermal and inadvertent ingestion exposure and their contribution to total body burden of the pesticides.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Biological monitoring has previously been used in studies evaluating occupational exposures to pesticides in both the agricultural and horticultural sectors. The aim of this study was to characterise the occupational exposures in amenity horticultural workers using a biomonitoring method for glyphosate in urine. The geometric mean of the urinary glyphosate concentrations in the post-work samples of all exposure groups combined was found to be 0.66 µg/L. When the relationship between urinary concentrations of glyphosate and systemic dose as established by Acquavella et al. (Acquavella et al. (2004) Environmental Health Perspectives, 112(3), 321-326) is taken into consideration, the daily systemic dose for the workers in this study is estimated to be 0.000021 mg/kg bw/day. The corresponding daily oral external dose is about 0.0001 mg/kg bw/day when an oral bioavailability of 20% is taken into account. This is 5,000 times lower than the ADI of 0.5 mg/kg bw/day.

This publication is considered relevant for glyphosate risk assessment and reliable without restrictions because it complies with all the reliability criteria of an exposure study.

2. Full summary of the study according to OECD format

The objective of this study was to conduct an exploratory glyphosate exposure assessment study among Irish adults, who were non-occupational users of glyphosate. A biomonitoring survey involving the collection and analysis of 20 ml spot urine samples from 50 Irish adults was conducted in June 2017. Participants completed a short questionnaire to collect information on demographics, dietary habits and lifestyle. Glyphosate was extracted using solid phase extraction (SPE) and analysed by liquid chromatography tandem mass spectrometry (LC-MC/MS). Of the 50 samples analysed, 10 (20%) contained detectable levels of glyphosate (0.80 – 1.35 µg/L). Exposure concentrations were higher than those reported in comparable studies of European and American adults.

Materials and methods

Using a convenient sampling method, 50 Irish adults (> 18 years) were recruited from 16 counties across the Republic of Ireland to participate in the study over June – August 2017. Participants with specific dietary habits (vegetarian/vegan) and those whose occupation involved the use of pesticides were excluded from the study, to prevent dietary exposure bias, due to a proportionally increased intake of wheat products, fruits

and vegetables or from occupational use of glyphosate-based pesticide products. Participants completed a project questionnaire and provided one, 20 mL first morning void urine sample. A questionnaire was designed to collect information on participant demographics, dietary habits and lifestyle.

Glyphosate was extracted using solid phase extraction (SPE) and analysed by liquid chromatography tandem mass spectrometry (LC-MC/MS). The method was linear over the calibration range 0 – 20 µg/L, the limit of detection (LOD) was set at 0.5 µg/L (signal to noise ratio of ≥ 3:1). Creatinine analysis was completed on all samples using an automated alkaline picrate method.

Results

Of the 50 study participants, 60% (n = 30) were female, the mean age was 42 (range 18 − 82), 60% (n = 30) were pet owners and only 10% (n = 5) were smokers. Participants reported that 70% (n = 35) of them consumed few or no portions of organic food. A large proportion of participants, 80% (n = 40), reported consuming 2 portions or less of bread per day.

Home use of pesticides was reported by 40% (n = 20) of participants and 16 of the 20 reported using glyphosate-based products such as Roundup, Gallup, and Weedol, they also reported wearing personal protective equipment when using pesticides (gloves, facemasks or both).

Of the 50 samples analysed, 10 samples (20%) contained detectable levels of glyphosate (0.79 – 1.32 µg/L). Based on results from urinary creatinine analysis, 47 samples were valid (creatinine values < 3.0 or > 30 mmol/L). The three invalid samples had no detectable level of glyphosate. Six of the detectable samples were from females, similar to the gender spread in the full data set. Of the detectable results, 3 out of the 10 participants used glyphosate-based products at home but none of them had used pesticides for at least a month previous (Table 1).

Table 1. Summary of the urinary glyphosate concentrations expressed as µg/L and as µmol/mol creatinine among 50 Irish adults sampled in 2017

Variable		
Samples	**Glyphosate**	
No. of samples analysed *n* (%)	50 (100)	
No. of valid samples *n* (%)	47 (94)	
No. of samples > LOD *n* (%)	10 (20)	
*Sample analysis of 10 samples > 0.5 µg L^{-1} (LOD)	µg L^{-1}	µmol/mol creatinine
Median	0.87	0.41
Maximum	1.35	0.89
Minimum	0.80	0.21

* 20% (10) of the samples analysed had detectable levels.

Conclusion

The proportion of detectable urinary glyphosate concentrations for samples collected from 50 Irish adults is low (20%), which could be due to less localised use of pesticides. A European study that had an LOD of 0.1 µg/L, reported low detection rates in Germany (32%), whereas in the USA, 93% of samples were above 0.5 µg/L (despite an LOD of 0.1 µg/L). The detection rate could possibly have underestimated the true population exposure proportion due to the small sample size and the higher limit of detection of the analytical method used in this study.

3. Assessment and conclusion

Assessment and conclusion by applicant:

This study is newly submitted for purpose of review. A biomonitoring survey involving the collection and analysis of 20 ml spot urine samples from 50 Irish adults on non-occupational setting was conducted. The LC-MC/MS analyses of urinary samples revealed that 10 out of 50 samples analysed (i.e. 20%) contained detectable levels of glyphosate (0.80 – 1.35 µg/L). The low proportion of detectable glyphosate levels could be due to lower localised use of pesticides, having a small sample size or the higher analytical detection limit used in this study (0.5 µg/L).

This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions because it complies with the quality criteria of a good exposure study.

2. Full summary of the study according to OECD format

The purpose of this study was to evaluate determinants of dermal and inadvertent ingestion exposure and assess their contribution to total body burden among amenity horticultural users using glyphosate-based pesticide products. A dermal and inadvertent ingestion exposure assessment was completed alongside a biomonitoring study among amenity horticultural workers. Linear mixed effect regression models were elaborated to evaluate determinants of exposure and their contribution to total body burden.

A total of 343 wipe and glove samples were collected from 20 workers across 29 work tasks. Geometric mean (GM) glyphosate concentrations of 0.01, 0.04 and 0.05 μg/cm^2 were obtained on wipes from the workers' perioral region and left and right hands, respectively. For disposable and reusable gloves, respectively, GM glyphosate concentrations of 0.43 and 7.99 μg/cm^2 were detected. The combined hand and perioral region glyphosate concentrations explained 40% of the variance in the urinary (μg/L) biomonitoring data. Data show the dermal exposure is the prominent route of exposure in comparison to inadvertent ingestion but inadvertent ingestion may contribute to overall body burden.

Materials and methods

Site description and study population

Exposure assessments were conducted at sites managed by the Irish Commissioner for Public Works (OPW) from September 2016 to September 2017. Workers were grouped into three similar exposure groups (SEGs): manual knapsack, pressurised lance and controlled droplet applicator, based on the applicator used to apply glyphosate-based pesticide products. The manual knapsack applicator SEG (typical capacity of 10 – 15 L), was carried as a knapsack with the pesticide product being applied with a handheld lance. The pressurised lance SEG applied the pesticide product using a handheld lance connected to a motorised knapsack. The controlled droplet applicator SEG, similar to the manual knapsack, but with a capacity 5 L, was purchased with a pre-mixed solution (eliminating the mixing and loading task) and had an adaptable applicator that could increase the droplet size, thus reducing the spray drift.

Study participants were recruited via oral presentation and circulated project information leaflets. Participation was voluntary and all participants gave informed consent. Ethics approval for this project was received from the National University of Ireland, Galway Research Ethics Committee (Ref: 16 July 2019) on the 5th September 2016.

Biomonitoring samples
A biomonitoring study involving the collection of individual full urinary void spot samples was completed and previously been reported (Connolly *et al*., 2018). A minimum of three urine samples were collected from each participant: a sample before the task began, within 1 h of task completion and the following first morning void. For 59% (n = 17) of tasks, participants gave samples for each void over the exposure assessment period (pre-task to the following first morning void). Urine samples were analysed separately for glyphosate, so the sample with the highest glyphosate concentration could be identified for each task. The urine sample with the highest glyphosate concentration measured during the sampling period was selected and referred to as the peak urinary sample for that participant.

Dermal and inadvertent ingestion sampling strategy
Wipe samples of the hands, perioral region and of potentially contaminated work surfaces (pesticide product container, worker mobile phones and steering wheels of work vehicles) were collected. Wipe sampling was conducted using Ghost Wipes™, pre-packaged polyvinyl alcohol wipes wetted with deionised water by the manufacturer. Dermal and perioral wipe samples were collected from the workers before and after the sampling task. Pre-work task wipe samples were required to evaluate whether detectable data collected post-task was as a result of the observed pesticide application task. Workers' glove and surface wipe samples were collected after the pesticide application tasks. The researcher wore disposable nitrile gloves for collecting samples and changed these gloves with each sample obtained. An appropriate number of Ghost Wipes™ and glove field blanks were also collected.

Following sampling, wipes were placed in 100 mL plastic pots and appropriately labelled. Samples were extracted and aliquots were frozen to −18°C within 24 h of collection, shipped and chemical analysis completed at the Health and Safety Executive's Laboratory, Buxton, UK.

Dermal sampling
Hand wipes were collected, using two wipes per hand. The front of the hand was wiped with five strokes from the base of the hand to the top of the palm and then five strokes across the palm, starting from the base of the palm of the small finger. The wipe was folded in half and the same sequence repeated on the back of the hand. The wipes were then folded once more and each individual finger was wiped, starting at the small finger to the thumb, going between the fingers and including the finger web areas. Followed by the tips of each finger wiped in a circular motion. The same procedure was completed again with a second wipe and repeated for both hands. Dermal wipe samples were collected from the hands when workers removed their gloves, either during the task (i.e. lunch break) or after the pesticide application task.

Glove contamination samples
PPE use varied from disposable to reusable chemical resistant nitrile gloves as per company policy. After the work task, disposable glove samples were collected for glyphosate analysis, while only some participants provided their reusable gloves for analysis. Worker gloves were collected after the pesticide application tasks or within the task if gloves were changed during the pesticide task. At the end of the pesticide application task, dermal wipe samples were collected of each hand after the gloves were removed.

Inadvertent ingestion sampling
Perioral wipes were collected starting from the upper lip area and wiped in a clockwise motion around the upper lip and philtrum area and down around to the mentolabial fold to the edge of the mouth of the lower lip area. The wipe was folded in half and similarly wiped in an anti-clockwise direction, starting at the lower lip area and finishing at the upper lip area. One wipe was used for the perioral region.

An inadvertent ingestion observational study was also conducted. The frequency of worker contacts per task, (which in the current study included all surfaces contacted by the worker), frequency of worker hand to mouth contacts, contacts with the body and surrounding area (i.e. potentially contaminated surfaces) were recorded. The frequency of contacts was recorded during only the pesticide task. Worker contacts pre- and post-work task or during work breaks were not recorded.

Potentially contaminated work surface sampling
Potentially contaminated work surfaces were wiped using one Ghost Wipe™, according to an object-specific sampling protocol developed within the study. Specifically, mobile phones were first wiped on the front of the phone, from the top to the bottom of the screen in one stroke. The wipe was folded in half and wiped on the back from top to bottom in one stroke. Finally, the wipe was folded once more and the edge of the phone was wiped, starting at the top right hand corner and completing the full edge in a clockwise motion.

Similarly, work vehicle steering wheel wipe samples were wiped from the top of the steering wheel in a clockwise direction, then folded it in half and repeated in an anti-clockwise direction. The wipe was folded once more and the centre of the wheel was wiped in a clockwise direction and the spokes were wiped from the edge to the base of the steering wheel.

Pesticide product containers were wiped from top to bottom for the full width of the container. The bottom of the container was wiped from right to left in one stroke. The wipe was folded and the top of the container was wiped in a clockwise motion. The container handle and surrounding area were wiped from top to bottom afterwards. The wipe was folded once more and the area around the lid was wiped, and then the lid itself, in a clockwise motion.

Chemical analysis
Wipe samples from the hands and perioral region, as well as the disposable glove samples, were placed into a 100 mL plastic pot and extracted by adding 50 mL of deionised water, shaken vigorously for 30 seconds, then placed on the Denley Spriamax 5 roller mixer for an hour. A 20 mL aliquot was transferred to a labelled Sterilin™ pot for storage and transport before analysis. Glyphosate was extracted from large reusable gloves at the laboratory. One glove was placed into a grip seal bag with 100 mL deionised water. Bags were placed on a gyratory rocker for 1 h with bags being turned over at 30 min. The liquid contents were then transferred to Sterilin™ pots for storage before analysis. The solubility of glyphosate in water (11.6 g/L at 25°C) made it an appropriate extraction solvent.

All samples were prepared and analysed for glyphosate. Glyphosate was extracted from dermal wipe, surface wipe and glove extracted water samples (100 µL diluted with 900 µL deionised water) using strong anion exchange solid phase extraction eluting into 10% formic acid in methanol. The eluent was evaporated under a stream of nitrogen and reconstituted in 200 µL of 0.1% formic acid. Quantitative analysis was performed by liquid chromatography tandem mass spectrometry. Chromatographic separation was achieved on a Zorbax XDB-C8, 150 x 4.6 mm, 5 µm (Agilent, Stockport, UK) column with mobile phases of 0.1% formic acid and acetonitrile with a gradient elution. The method was linear over the range 1–1000 µg/L and the LOQ was 1 µg/L and the LOD was 0.5 µg/L. Where results exceeded the top of the linear range (1000 µg/L) the samples were repeated with dilutions. The method was reproducible with an intra assay CV of 2.9% (n = 12) and an inter assay CV of 4.2% (n = 42, over four runs).

Data processing and analysis
All 23 wipe field blanks had non-detectable glyphosate concentrations. Seventeen glove field blanks were collected from the sites (as some workers used reusable gloves), six having non-detectable glyphosate concentrations, whereas detectable levels were found in the remainder. For each task with detectable glyphosate levels found on the blank glove, each glove sample within that task was field blank corrected. All the samples were corrected for the sample volume and for the surface area wiped. Although samples were not corrected for recovery efficiencies, the mean recovery percentage for plastic containers, disposable chemical resistant nitrile gloves and mobile phones, spike at 20 µg, was 122, 104 and 125%, respectively. Ghost wipes™ have a mean recovery for three samples spiked at 200 µg of 106%.

The average hand surface area measurements were assigned according to published US EPA guidance (US EPA, 2011). The glove adjustments were assigned in the same manner as the surface area for hands. This assumes a 1070 cm^{-2} for both male hands, or 535 cm^{-2} surface per hand and 890 cm^{-2} for both female

hands, or 445 cm^{-2} per hand. Average surface area measurements for the perioral region were assigned as 40 cm^{-2}.

Surface area calculations for the steering wheel were assigned as 1100 cm^{-2} surface area. An average mobile phone surface area of 202 cm^{-2} was calculated using the physical phone dimension measurements, based on the phone type sampled. Similarly, for the product containers, an average surface area value of 2300 cm^{-2} was calculated.

Statistical analysis
Before the conducting statistical analysis, all concentration levels below the LOQ were imputed, in SAS v 9.4 (SAS Institute, North Carolina, USA). A single random imputation method based on maximum likelihood estimation was used. The remainder of the statistical analysis was performed using Stata Statistical Software 15 (StataCorp, 2015).

The data were log normally distributed and thus all statistical analysis was performed with log transformed exposure concentrations. Summary and descriptive analysis was performed on the work demographics and glyphosate concentrations levels for the combined dataset and by SEG. The results for the potentially contaminated surfaces are only shown for the combined dataset.

Pearson's correlation coefficients were estimated to evaluate relationships between glyphosate concentrations on the right and left hand, the dominant hand and both hands combined. Similar tests were performed on the glove data.

A linear mixed effect regression model was elaborated based on exposure determinants for inadvertent ingestion previously identified and evaluated in regression analysis against measurements of metals (Gorman Ng *et al.*, 2017). In this model, the hand contamination and the frequency of contacts per task were entered as fixed effects whereas the worker's id was entered as a random effect to account for correlations between repeated measurements from the same worker. This model had some differences to Gorman Ng *et al.*, 2017 model, including that respiratory protective equipment (RPE) was not considered as it was used by all workers participating in the study and that we used frequency of contacts per task, not just hand to perioral/oral contacts per task. Further models using a forward model-built approach were elaborated to examine the robustness of the derived model as well as to identify determinants for inadvertent ingestion and dermal exposure and their relative contribution to overall body burden. In these models, parameters were entered sequentially based on their level of significance and kept within the model if they had a statistical significance of ($P < 0.1$).

Results

Demographic and working characteristics
Twenty amenity horticulturists who applied glyphosate-based pesticide products as part of their daily duties participated in the study (18 males and 2 females) were grouped into 3 SEGs. The pesticide task duration ranged from approximately a half hour to 6 hours. Work tasks involving the manual knapsack, controlled droplet applicator and the pressurised applicator were, on average, ~3, 3½ and 6 h, respectively.
Good worker compliance with PPE use was observed, with workers using PPE for most of the work tasks sampled; gloves, Tyvek suits and RPE were used for 29 (100%), 26 (90%) and 28 (97%) of the observed tasks, respectively.

Levels of glyphosate concentrations on wipes, gloves and contaminated surfaces
A total of 343 wipe and glove samples across 29 work tasks were collected and analysed for glyphosate. A minimum of seven sets of wipe samples were collected for each task sampled. A sample set consists of a blank wipe, perioral sample and each hand sample (two wipes per hand), before and after each work task.

Glyphosate concentration data for perioral and hand wipes (µg/cm), collected pre and post the work tasks are presented in Table 1 for overall samples and per SEG. Table 2 details the glyphosate concentration data

for the disposable and reusable gloves samples. Seventeen pairs of disposable gloves and seven pairs of reusable gloves were analysed in this study. For three of the work tasks analysed, workers wore disposable gloves over a pair of reusable gloves and gave both sets of gloves for analysis. For eight of the tasks, the workers refused to give their gloves. Glyphosate was detected in all the pre- and post-work task hand wipe samples, as well as on the post-work task glove samples. Only 11 (38%) of the pre-work task and 6 (21%) post-work task perioral wipes had non-detectable glyphosate concentrations. For a third of work tasks sampled (n = 10), workers had started the pesticide task prior to the collection of pre-work task samples. Detectable glyphosate concentrations were also found on 11 (65%) of the blank gloves samples, collected from PPE field stores. Field observations suggest that cross contamination may occur when storing new gloves in close proximity of the pesticide chemical storage area or when handling unused gloves with contaminated hands.

In the current study, arithmetic mean (range) glyphosate concentrations of 2708 (3.0–21 845) µg wipe^{-1} and 2797 (5.0–27 354) µg wipe^{-1}, (right and left hand, respectively) were found on worker hand wipe samples collected after the pesticide application task. Glyphosate concentration levels of 41 (< LOQ–321) µg per wipe were detected on wipes collected from the perioral region. Values reported for hand wipes in this study were higher than those found for agricultural pesticide users 647 (83–2081) µg (Christopher, 2008). However, the perioral glyphosate concentrations were within a range of that reported in Christopher (2008), with an arithmetic mean and range of 39.5 (2.6 – 91) µg. Christopher (2008) also detected glyphosate in worker saliva samples with an arithmetic mean and range of 140 (56–440) ng, which could suggest comparable inadvertent ingestion levels for the current study workers.

Strong positive associations were found between left and right hands, and between the dominant hand, the individual hands and the combination of both hands. Between SEGs, similar glyphosate concentrations were detected on perioral wipes, with the highest geometric mean (GM) and maximum value found in the pressurised lance SEG. Within SEGs, similar glyphosate wipe concentrations were found on both the right and left hands in the manual knapsack group and the pressurised lance applicator. Glyphosate concentrations on reusable gloves were two orders of magnitudes higher than those on disposable gloves.

On some occasions, additional dermal and gloves samples were collected for workers who took a break during the pesticide application task. For three of the work tasks, dermal wipe samples were collected from three participants before taking a break and the glyphosate concentrations for the perioral and both hands (combined) ranged from 0.01 to 0.15 and 0.002 to 0.41 µg/cm, respectively. Similarly, three participants provided their disposable gloves during the break for five of the work tasks, which included two of these participants giving samples on two consecutive days and found glyphosate concentrations that ranged from 1.27 to 20.89 µg/cm. As concentrations were similar to the post-work task samples and due to the limited sample numbers, this data were not included in further analysis. The additional samples collected could only have had a negligible effect on the post-work task samples due to similar detection levels. The assumption would be that workers would wash hands and dispose of contaminated work gloves before their break, removing the contaminant, thus no accumulation of glyphosate concentration occurs on the post-work task samples.

Wipe samples data from pesticide product containers (n = 21), work vehicle steering wheels (n = 10) and participant's personal mobile phones (n = 18) are presented in Table 3. Of all the potentially contaminated work surfaces sampled in this study (n = 49), the highest glyphosate concentrations were detected on the pesticide product containers. A pesticide product container is considered to be handled up to 50 times by the worker before disposal.

Glyphosate was also detectable on all wipes from work vehicle steering wheels (n = 21), with a mean and range of 1928 (478–5984) µg wipe^{-1} (unadjusted values). These included small tractors and vehicles (e.g. vans, cars) used to transport equipment to and around field sites. Participating workers drove the work vehicle, on some occasions to travel to multiple sites within a day, and performed the required pesticide application tasks. Only two (11%) of the mobile phone samples had non-detectable glyphosate concentrations. Most mobile phones were personal use phones.

Table 1. Glyphosate wipe concentration data (µg/cm) for pre- and post-work task perioral and hand (left and right) measurements. Results are presented as for the overall sample and per similar exposure group concerned

Samples that are below the limit of quantification (<LOQ) (1 µg l^{-1}) by number (*N*) and percentage (%). GM is the geometric mean, GSD the geometric standard deviation and the range (min–max).

Differences in exposure levels across SEGs, sampling and working parameters
Disposable worker gloves had the highest glyphosate concentrations, followed by worker hands (post-work task). Glyphosate concentrations were lowest on perioral wipes (Fig. 1a). The highest glyphosate concentrations were detected on wipe samples collected from the pesticide product containers, followed by much lower levels on the work vehicle steering wheel. The lowest concentrations were detected on the worker mobile phones (Fig. 1b). Three of the participants in this study had their mobile phone wiped on two separate occasions, and on both occasions, glyphosate concentrations were detected.

A strong positive relationship was found between urinary glyphosate concentrations (µg/L) and glyphosate wipe concentrations (µg/cm) on the worker perioral wipe samples (Fig. 2a). Similarly, perioral region and worker hands glyphosate concentrations (µg/cm) correlated positively and strongly (Fig. 2b). Some of the participants started the work task before monitoring began. Although this has no influence on the dermal exposure assessments measurements as samples were taken before and after the work task but it could potentially impact on the urinary concentrations which may not accurately reflect the full day's exposure. The precision of peak urinary concentration estimates used within our analysis may be dependent on the number of samples available for participants. However, no statistically significant differences were found in peak urinary concentrations between participants.

Figure 1. Boxplot showing the post-work task glyphosate concentrations for (a) disposable gloves, the workers hands (under the glove) and the perioral region and (b) for potentially contaminated work surfaces, pesticide product containers, the steering wheel of work vehicles and participants mobile phone (µg/cm). The box is the 25th to the 75th percentile, the line within the box is the median and the whiskers the lower and the upper adjacent values. Single points indicate outliers. *n is the number of samples. Reusable gloves were not included in the boxplot (a) due to the low number of samples. Mean measured concentrations were statistically different between all types of samples (*t*-tests; P < 0.001).

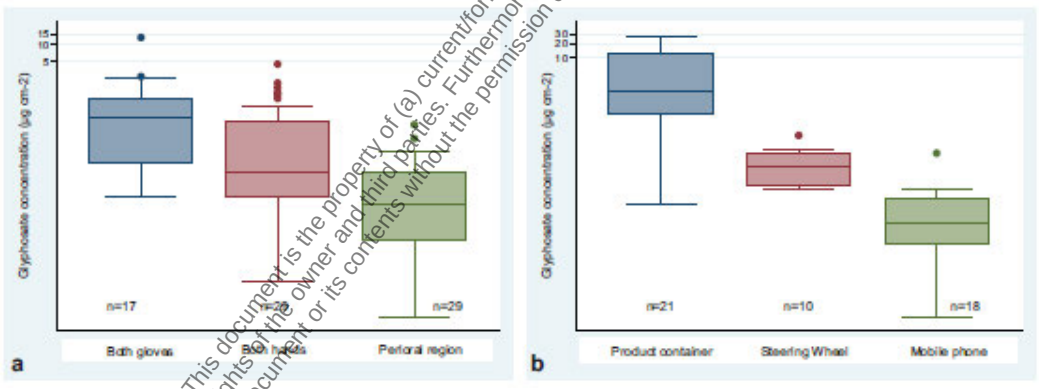

Figure 2. Scatter graph showing moderate relationships between glyphosate perioral glyphosate wipe contamination levels (µg/cm) and (a) peak urinary glyphosate concentrations (µg/L) and (b) both hands glyphosate surface loading contamination levels after a pesticide application task (µg/cm).

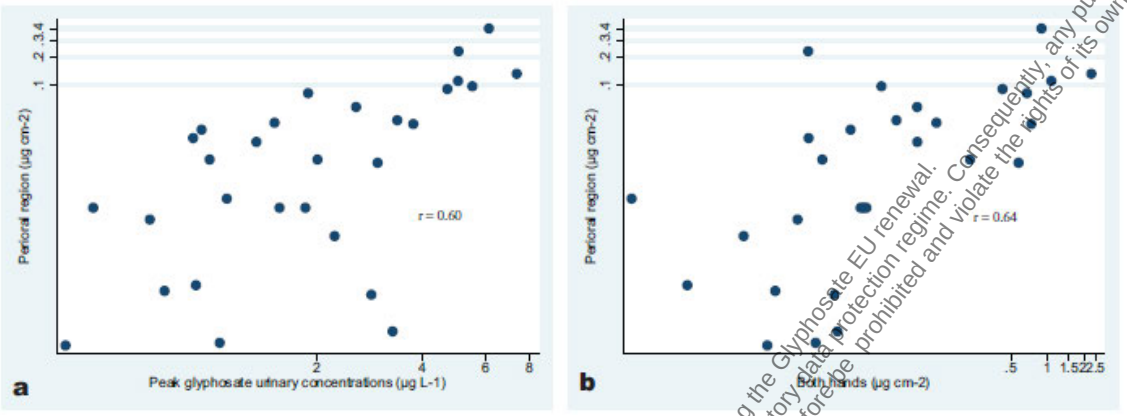

Elaborated linear mixed effect regression models are presented in Table 4. The model evaluating previously documented determinants of inadvertent ingestion exposure Gorman Ng *et al.* (2017), explained 45% of the variability for the glyphosate concentrations found on the perioral region. In this model (Model 1), an increase in the frequency of contacts per task and post-task hand contamination was significantly associated with an increased in perioral glyphosate concentrations.

Forward building of the same model on the basis of improvement of the fit parameters resulted with the same parameters being included alongside sampling time. The effects for hand contamination and frequency of contacts per task were comparable to those of the Model 1, whereas perioral concentrations also increased with increasing sampling time ($\beta = 0.01$; $P < 0.08$). This model explained ~50% of the total variability in perioral glyphosate concentrations.

The forward built model examining determinants of participants' hand contamination (Model 2) comprised of the task sampling time, the age of the participant and the SEG and explained 62% of the total variability of glyphosate concentrations measured on the hands.

All the workers who participated in this study wore gloves when applying pesticides. Gloves were used throughout the task however it was observed that on a number of occasions workers would remove their gloves for various reasons (e.g. checking mobile phones, to drive work vehicles, when going on a break, etc.). All had detectable glyphosate concentrations on their hands. Field observations suggest that poor glove doffing procedures or removing gloves during the work task (e.g. answering the phone, adjusting facemasks) may be responsible for hand contamination.

Table 4. Mixed effect models with participants' identification number included in the models as a random effect. Model 1 results are describing the effects of hand contamination and the frequency of contacts per task on glyphosate concentrations measured on the perioral region. Model 2 results describe the effects of sampling time, the age of the workers and work task characteristic on glyphosate surface loading concentrations measured on the hands. Measurements are given as on the log-transformed glyphosate concentrations per surface area (µg cm−2) and were taken from 20 workers over 29 pesticide application tasks.

Covariate	Model 1			Model 2		
	β	SE	*P*	β	SE	*P*
Intercept	−3.91	0.70	0.00	−10.05	1.67	0.00

Between variance (naive model)	1.18 (2.32)			0.00 (3.94)		
Within variance (naive model)	1.55 (2.62)			1.85 (0.97)		
Total variance explained	45%			62%		

β, regression coefficient for log-transformed exposure data; SE, standard error. The naive model is the results from the model without the inclusion of any fixed effects.

To identify the relative contribution of the routes of exposure to the total uptake of glyphosate, a separate model was forward built using the log-transformed results of the biomonitoring exposure measurements as the dependent covariate. The final elaborated model comprised of only the combined hand and perioral region glyphosate concentration (Table 5). Overall, the model explained 40% of the total variance in urinary concentrations. The hands and perioral data were not entered as separate covariates in the model, as they were highly correlated ($r = 0.64$; $P < 0.001$). Hand and perioral glyphosate concentrations are important determinants of total glyphosate body burden (glyphosate urinary concentrations), explaining 40% of variance in the urine data. Discriminating the individual contribution for each route to the total body burden was not possible. However, hand glyphosate concentrations alone explained approximately one third of the variance in the glyphosate urine concentrations, which would indicate that dermal exposure was the predominant route but that inadvertent ingestion may contribute to overall body burden since the presence of glyphosate contamination in the perioral region may result in ingestion and/or dermal absorption.

Table 5. Mixed effect model describing the effects of glyphosate concentration of the combined hands and the perioral region on the log-transformed glyphosate concentrations (µg/L) measured of 20 workers over 29 pesticide application tasks. Mixed models build with participants' identification number as a random effect.

Covariate	β	SE	*P*
Intercept	1.20	0.19	0.00
Ln concentrations in hand and perioral region surfaces	0.26	0.06	0.00
Between variance (naive model)		0.15 (0.36)	
Within variance (naive model)		0.22 (0.27)	
Total variance explained		40%	

β, regression coefficient for log-transformed exposure data; SE, standard error. The naive model is the results from the model without the inclusion of any fixed effects.

Conclusion

The analysis of a total of 343 wipe and glove samples were collected from 20 workers across 29 work tasks revealed the GM glyphosate concentrations of 0.01, 0.04 and 0.05 µg/cm^2 on wipes from the workers' perioral region and left and right hands, respectively. For disposable and reusable gloves, respectively, GM glyphosate concentrations of 0.43 and 7.99 µg/cm^2 were detected. The combined hand and perioral region glyphosate concentrations explained 40% of the variance in the urinary (µg/L) biomonitoring data. The results of the study show dermal to be a prominent route of exposure but support inadvertent ingestion potential contribution to the total body burden among this worker group. The study also identified a potential for the spread of contamination among non-pesticide users in the workforce and para-occupational exposures. Study results also showed that PPE practice is an important determinant of both inadvertent ingestion and dermal exposure. An implementation of PPE management and work practices policies for pesticide use could potentially reduce both occupational exposures and para-occupational exposures.

3. Assessment and conclusion

Assessment and conclusion by applicant:

This study is newly submitted for purpose of review. The total uptake of glyphosate was assessed in parallel with dermal and inadvertent exposure routes, using urine, wipes and glove samples collected from 20 workers across 29 work tasks. The average hand surface area measurements were assigned according to published US EPA guidance. Geometric mean (GM) glyphosate concentrations of 0.01, 0.04 and 0.05 µg/cm^2 were obtained on wipes from the workers' perioral region and left and right hands, respectively. For disposable and reusable gloves, respectively, GM glyphosate concentrations of 0.43 and 7.99 µg/cm^2 were detected. The combined hand and perioral region glyphosate concentrations explained 40% of the variance in the urinary (µg/L) biomonitoring data. Data show the dermal exposure is the prominent route of exposure in comparison to inadvertent ingestion, but inadvertent ingestion may contribute to overall body burden. The study also identified potential exposure to non-pesticide users in the workplace and para-occupational exposures.

This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions because it complies with the quality criteria of a good exposure study.

Assessment and conclusion by RMS:

Reliability criteria of exposure studies

1. Information on the study

Data point:	CA 5.9/006
Report author	Conrad, U. *et al.*
Report year	2017
Report title	Glyphosate in German adults – Time trend (2001 to 2015) of human exposure to a widely used herbicide
Document No	doi.org/10.1016/j.ijheh.2016.09.016100898843 E-ISSN: 1618-131X
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
Previous evaluation	None
GLP/Officially recognised testing facilities	Not applicable

Acceptability/Reliability:	Yes/Reliable without restrictions

2. Full summary of the study according to OECD format

The purpose of this study was to elucidate the internal exposure of the general German population to glyphosate and aminomethylphosphonic acid (AMPA) and its change over time.

The broadband herbicide glyphosate (N-[phosphonomethyl]-glycine) and its main metabolite AMPA were analysed by GC-MS-MS in 24 h-urine samples cryo-archived by the German Environmental Specimen Bank (ESB). Samples collected in 2001, 2003, 2005, 2007, 2009, 2011, 2012, 2013, 2014, and 2015 were chosen for this retrospective analysis. All urine samples had been provided by 20 to 29 years old individuals living in Greifswald, a city in north-eastern Germany.

Out of the 399 analysed urine samples, 127 (= 31.8%) contained glyphosate concentrations at or above the limit of quantification (LOQ) of 0.1 g/L. For AMPA this was the case for 160 (= 40.1%) samples. The fraction of glyphosate levels at or above LOQ peaked in 2012 (57.5%) and 2013 (56.4%) after having discontinuously increased from 10.0% in 2001. Quantification rates were lower again in 2014 and 2015 with32.5% and 40.0%, respectively. The overall trend for quantifiable AMPA levels was similar. Glyphosate and AMPA concentrations in urine were statistically significantly correlated (spearman rank correlation coefficient = 0.506, $p \leq 0.001$). Urinary glyphosate and AMPA levels tended to be higher in males. The possible reduction in exposure since 2013 may be due to changes in glyphosate application in agricultural practice.

Materials and Methods

Sampling and study group; This retrospective monitoring study was based on 24 h-urine specimen collected in the annual sampling of the German ESB. To reduce the risk of contamination, all containers needed for sampling and aliquoting were carefully cleaned before use according to standard operating procedures. All samples have been provided by young adults (predominantly students) aged 20 to 29 years. To follow the time trend of human exposure to glyphosate and AMPA, cryo-preserved urine samples collected in 2001, 2003, 2005, 2007, 2009, 2011, 2012, 2013, 2014, and 2015 were analysed. All urine samples were collected from individuals living in Greifswald, a city in north-eastern Germany. Annual ESB sampling in Greifswald was regularly carried out in the period of March and April. From each of the ten study years, 24 h-urine samples donated by 20 male and 20 female participants were randomly selected for analyses. The only inclusion criterion for this main study sample was that no specifically restricted diet – mainly vegetarian or vegan – had been reported by the sample provider in the self-administered ESB questionnaire. In 2001 the questionnaire item on dietary restrictions had not yet been implemented. Therefore, some samples from 2001 may have been provided by vegetarians or vegans. The fraction of vegetarian or vegan ESB participants, however, remained roughly between 2 and 14% from 2002 to 2014 followed by fractions up to 18% in 2015. Therefore, it can be assumed that, if any, only very few participants with restricted diets might have erroneously been included in the 2001 sample. One 2013 measurement had to be excluded from the main study sample, as the participant was later identified not to fulfil the inclusion criterion.

Hence, the main sample of this study consisted of 399 participants living in the ESB sampling location Greifswald with virtually equal sample sizes and sex ratios in each study year (cf. Table 1).

Table 1. Description of sample composition (ESB participants from Greifswald analysed for glyphosate and AMPA concentrations in 24 h-urine (no self-reported specific dietary restrictions)

Year	Sample size (male/female)	Age [years] AM (range)	24 h-urine volume [mL] AM (range)	Creatinine in urine [g/L] AM (range)	BMI [kg/m²] AM (range)

Notes: AM = arithmetic mean, BMI = body mass index.

Male ESB participants tended to have higher BMI values and urinary creatinine levels than females. To investigate possible regional/seasonal differences of glyphosate and AMPA levels 40 urine samples collected in January 2005 and 2015 at the ESB sampling location Muenster (a city in north-western Germany) have additionally been analysed. Moreover, 20 urine samples from vegetarian or vegan participants have been analysed as well, in order to investigate differences due to diet. These samples were collected in Greifswald in the years 2007 (10 females) and 2015 (5 males and 5 females) and represent all available samples from vegetarian or vegan participants. A description of the two additionally analysed comparative ESB sub-populations is provided in Table 2. Participants in Muenster tended to have slightly lower BMI values. The other sub-population of self-reported vegetarians/vegans also exhibited lower average BMI values as well as higher 24 h-urine sample volumes and lower urinary creatinine concentrations.

Table 2. Description of two sub-populations from Muenster (no self-reported specific dietary restrictions) and Greifswald (self-reported vegetarians/vegans) analysed for comparison with the main study sample

Year	Sample size (male/female)	Age [years] AM (range)	24 h-urine volume [mL] AM (range)	Creatinine in urine [g/L] AM (range)	BMI [kg/m²] AM (range)
ESB sampling location Muenster (no self-reported specific dietary restrictions)					
2005	40 (20/20)	23.6 (20–28)	1790 (691–2962)	1.03 (0.19–2.41)	22.2 (17.4–29.3)
2015	40 (20/20)	23.6 (20–28)	1991 (271–4601)	0.75 (0.35–1.73)	22.1 (18.3–28.6)
Total	80 (40/40)	23.6 (20–28)	1891 (271–4601)	0.89 (0.19–2.41)	22.1 (17.4–29.3)
Male	40	24.0 (20–28)	1934 (797–2952)	0.98 (0.19–2.41)	23.1 (19.6–28.6)
Female	40	23.3 (20–28)	1847 (271–4601)	0.80 (0.35–1.65)	21.1 (17.4–29.3)

Notes: AM = arithmetic mean, BMI = body mass index.

Analytical procedure; The chemical analysis was based on the method by Alferness and Iwata (1994) initially developed for trace analysis of Glyphosate and AMPA in food which uses gas chromatography (GC) coupled with a single quadrupole mass selective detector (MSD). The newly developed method applied in the present study used GC with tandem mass spectrometry (GC-MS-MS) to reach a low limit of quantification (LOQ) in human urine along with high selectivity. Isotope labelled internal standards have been used for further increasing the method's performance.

Standards and reagents; All chemicals were of analytical grade unless stated otherwise. Reference compounds (glyphosate and AMPA) and internal standards (1,2-13C2-15N-glyphosate and 13C-15N-AMPA) were obtained from Dr. Ehrenstorfer (Augsburg, Germany) as solutions in water (10 g/mL each). 2,2,2-trifluoroethanol (99%), trifluoroacetic anhydride (99%) and acetonitrile were purchased from Sigma-

Aldrich (Seelze, Germany). Methanol was obtained from Merck (Darmstadt, Germany). Water was purified by an ultra-water purification system from ELGA (Ransbach-Baumbach, Germany).

Sample preparation; 50 L of urine sample and 25 L of the internal standard (IS) solution (containing 4 ng/mL of each IS) were transferred to 10 mL screw-capped glass tubes containing 1 mL of acetonitrile. After evaporation to dryness in a vacuum centrifuge, 0.5 mL of 2,2,2-trifluoroethanol and 1 mL of freezing cold (-40 °C) trifluoroacetic anhydride were added cautiously to the residue. The derivatization of the analytes was started by heating the closed tubes to 85 ◦C for 1 h in a heating block. After cooling down to room temperature the mixture was cautiously evaporated to dryness. The oily residue was then dissolved in 100 L of methanol and transferred into a microvial. This final solution was used for GC-MS-MS analysis. Mixed glyphosate and AMPA calibration solutions were prepared by serial dilution of a stock solution (each 5 ng/mL) in solutions of 50 L water in 1 mL acetonitrile containing 25 L of the IS-solution. These solutions were processed in the same way as described for human urine samples and represent sample concentrations from 0.1 to 10 g/L.

GC-MS-MS analysis; The derivatised analytes were separated by gas chromatography using a GC system7890 equipped with a split/split less injector (Agilent) and a MPS2 autosampler (Gerstel). The GC column was a HP INNOWAX, 30 m length, 0.25 mm internal diameter and 0.25 m film thickness (Agilent). The mass spectrometric parameter and ion transitions used are summarised in Table 3. While the primary transitions are well suitable for quantification of glyphosate and AMPA at low environmental internal exposure levels, the secondary transitions of glyphosate and AMPA only worked well at urine concentrations beyond approx. 20 g/L to confirm the identity of analytes. As the method was clearly focused on reaching the lowest quantification limits in human urine, the secondary transitions were not considered. The high specificity of the primary ion transition was evaluated during the validation of the analytical method.

Table 3. Mass spectrometric parameter and ion transitions used in glyphosate and AMPA analyses

Mass spectrometric parameters	
Instrument	Agilent 7000
Ion source temperature	150 °C
Ionization type	Negative chemical ionization (NCI)
Chemical ionization gas	Methane 4.5
Collision gas	Argon 5.0
Electron multiplier	Relative +200 V

Mass transfers of analytes and internal standards

Transition	Precursor ion [m/z]	Product ion [m/z]	Collision energy [V]	Use
Glyphosate 1st transition	370	245	10	Analyte quantifier
Glyphosate 2nd transition	351	268	5	Of limited suitability
AMPA 1st transition	351	268	5	Analyte quantifier
AMPA 2nd transition	271	188	5	Of limited suitability
1,2-$^{13}C_2$-^{15}N-glyphosate	371	246	10	Internal standard
^{13}C-^{15}N-AMPA	353	270	5	Internal standard

Notes: The secondary transitions of glyphosate and AMPA are listed for sake of completeness only. As they provide reliable confirming information only at concentrations beyond 20 µg/L, they have not been used in this study.

Validation and quality assurance measures of analytical method; For evaluation of the method performance the requirement of SANCO guideline 825 (European Commission, 2010) were considered which are mandatory for analytical methods in the context of pesticide registration and monitoring. Specificity, linearity, working range, accuracy, precision and LOQ were investigated for method evaluation. It can be concluded that the primary transition was very selective for a reliable quantification of glyphosate and AMPA.

The specificity of the analytical method was checked by the chromatography of unfortified human urine samples which showed no other interfering peaks besides the analytes. Further, the sample solutions of 44 unfortified human urine samples containing residues of glyphosate were analysed in parallel using separation columns with phases of different selectivity. Analysed concentrations of glyphosate (n = 44 > LOQ) and AMPA (n = 25 > LOQ) ranged from 0.2 to 5 µg/L on both columns and correlated well: The respective slopes of the linear regression lines were close to unity (1.03 for glyphosate and 1.12 for AMPA)

and the coefficients of determination (R2) reached satisfactory values (0.9968 for glyphosate and 0.9893 for AMPA). Therefore, it could be concluded that the primary transition was very selective for a reliable quantification of glyphosate and AMPA.

Basic calibration was performed by the measurement of 8 calibration solutions with concentrations ranging from 0.1 to 10 µg/L. A linear relationship between concentration and the ratio of the peak area of glyphosate and AMPA and its internal standards was observed. All calibration curve points were within 15% of their respective theoretical value. The linear correlation coefficients were typically > 0.99. Calibration curves for glyphosate and AMPA based on water and pooled human urine were both linear (each R2 > 0.99) and ran parallel. The slopes differed only by approximately 2%. This indicates that possible matrix effects are well compensated by the internal standards and matrix matched calibration solutions are not required for accurate determination of glyphosate and AMPA. The LOQ for glyphosate and AMPA was determined by fortification of human urine samples. The lower level at 0.1 µg/L demonstrated sufficient recovery (86 to 115%) and precision (8.9to 9.1%) for both analytes. This concentration was set as the LOQ of the GC-MS-MS method. The urine samples were analysed in a randomised order. Blank values (urine substituted by water) were measured during the analysis of urine samples regularly every 15th sample. All blank values were below the LOQ of 0.1 µg/L. Evaluation of the accuracy and precision of the method was performed through recovery experiments. Pooled human urine samples with no detectable amount of glyphosate and AMPA (each <0.1 µg/L) were fortified at 0.5, 1.0, 2.5, and 5 µg/L on 8 replicates each level. The recovery values ranged from 81 to 106% with are lative standard deviation (RSD) below 8.3%. Further, we performed recovery experiments using individual human urine samples to check for possible matrix effects caused by variations in the composition of the samples. Ten individual urine samples free of glyphosate and AMPA (each < 0.1 µg/L) were spiked at 0.5, 2.5 and 5 µg/L and were analysed in triplicate. The recoveries ranged from 87 to 110% proving that possible matrix effects were compensated by the internal standards $^{13}C_2$-^{15}N-glyphosate and ^{13}C-^{15}N-AMPA. In addition, the performance of the method was checked by measuring of control samples spiked at 0.5 and 2.5 µg/L during the analysis of the samples from this study (about every 33rd sample). A summary of the results of the control samples is provided in Table 4.

Table 4. Results of control samples concurrently analysed with the study samples

Analyte	Spiking level [µg/L]	Mean recovery [%]	Range [%]	RSD [%]	Number of samples
Glyphosate	0.5	103.0	84.4–113.3	8.6	15
	2.5	102.9	94.2–111.3	5.1	15
AMPA	0.5	102.1	82.4–112.4	9.4	15
	2.5	101.3	91.2–111.0	5.7	15

Statistical analysis; Glyphosate and AMPA concentrations below the LOQ were set to LOQ/2 prior to statistical evaluation. All data analyses were carried out in SPSS Statistics Version 20 (IBM Corporation, 2011). Differences between frequencies were tested with Pearson's Chi^2 test of independence after cross tabulation. Correlations between variables were quantified by Spearman's rank correlation coefficients, as concentration and other data mostly contained few extreme values. Box-plots were created in R Version 3.2.3 (R Core Team, 2015) displaying the 25th, median and 75th percentile as a box. The whiskers were set to extend to the minimum and maximum value, due to considerable skewness and obvious non-normality of the data. All p-values of 0.05 or lower were considered to indicate statistical significance.

Results

Urinary concentrations of glyphosate and AMPA in the main study sample

Frequency of quantifiable concentrations; Out of the 399 analysed urine samples, 127 (= 31.8%) contained glyphosate concentrations that reached or exceeded the LOQ of 0.1 g/L. For AMPA this was the case for 160 (= 40.1%) of all samples. The fraction of samples at or above LOQ varied significantly over the years investigated, both for glyphosate ($p \leq 0.001$) and AMPA ($p = 0.005$). As displayed in Table 5 and Fig. 1, years with the highest quantification rates were 2012 (57.5%) and 2013 (56.4%) after rates having

discontinuously increased from 10.0% in 2001. Fractions of at least 0.1 g/L were lower again in 2014 and 2015 with 32.5% and 40.0%, respectively. The overall trend for quantifiable AMPA levels was quite similar. The highest fraction of samples reaching or exceeding the LOQ was observed for samples taken in 2012 (60.0%). The fractions of quantifiable levels of glyphosate and AMPA per year were generally higher in males. Especially for glyphosate, the principally increasing trend in urine concentrations was mainly due to samples provided by males (cf. Table 5).

Fig. 1. Temporal trend of glyphosate and AMPA in human 24 h-urine (fraction of samples at or above limit of quantification of 0.1 µg/L, ESB sampling location Greifswald , no self-reported specific dietary restriction)

	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015
Glyphosate	10.0%		17.5%		30.0%		15.0%		27.5%		32.5%	57.5%	56.4%	32.5%	40.0%
AMPA	15.0%		30.0%		40.0%		30.0%		50.0%		42.5%	60.0%	48.7%	42.5%	42.5%

Fractions of quantifiable glyphosate levels in samples from females were particularly high only in 2012 (55.0%) and 2013 (47.4%). The same difference between males and females was also apparent for AMPA, although the difference was less pronounced. Glyphosate sales in Germany have increased substantially from approximately 3300 t in 2000 to approximately 5400 t in 2014. The interim peak of approximately 7600 t in 2008 might be interrelated with the abolishment of EU set-aside requirements announced in 2007. Against the background of these data, the increase in quantifiable glyphosate and AMPA concentrations in analysed ESB urine samples were in agreement with expectations. Although the internal exposure to glyphosate and AMPA seems to have decreased again since 2013, there was a clear increase in comparison to 2001. The possible reduction in exposure since 2013 indicated by ESB data may be due to changes in application of glyphosate in agriculture: Austria, for example, banned the pre-harvest use of glyphosate in 2013. Also in Germany, intended glyphosate uses as pre-harvest treatment have been restricted (e.g. to partial applications instead of whole field treatments) from 2014 onwards. Currently, no German sales data are available for the year 2015.

Distribution of concentrations; The 50th, 75th, and 95th percentiles and maximal values for glyphosate and AMPA levels by sex and study year are provided in Table 5. Only in 2012 and 2013 the median concentration of glyphosate was slightly above the LOQ of 0.1 g/L. The 75th percentile exceeded the LOQ in all study years after 2007, reaching highest values in 2012 and 2013. The 95th percentiles of glyphosate

concentrations in 24 h-urine were substantially higher in 2013 (1.25 g/L) and 2014 (0.80 g/L) compared to all other years. Also the maximum concentrations of glyphosate peaked in these two years (2013: 2.80 g/L, 2014: 1.78 g/L). The median urinary AMPA concentration only slightly exceeded the LOQ in 2012. With the exception of the first year of the study, 2001, all 75th percentiles exceeded the LOQ with the highest level observed in 2013. The 95th percentiles of AMPA levels peaked in 2013. The two highest AMPA concentrations were observed in samples from 2013 (1.88 g/L and 1.54 g/L). The observed urinary glyphosate and AMPA concentrations were in good agreement with findings from other studies. In view of these results, ESB data was considered to provide a reliable indication of the background exposure to glyphosate and AMPA in Germany and its change from 2001 to 2015. Comparability with other studies was limited, partly due to differences in the study population and in the type of urine samples.

Table 5. Summary statistics for glyphosate and AMPA concentrations in 24 h-urine samples (µg/L) by sex and year of sampling at ESB sampling location Greifswald (no self-reported specific dietary restrictions)

			Glyphosate					*AMPA*

Notes: N = sample size, LOQ = limit of quantification, P = percentiles, Max. = maximum value.

As displayed in Figs. 2 and 3 glyphosate and AMPA concentrations were generally higher in samples from male ESB participants compared to samples from female participants. From 2011 onwards, median levels and 75th percentiles for glyphosate were higher in males. Box-plots for AMPA concentrations showed the same pattern. The maximum values for glyphosate and AMPA concentrations in urine, however, were observed in samples from female ESB participants. The differences in urinary glyphosate might be due to differences in exposure patterns between males and females or to sex-related differences in physiological determinants of glyphosate and AMPA in urine.

Fig. 2. Box-plots of glyphosate concentrations in 24 h-urine samples by study year and sex (ESB sampling location Greifswald, no self-reported specific dietary restriction, concentrations below LOQ of 0.1 µg/L set to LOQ/2 = horizontal solid line, box displays 25th, median and 75th percentile, whiskers extend to minimum and maximum value)

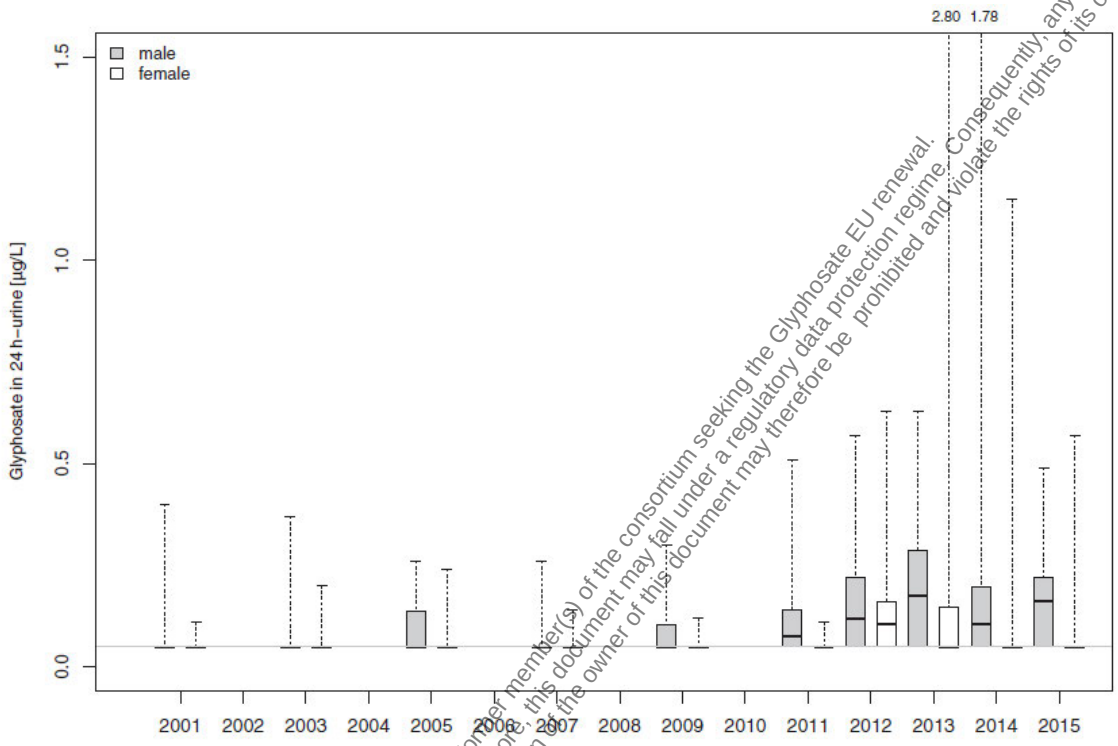

Fig. 3. Box-plots of AMPA concentrations in 24 h-urine samples by study year and sex (ESB sampling location Greifswald, no self-reported specific dietary restriction, concentrations below LOQ of 0.1 µg/L set to LOQ/2 = horizontal solid line, box displays 25th, median and 75th percentile, whiskers extend to minimum and maximum value

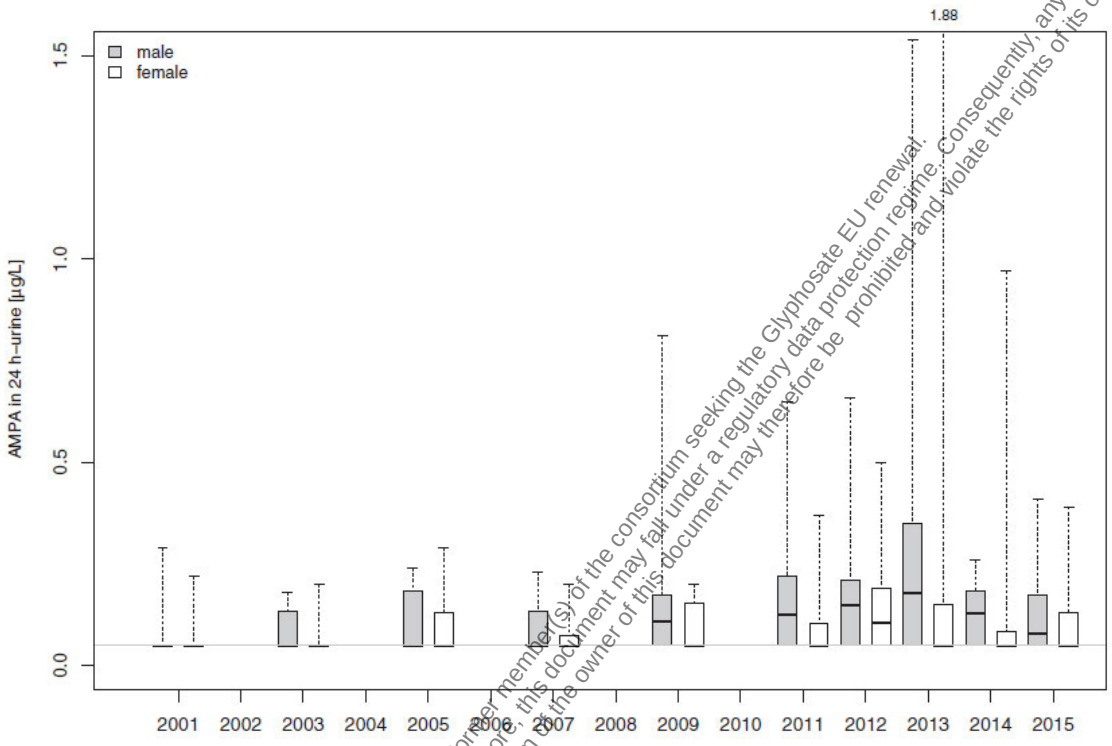

Correlations between glyphosate, AMPA and physiological parameters; Spearman rank correlations between glyphosate and AMPA levels in urine and physiological parameters observed in the main study sample are summarised in Table 6.

Table 6. Spearman rank correlation coefficients between glyphosate and AMPA concentrations in 24 h-urine and physiological parameters

		AMPA in 24 h-urine [µg/L]	Body mass index [kg/m²]	Volume of 24 h-urine sample [mL]	Creatinine in 24 h-urine [g/L]

	p-value				≤0.001
	N				397

Notes: N = sample size, statistically significant correlation coefficients ($p \leq 0.05$) highlighted in bold

Glyphosate and AMPA concentrations in urine were statistically correlated (spearman rank correlations coefficient $r_S = 0.506$, $p \leq 0.001$). When calculating coefficients of rank correlation separately for each study year, glyphosate and AMPA levels correlated statistically significantly in all years except for the first two, 2001 and 2003. For the following eight years of the study, r_S ranged between 0.360 and 0.616 (all p-values ≤ 0.05). A statistically significant association between glyphosate and AMPA concentrations in urine was also observed when cross tabulating all quantifiable and non-quantifiable levels for both analytes as

well as when calculating the Pearson product-moment correlation coefficient (data not shown). There were, however, urine samples with comparatively high glyphosate and quite low AMPA concentrations, and vice versa. The coefficients of correlation of glyphosate and AMPA with BMI were comparatively low and statistically significant only for glyphosate. Correlations between BMI and glyphosate concentrations in urine were only statistically significant at the 5% level in 2011 (r_S = 0.344) and 2015 (r_S = 0.365). For AMPA, only the correlation of the concentrations in urine with the participants' BMI in 2015 reached statistical significance (r_S = 0.346). Glyphosate and AMPA concentrations in urine were consistently negatively correlated with the urine sample volume (r_S = -0.278 and -0.327) and positively correlated with urinary creatinine levels (r_S = 0.347 and 0.373). All these coefficients of correlation were statistically significant ($p \leq 0.001$). The BMI was positively correlated with the creatinine concentration in 24 h-urine samples (r_S = 0.252, $p \leq 0.001$). Glyphosate and AMPA concentrations in urine were positively associated with urinary creatinine in all study years. The coefficients of correlation were statistically significant at the 5% level in almost all study years. Examined for the individual years of the study, the r_S of urine sample volume and glyphosate as well as AMPA levels were consistently negative. The correlation, however, was often not statistically significant. These results warrant a further discussion on options for a combined consideration of glyphosate and AMPA in exposure assessment. The quite low, but statistically significant correlation between BMI and glyphosate deserves attention when further investigating glyphosate exposure via food consumption. The negative association of glyphosate and AMPA concentrations with 24 h-urine sample volumes and positive association with urinary creatinine concentrations were in line with expectations, as both parameters reflect the individual urinary dilueness. 24 h creatinine excretion was usually higher in males.

Comparison with other ESB sub-populations

To get a first insight into differences in exposures due to the place of residence and season of sampling, 40 urine samples collected in 2005 and 2015 at the ESB sampling location Muenster were also analysed for glyphosate and AMPA. In contrast to samples being taken in April/May in Greifswald, the annual Muenster sampling is carried out in January. The summary statistics for glyphosate and AMPA in this sub-population are given in Table 7.

Table 7. Summary statistics for glyphosate and AMPA concentrations in 24 h-urine samples (µg/L) by sex and year of sampling in two sub-populations from Muenster (no self-reported specific dietary restrictions) and Greifswald (self-reported vegetarians/vegans) analysed for comparison with the main study sample

			Glyphosate					*AMPA*

	Total	10	40.0	<LOQ			0.61	30.0	<LOQ			0.43

Notes: N = sample size, LOQ = limit of quantification, P = percentiles, Max. = maximum value.

In 2005 and 2015 the percentage of quantifiable glyphosate levels was significantly higher in the main study sample (Greifswald) than in Muenster (2005: 30.0% vs. 5.0%, p = 0.003 and 2015: 40.0% vs. 15.0%, p = 0.012). For AMPA no statistically significant differences between Greifswald and Muenster samples were observed in 2005 (40.0% vs. 27.5%, p = 0.24) and 2015 (42.5% vs. 35.0%, p = 0.49). Also the 75th and 95th percentile of urinary glyphosate concentrations in the main study sample were higher than in samples collected in Muenster. For AMPA these percentiles were quite similar for both populations. A second comparative subsample analysed for glyphosate and AMPA consists of 10 samples provided in

2007 and 2015 by self-reported vegetarians/vegans taking part in Greifswald (cf. Table 7). There was virtually no difference between self-reported vegetarians/vegans and the main study sample concerning quantifiable percentages of glyphosate in 2007 and 2015. For AMPA the fractions of samples with levels of at least 0.1 g/L tended to be lower for vegetarians/vegans (2007: 0.0% vs. 30.0%, p = 0.047 and 2015: 30.0% vs. 42.5%, p = 0.47), being statistically significant only in 2007. In that year, all self-reported vegetarians/vegans who participated in Greifswald were female. When limiting the comparison to samples collected from women, the difference observed in 2007 was less pronounced and no longer statistically significant (0.0% vs. 25.0%, p = 0.083). Glyphosate concentrations in urine seem slightly higher in the main study sample in comparison to the Muenster sub-population. Although there were virtually no differences in urinary AMPA, this result indicated possible regional or seasonal differences in exposure. Against expectations, the results of this study did not considered to advocate urinary glyphosate and AMPA levels being higher in vegetarian/vegan participants. No equal sex distribution could be achieved for the sub-population of self-reported vegetarians/vegans, due to a low participation rate of male vegetarians/vegans. This might have reduced comparability of this sub-population, as males showed a tendency to exhibit higher glyphosate and AMPA concentrations in urine. Another limitation of this comparison was that vegetarian/vegan participants exhibit on average higher 24 h-urine sample volumes than in the main study sample without self-reported specifically restricted diet. In general, the sample sizes of the two sub-populations analysed for comparison were possibly too small to draw general conclusions on seasonal or regional effects and on effects of dietary preferences.

Health-relevance of observed internal exposure; The acceptable daily intake (ADI) for glyphosate derived by the European Food Safety Authority (EFSA) is 0.5 mg/kg/d (EFSA, 2015). Assuming a bodyweight of 60 kg, an oral absorption of 20% with fast elimination via urine, and a daily urine excretion of 1500 to 2000 mL, the concentration in 24 h-urine associated with this ADI resulted in 3000 to 4000 g/L. This concentration was higher than the maximum concentration observed in this study (2.8 g/L) by a factor of 1000. Considering EFSA's risk assessment, none of glyphosate concentration measured in ESB samples was considered problematic for human health. The International Agency for Research on Cancer (IARC), however, classified glyphosate in Group 2A ("probably carcinogenic to humans"; IARC,). Taking this assessment into account, especially the increasing trend in internal glyphosate exposure documented by ESB samples needs an attention with regard to human health.

Conclusion

Retrospective GC-MS-MS analyses of the general German population urinary samples collected during a period covering 2001 – 2015 revealed that 31.8% of analysed samples contained detectable level of glyphosate. For AMPA this was the case for 40.1% samples analysed. A peak of detectable glyphosate level was observed in 2012 (57.5%) and 2013 (56.4%), followed by a decrease in 2014 (32.5%) and 2015 (40.0%), which may be due to changes in glyphosate application in agricultural practice. Urinary glyphosate levels tended to be higher in males. Overall, the urinary level of AMPA showed a similar trend as glyphosate, with a statistically significantly correlation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The internal exposure levels of glyphosate and its main metabolite AMPA were analysed using the general German population urinary samples collected during a period covering 2001 – 2015 with similar sample sizes and sex distributions. Retrospective GC-MS-MS analyses revealed that 31.8% of analysed samples contained detectable level of glyphosate. For AMPA this was the case for 40.1% samples analysed. A peak of detectable glyphosate level was observed in 2012 (57.5%) and 2013 (56.4%), followed by a decrease in 2014 (32.5%) and 2015 (40.0%), which may be due to changes in glyphosate application in agricultural practice. Urinary glyphosate levels tended to be higher in males. Overall, the urinary level of AMPA showed a similar trend as glyphosate, with a statistically significantly correlation.

2. Full summary of the study according to OECD format

This longitudinal study measured the glyphosate concentrations found in maternal and umbilical cord serum in 82 pregnant women who gave birth in three provinces of Thailand. Through questionnaires and biological samples collected at childbirth, factors such as personal characteristics, family members occupation, agricultural activities, and herbicide use in agricultural work were evaluated as predictors of glyphosate levels in the pregnant women. Statistical analysis used univariate and binary multiple logistic regression, where the outcome was the probability of exposure to glyphosate above the limit of detection associated with occupation and household factors. The glyphosate concentrations in the pregnant women's serum at childbirth (median: 17.5, range: 0.2–189.1 ng/mL) were significantly higher ($P < .007$) than those in the umbilical cord serum (median: 0.2, range: 0.2–94.9 ng/mL). Women with glyphosate levels >limit of Detection (LOD) in serum at childbirth were 11.9 times more likely to report work as an agriculturist ($P < .001$), 3.7 times more likely to live near agricultural areas ($P = .006$), and 5.9 times more likely to have a family member who worked in agriculture ($P < .001$).

Materials and Methods

Subjects for a pilot birth cohort were recruited from pregnant women who came for prenatal care at three hospitals in Thailand: Amnatchareon Hospital in Amnatchareon Province in the northeast, Sawanpracharak Hospital in Nakhorn Sawan Province in the lower north, and Paholpolpayuhasena Hospital in Karnjanaburi Province in the west of Thailand, from May to December 2011. To be recruited, the women had to be in their 7th month of pregnancy, 19–35 years of age, not have diabetes or hypertension, and plan to give birth and have follow-up infant care at the recruiting hospital. The 82 subjects for this study included 81 full-term normal birth neonate and 1 full-term cesarean birth neonate.

During their 7th month of pregnancy, the women were interviewed about their general health, diet, and work exposures, including agricultural work, as well as about use of pesticides at home and work. Several questionnaires, each with several sections, constituted the data collection. The questionnaire was based on the type of information collected in previous studies of agricultural workers and modified for the conditions of agriculture and types of pesticide exposures experienced in Thailand. The questionnaires were reviewed by staff at each hospital, then piloted and revised based on comments. One questionnaire collected data on demographics and the mother's general health, whereas another collected birth data. The pesticide exposure questionnaire consisted of six sections; the first section contained 12 items related to pesticide use in the home or outside the home, as well as sources of drinking water. The second section contained 9 items about the woman's work history outside the home. The third section, with 10 items, covered agricultural activities if conducted by the woman. The fourth section, with 3 items, covered agricultural activities conducted by the woman during pregnancy. The fifth section, with 6 items, asked about the agricultural work of family members. The sixth section, with 30 items, collected detailed information only from those who were agricultural workers or had family members who were agricultural workers and included detailed information on the mixing and spraying of pesticides. To summarize, the pesticide exposure questionnaire had 40 items for all subjects and 30 items only for those who were self-identified as agricultural workers or who had family members who were agricultural workers. For comparisons with agriculturists, women with other occupations were used as the control group. The nurses at the prenatal clinics in the three study hospitals were trained to recruit and interview subjects. The maternal and umbilical cord serum was collected during delivery by the delivery nurses and was frozen at -45°C until analysis. This study was reviewed and approved by the Ethics Committee on Human Rights Related to Human Experimentation,

Mahidol University, and the University of Massachusetts Lowell Institutional Review Board.

Glyphosate was obtained from Sigma-Aldrich Inc., Singapore. Acetonitrile, trimethylamine, methylene chloride, dichloromethane (all high-performance liquid chromatography [HPLC] grade), and sodium dodecyl sulfate (SDS) (gas chromatography [GC] grade) were purchased from Apex Chemical, Bangkok, Thailand. Other chemicals were of analytical grade. Analysis was performed with an HPLC system (Agilent 1200 Series) with a fluorescence detector for glyphosate. The serum sample was analysed on Luna 5 µm C18 (150 × 4.6 mm) column (Phenomenex, Torrance, CA, USA) with guard column at 45°C. A calibration curve was developed using hospital serum samples of non-subjects tested for the non-presence of glyphosate and then spiked with glyphosate to yield final concentrations of 12.5, 25, 50, 100, 150, and 200 ng/mL (n = 3 replicates). Samples of glyphosate were prepared using 250-µL of serum and 30 µL of derivatized glyphosate and injected into the HPLC. Evaluation of the detection limit was performed following the National Institute for Occupational Safety and Health method. For determination of accuracy and precision, concentrations of hospital serum samples of non-subjects tested for the non-presence of pesticide were used to prepare concentrations of 50, 100, and 150 ng of glyphosate/mL. Three replicates of each concentration were analysed on three separate days. The calibration curve for glyphosate was linear over the concentration range of 12.5–200 ng glyphosate/mL serum with the correlation coefficient of 0.998. The detection limit for the analysis of glyphosate in serum was0.4 ng/mL. Values below the detection limit for serum glyphosate were used as the detection limit divided by 2 since the data were highly skewed. The recovery of the method ranged from 94.33% to 99.03% with a relative standard deviation (RSD) of <3% for glyphosate concentrations of 50–150 ng/mL.

The descriptive statistics were calculated using SPSS (SPSS version 18; PASW Statistics Base 18, Bangkok, Thailand). Since exposures were highly skewed due to the large percentage of values below the limit of detection (LOD), concentrations were reported as the median and range. For comparison of the paired mother and cord blood serum concentrations, only pairs with both measurements above the LOD levels were used with the Wilcoxon signed-rank test. Binary logistic regression was used to evaluate whether various factors were significantly associated with the probability of having glyphosate concentrations over the LOD. Several a priori factors were evaluated for inclusion as potentially significant covariates, such as maternal location/province and educational level of the mother, but these were found not to be significantly associated with the probability of having glyphosate concentrations over the LOD. Thus, occupational factors were evaluated in single-factor models and reported as unadjusted odds ratios (ORs). In models examining secondary exposure factors, maternal occupation was included as a covariate in the model to control for the influence of maternal agricultural work on serum levels.

Results

The average age of the 82 women who gave birth during the study was 26 years old (range: 19–34 years), with most having completed secondary school (41%), although 26% only completed primary school. Of the 82 women, 39% of the women described their occupation as agriculturist/farmer, whereas 21% listed themselves as a housewife, and about 13% were employees or owned their own business (often these are small retail stands with food or other items for sale). Of the 82 pregnant women who gave birth during the study, cord blood was only collected from 75 newborns, all born full term (37–41 weeks).

The percentage of maternal samples of glyphosate that were at or below the LOD was 46.3%, whereas for cord serum 50.7% were ≤LOD. Comparison of the glyphosate concentrations in paired serum samples of mother and cord blood that were both >LOD (n = 36) found that they were significantly different (P < .001), with the mother's serum levels the higher of the two. With regard to occupational factors predicting glyphosate exposures, the odds of having a detectable level of glyphosate in serum were 11.9 higher (95% confidence interval [CI] 3.6-39.5) than the LOD among women who worked in the fields compared with those who did not. Pregnant women who worked in agricultural fields during the first, second, or third trimester of pregnancy also had significantly elevated ORs of 13.5 (95% CI 2.8-64.3), 7.7 (95% CI 2.0-29.8), and 12.4 (95% CI 1.5-102.7), respectively, of having serum levels >LOD compared with those women who never worked in the fields. Likewise, pregnant women who reported picking crops during

pregnancy had a significantly elevated OR (5.4; 95% CI 1.4-20.8)), whereas those who reported the agricultural activity of digging in farm soil or controlling weeds during pregnancy did not have elevated ORs.

With regard to secondary factors, pregnant women who lived near agricultural fields (<0.5 km) were significantly more likely to have serum glyphosate levels >LOD than those women living far from agricultural fields (OR=3.7, 95% CI 1.5-9.2). Note that there was no significant relationship between home location and agricultural occupation; thus, the adjusted OR did not reflect collinearity or confounding. Those pregnant women who reported a family member who was an agriculturist/farmer living in the same house were significantly more likely to have elevated serum glyphosate than those who did not (OR=5.9; 95% CI 2.2-16.1); however, when adjusted for occupation, the OR became non-significant because of the high correlation between having a family member who was a farmer in the same house and maternal occupation as a farmer.

The most striking finding of this study was that glyphosate concentrations over the LOD were significantly more likely to be found in the serum of pregnant women collected at childbirth if their occupation was an agriculturist/farmer or conducted various agricultural tasks or if they lived near agricultural fields sprayed with pesticides (unspecified), when compared with women who had no agricultural exposures. Researchers measured glyphosate levels in urine among farmers in the United States and found that farmers who had skin contact with pesticides or did not use rubber gloves had significantly higher glyphosate concentrations in their urine. Among those who did not wear rubber gloves, appreciable differences were found in the urinary glyphosate levels between those who repaired equipment during applications or spilled during mixing/loading or application. This supports the notion that dermal contact is an important route of exposure for this herbicide. Researchers also reported urinary glyphosate in one of the children who lived 1.5 km away from the farm where their father sprayed glyphosate in France. However, in a US study, very few of the spouses (4%) and children (12%) who lived in a home within 1 mile of the sprayed farm fields had measurable urinary glyphosate on the day of spraying, and an even lower percentage had measurable levels on days 1–3 post application. Among the applicators, 60% had measurable glyphosate on the spraying day, with a decrease to 27% on the third day post application. This raises the question of the half-life of glyphosate and how the Thai agricultural women giving birth had measurable levels of glyphosate in their serum. Although these women had regular, repeated exposures to glyphosate, even during their final trimester of pregnancy, it is unlikely that they were exposed in the field on the day prior to giving birth. It is possible that these serum levels were caused by the drift of glyphosate spray, skin contact with the pesticide contaminated family member working in the fields, contamination of the home through clothing (take home exposure), or through poor storage of pesticides near the home. Alternatively, little is known about the metabolism and storage of pesticides during pregnancy and the impact on pesticide half-life. The median (range) glyphosate concentrations of maternal and umbilical cord serums in this current study were 17.5 (0.2–189.1) and 0.2 (0.2–94.9) ng/mL, respectively. The maternal serums of glyphosate at birth were significantly higher than those in cord blood serums. It is not known why maternal serum levels were higher than cord serum samples. At this time, only one study has looked at serum levels of pesticides in pregnant and non-pregnant Canadian women who were not agriculturists or living with a spouse who worked with pesticides. They found no detectable levels of glyphosate in the pregnant women before birth or in their cord blood samples. However, 5% (2/39) of the non-pregnant women in that study had measurable glyphosate serum levels (including one with a level of 93.6 ng/mL). Potential exposures in that study were assumed to be through consumption of pesticides associated with genetically modified foods. In our study, we found measurable glyphosate levels (>LOD) in 14.7% of the maternal serum samples of women who were not agriculturists/farmers by occupation. This is concerning, because researchers studied the effect of glyphosate exposures on the risk of miscarriage among women living on farms in Ontario, Canada, and found that women who were exposed to glyphosate before conception (from 3 months before up to conception) had a higher risk of spontaneous abortion.

Conclusion

This study suggests that agricultural activities do increase maternal serum levels of glyphosate even in

samples taken on the day of birth. In the case of glyphosate, living near farmland where pesticides are sprayed can also significantly increase the risk of serum levels >LOD at birth. These results suggest that a study evaluating the long-term health of children exposed to herbicides during gestation should be considered. Given that herbicides make up the largest volume of pesticide imports in Thailand, and that imports continue to increase, further regulation of the sale and use of pesticides may help safeguard the health of Thai children.

3. Assessment and conclusion

Assessment and conclusion by applicant:

This study suggests that agricultural activities increase maternal serum levels of glyphosate, even in samples taken on the day of birth. Living near farmland where pesticides are sprayed can also significantly increase the risk of serum levels >LOD at birth. Limitations of this study include a small sample size (N=82) and large percentages of maternal samples cord serum that were at or below the LOD for glyphosate (46.3% and 50.7%, respectively).

This publication is considered relevant to the risk assessment of glyphosate but reliable with restrictions because the analytical method used for glyphosate could have been described in more detail.

2. Full summary of the study according to OECD format

It was sought to determine whether glyphosate and its metabolite aminomethylphosphonic acid (AMPA) could be detected in milk and urine produced by lactating women and, if so, to quantify typical consumption by breastfed infants. Milk (n = 41) and urine (n = 40) samples from healthy lactating women living in and around Moscow, Idaho and Pullman, Washington was collected. Milk and urine samples were analysed for glyphosate and AMPA with the use of highly sensitive liquid chromatography–tandem mass spectrometry methods validated for and optimized to each sample matrix. The milk assay, which was sensitive down to 1 µg/L for both analytes, detected neither glyphosate nor AMPA in any milk sample. Mean ± SD glyphosate and AMPA concentrations in urine were 0.28 ± 0.38 and 0.30 ± 0.33 mg/L, respectively. Because of the complex nature of milk matrixes, these samples required more dilution before analysis than did urine, thus decreasing the sensitivity of the assay in milk compared with urine. No difference was found in urine glyphosate and AMPA concentrations between subjects consuming organic compared with conventionally grown foods or between women living on or near a farm/ranch and those living in an urban or suburban non-farming area.

Materials and Methods

Human subjects – A total of 41 healthy lactating women living in and around Pullman, Washington, and Moscow, Idaho, were included in the study. To be eligible for participation, women had to be 1–3 months postpartum, breastfeeding and/or pumping milk 5 times/day and more, and aged 18 years and older. All but 1 subject also completed a 5-question survey documenting potential glyphosate exposure from the environment and diet.

Milk and urine collection and preservation - After cleaning the breast, approx. 30 mL milk was collected with an hospital-grade electric breast pump into a single-use sterile collection container. A midstream urine sample was also collected into a single-use sterile collection container. The sample containers were immediately placed in ice, separated into aliquots and frozen at -20^{0}C pending analysis. One subject failed to provide a urine sample.

Glyphosate and AMPA analyses - Milk and urine samples were analysed for glyphosate and AMPA using liquid chromatography-tandem mass spectrometry in the multiple reaction monitoring mode. Two precursor product ion transitions for each analyte and a stable isotope labelled internal standard for each analyte were used to ensure the selectivity of the analytical method. Although 2 quantitative precursor-product ion transitions were monitored, the results were reported using the most sensitive transition for each analyte. The assay was validated separately for milk and urine. Limits of detection (LOD) and quantification (LOQ) for glyphosate in milk were 1.0 and 10.0 µg/L, respectively. The LOD and LOQ for glyphosate in urine were 0.02 and 0.10 µg/L, respectively. The LOD and LOQ for AMPA in milk were 1.0 and 10.0 µg/L, respectively and those for AMPA in urine were 0.03 and 0.10 µg/L, respectively. Glyphosate and AMPA concentrations in milk were independently confirmed by another laboratory using the same liquid chromatography-tandem mass spectrometry method with minor modifications. Because of differences in instrumentation, the LODs with the more sensitive quantitative ion transitions were 6.0 and 9.0 µg/L for glyphosate and AMPA in human milk, respectively. The LOQ for human milk was 25.0 µg/L for both analytes. Duplicate aliquots from each milk sample were sent to each laboratory separately.

Statistical analyses - For glyphosate and AMPA concentrations in urine a generalized linear mixed model was used assuming a Poisson distribution with a logarithmic link function. For concentrations less than the respective LOD values, one-half LOD (0.01 and 0.015 µg/L for glyphosate and AMPA, respectively) nominal values were used for assessment. For concentrations between the LOD and LOQ, one-half LOQ (0.05 µg/L for both glyphosate and AMPA) nominal values were used for assessment. All values are presented as means ± SDs.

Results

Description of study population and glyphosate exposure - Women were aged 29 ± 5 years, 67 ± 17 days postpartum, and had a BMI (kg/m^2) of 26.8 ± 8.6. 75% of them lived in an urban or suburban non-farming region of the Palouse, and 58% of them reported that they made no effort to eat foods characterized as organic, although they sometimes included them in their diets for convenience. 15% reported ever having personally mixed or used any type of weed killer. All but one of the women having reported ever doing so had mixed or used a weed killer containing glyphosate.

Glyphosate and AMPA concentrations in milk - Regardless of where the samples were analysed, none of the milk samples contained detectable amounts of either glyphosate or AMPA.

Glyphosate and AMPA concentrations in urine - Glyphosate was detectable in nearly all (n =37) of the urine samples and was quantifiable in 29 of them. Glyphosate values ranged from below the LOD (<0.02 µg/L) to 1.93 µg/L, with a mean concentration of 0.28 ± 0.38 µg/L. AMPA was also detectable in nearly all (n = 38) of the urine samples and quantifiable in 29 of them. Urine AMPA values ranged from below the LOD (<0.03 mg/L) to 1.33 µg/L, with a mean concentration of 0.30 ± 0.33 µg/L. There were no statistically significant effects of consuming organic compared with conventional foods or living on/near a farm compared with living in an urban/suburban region on concentrations of glyphosate in urine, respectively. Neither were there statistically significant effects of consuming organic compared with conventional foods or living on/near a farm compared with living in an urban/suburban region on concentrations of AMPA in urine. Adjusting for potential covariates (age, time postpartum, BMI, parity) did not alter these conclusions. When raw, untransformed values were used in the analysis, there was a statistically significant positive correlation between urinary glyphosate and AMPA concentrations.

Discussion and Conclusion

The results provide evidence that the concentrations of glyphosate and AMPA in milk produced by healthy women are below the detection limits of available validated analytical assays. In urine, glyphosate and AMPA were detectable in many samples, but the concentrations were very low (<0.02 to 1.93 and <0.03 to 1.33 µg/L, respectively) and well below values reported in other healthy adult populations. The RfD for glyphosate is 1.75 mg/kg bw/day. US EPA considers AMPA to be of similar or lesser toxicity than

glyphosate and determined that it should be exempt from regulation regardless of concentrations observed in food or feed. Thus, a woman with a typical weight for the study participants, 75 kg, could consume as much as 131.25 mg glyphosate/day with no expected negative effects. Taking an oral bioavailablity of 20% into account and assuming that all glyphosate absorbed is excreted within 24 hours and all absorbed glyphosate is excreted in urine, the urinary output would be 26,250 µg/day. In the current study, the highest reported glyphosate concentration in urine was 1.93 µg/L. As such, even allowing for a relatively high urine output (3 L/day), the highest glyphosate excretion in our study would be 5.79 µg/day, a value which is more than 4,500 times lower. Applying similar parameters and logic to a 5-kg infant with a mean milk intake of 0.7 L/day and a milk glyphosate concentration of 1 µg/L (the LOD value), then the maximum daily consumption of glyphosate would be 0.7 µg/day which is more than 12,000 times lower than the RfD. It is important to emphasize that the larger international study from which these samples originate was not designed to detect small differences in urine glyphosate and AMPA concentrations based on dietary choices, location of residence (e.g., urban compared with rural), or occupational glyphosate exposure. Detecting small-effect sizes at statistically significant concentrations and adequate statistical power would require 4–5 times as many observations than used in this study.

3. Assessment and conclusion

Assessment and conclusion by applicant:

In this study breast milk and urine samples from lactating women were analysed for glyphosate and AMPA. The results provide evidence that the concentrations of glyphosate and AMPA in milk produced by healthy women are below the detection limits of available validated analytical assays. In urine, glyphosate and AMPA were detectable in many samples, but the concentrations were very low and well below the values reported in other healthy adult populations.

This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions because it complies with all the reliability criteria of an exposure study.

2. Full summary of the study according to OECD format

The objective of this study was to measure the concentration and prevalence of pesticides in a cross-sectional study involving children and adolescents under 15 years of age in two small farming communities located in in State of Jalisco in Mexico, with both communities having very similar characteristics.

Urine samples (first-morning urine) were taken from children under 15 years of age in Agua Caliente located near the largest lake in Mexico (n = 192) and in Ahuacapán located in the south coast of the state (n = 89). A total of 281 urine samples obtained in both communities and processed for the determination of pesticides with high-performance liquid chromatography together with tandem mass spectrometry.
In 100% of the samples, at least two pesticides of the 17 reported in the total samples were detected. The presence of glyphosate was detected in more than 70% of the cases. The mean urinary level of glyphosate 0.363 ± 0.3210 ng/mL in Agua Caliente and 0.606 ± 0.5435 ng/mL in Ahuacapán, detected in 72.91% and

100% of their respective total samples. Substantial differences were detected regarding the other compounds.

Materials and methods

A cross-sectional study was carried out simultaneously in two communities in State of Jalisco, which is one of the three states in Mexico with the greatest index of people poisoned due to the application of pesticides. The first of these was, Agua Caliente, near Lake Chapala, the largest lake in Mexico, and the second was a community in the region of the south coast of the state (Ahuacapán).

Beginning hundreds of years ago, multiple autochthonous communities of people of Nahua native origin who were dedicated to fishing and agriculture settled on the bank of Lake Chapala. Since 2016, the Department of Public Health of the University of Guadalajara has carried out studies in the zone, specifically in the community of Agua Caliente, Poncitlán Municipality, State of Jalisco. In this community, health problems have been detected such as malnutrition and albuminuria, specifically in children and adolescents under the age of 17 years.

The community is inhabited by 998 persons, whose main activities are farming (37.9%), construction work (29.3%), and laboring 7.2% and who alternate with fishing as a means of subsistence. The most common local crops are corn, seasonal beans, and chayote (*Sechium edule*), which the inhabitants irrigate with lake water. The weekly average family income is approximately 52.63 USD.

The community of Ahuacapán is found toward the coast of the Pacific Ocean, in a 180 km straight line from Agua Caliente. A total of 950 inhabitants live there and their principal economic activity is agriculture, producing sugar cane, corn, tomatoes, citrus, and horticultural products. The water necessary for agriculture derives from springs, deep wells, and the Ayuquila River. The weekly family income in this community is approximately 75 USD. In both localities, there is a total of 550 children and adolescents (58%) aged between less than 1 year and 15 years.

For the urine sampling, communities were invited to participate voluntarily, with the approval of the Department of Public Health of the University of Guadalajara and the local authorities of the two communities. The sample included only children and adolescents aged under 17 years in Agua Caliente and those under 12 years of age in Ahuacapán. Their parents were informed concerning the objective of the study and, after obtaining the parents' signed consent, the minors were asked for a urine sample (first-morning urine). In both communities, anthropometric measurements (weight and height) were performed on the minors.

Urine samples were transported to the laboratory and were processed for the determination of pesticides with the HPLC/MS/MS (high-performance liquid chromatography coupled with tandem mass spectrometry) method with Agilent Technologies® Model 1200 equipment for HPLC and Model 6430B for MS/MS spectrometry. The method for HPLC used a column Zorbax Eclipse XDB C18, Rapid Resolution, 2.1 × 50 mm, 3.5 µm. Mobile phases: A, 0.1% formic acid in water; B, acetonitrile (ACN); gradient of 40% to 100% B; injection volume, 5 µL; flow, 0.5 min; curve range for each pesticide, 0.01 to 1000 µg/mL. The latter was performed at the Laboratory of Applied Pharmacokinetics of the University Center of Exact and Engineering Sciences of the University of Guadalajara. With this method, it was possible to determine the presence of 16 pesticides, as presented in Table 1.

Table 1. Category of pesticides analysed in urine samples from the two communities.

Name	IUPAC ID	PubChem CID	Agrochemical Category
Acetochlor	2-chloro-N-(ethoxymethyl)-N-(2-ethyl-6-methylphenyl)acetamide	1988	Herbicide
Atrazine	6-chloro-4-N-ethyl-2-N-propan-2-yl-1,3,5-triazine-2,4-diamine	2256	Herbicide
Carbendazim	methyl N-(1H-benzimidazol-2-yl)carbamate	25429	Fungicide
Carbofuran	(2,2-dimethyl-3H-1-benzofuran-7-yl) N-methylcarbamate	2566	Insecticide, Nematicide, Acaricide
Cyhalothrin	[cyano-(3-phenoxyphenyl)methyl] 3-[(Z)-2-chloro-3,3,3-trifluoroprop-1-enyl]-2,2-dimethylcyclopropane-1-carboxylate	5281873	Insecticide
Diazinon	*O,O*-Diethyl O-[4-methyl-6-(propan-2-yl) pyrimidin-2-yl] phosphorothioate	3017	Insecticide, Acaricide
Dimethoate	2-dimethoxyphosphinothioylsulfanyl-N-methylacetamide	3082	Insecticide, Acaricide
Emamectin	4″-Deoxy-4″-epi-methylamino-avermectin B1; Epi-methylamino-4″-deoxy-avermectin	11549937	Insecticide
Enilconazole (imazalil)	1-[2-(2,4-dichlorophenyl)-2-prop-2-enoxyethyl]imidazole	37175	Fungicide
Glyphosate	2-(phosphonomethylamino)acetic acid	3496	Herbicide
Malathion	diethyl 2-dimethoxyphosphinothioylsulfanylbutanedioate	4004	Insecticide, Acaricide
Methomyl	methyl (1E)-N-(methylcarbamoyloxy)ethanimidothioate	5355758	Insecticide
Metoxuron	3-(3-chloro-4-methoxyphenyl)-1,1-dimethylurea	29863	Herbicide
Molinate	S-ethyl azepane-1-carbothioate	16653	Herbicide
Pyraclostrobin	Methyl N-[2-[[1-(4-chlorophenyl) pyrazol-3-yl]oxymethyl]phenyl]-N-methoxycarbamate	6422843	Fungicide, plant growth regulator
Thiabendazole	4-(1H-benzimidazol-2-yl)-1,3-thiazole	5430	Fungicide

Conditions for MS/MS spectrometry are described in Table 2 and Figure 1 shows a chromatogram urine sample.

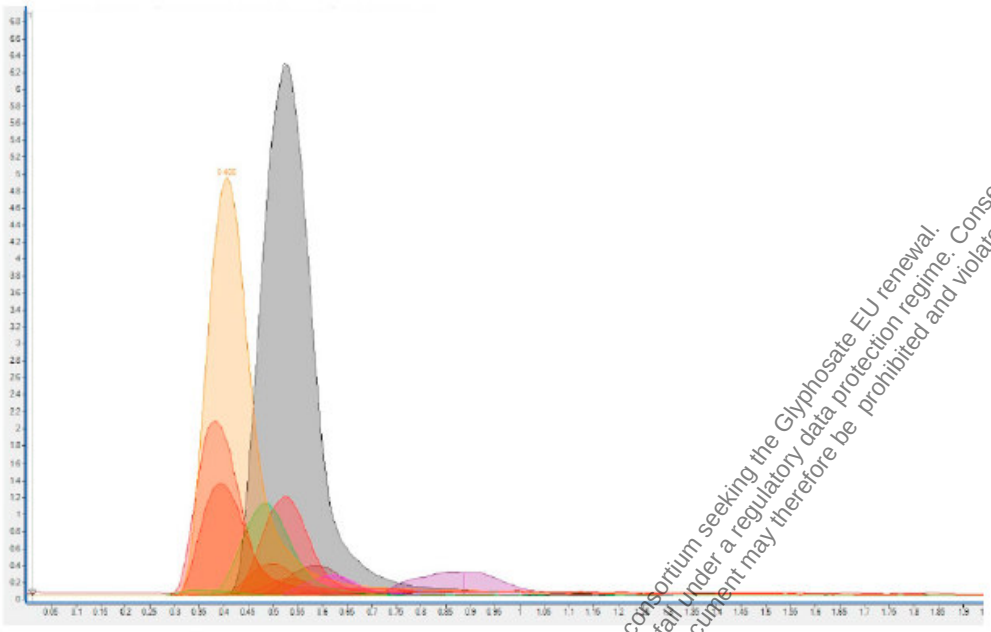
Figure 1. Shows a chromatogram of a urine sample.



Statistical analysis

For the statistical description, absolute frequencies, percentages, means, and standard deviations (SD) were used. Statistical significance was evaluated by means of the Mann–Whitney U, the Chi-squared, and the Fisher exact tests. To compare the two populations and evaluate the differences in the urine pesticide levels, the Mann–Whitney U test was used. Similarly, to compare the frequency of detection rate, the Fisher test was used. Statistical significance was considered with a p of ≤ 0.05. For data processing, Excel® (Microsoft, Redmond, WA, USA) and Epi Info ver. 7.2 (Centers for Disease Control and Prevention (CDC) Atlanta, GA, USA) statistical software were used.

This research was carried out with the authorization of the ethics committee of the Department of Public Health of the University of Guadalajara (registration number DCSP/CEI/2016/260618/038).

Results

A total of 281 children participated, of whom 192 (68.3%) corresponded to the community of Agua Caliente with an average age of 9.4 years (range, 5–15 years). In the community of Ahuacapán, 89 (31.7%) samples were collected, with an average age of 8.31 years (range, 5–13 years; Table 3).

Table 3. Demographic and anthropometric data of the children in both communities.

Variable	Agua Caliente (n = 192)	Ahuacapán (n = 89)
Gender		
Female	84 (43.8%)	40 (44.9%)
Male	108 (56.3%)	49 (55.1%)
Age (years)	9.40 (SD 2.52)	9.31 (SD 2.05)
Age groups		
5–8 y	78 (40.6%)	49 (55.1%)
9–11 y	67 (34.9%)	34 (38.21%)
12–15 y	47 (24.5%)	6 (6.7%)
Weight (kilograms)	29.39 (SD 10.06)	32.27 (SD 11.73)
Height (centimeters)	131.58 (SD 14.12)	132.94 (SD12.97)
Body mass index (k/m^2)	16.46 (SD 2.44)	17.72 (SD 3.66)

Detection of the pesticides was frequent in both communities. Substantial differences in exposure and detection rate were also identified (Table 4). Glyphosate was detected with a higher frequency in Ahuacapán than in Agua Caliente, which presented in 100% of the minors studied in Ahuacapán vs. 73% in Agua Caliente ($p > 0.001$), with minimal values of 0.0020 ng/mL and maximal values of 2.63 ng/mL. Glyphosate is currently one of the most utilised herbicides in Mexico. The differences between the two localities were considered to be associated with the agro-industrial activity and the practices that have become generalised among the small producers of basic crops.

In general terms, 100% of the study subjects were exposed to at least two of the compounds identified in urine. Positive results are noteworthy of six of the compounds in more than 70% of the subjects studied in both communities: malathion, metoxuron, glyphosate, dimethoate, enilconazole, and acetochlor. The greatest prevalence was for the herbicides (60.49%), in second place, fungicides (39.05%), and lastly, the insecticides (20.92%).

The urinary samples in this study was collected during winter, during which there is a significant diminution in the agricultural use of pesticides. However, the authors emphasised that consumption of a conventional diet with seasonal products could play a very important role regarding the presence of these pesticides in urine.

Table 4. Frequencies, percentages, means, and standard deviations (SD) of pesticides in urine.

Pesticide	Agua Caliente	Ahuacapán	
	n (%)	*n* (%)	*p* (Fisher Test)
	Mean ng/mL (SD)	Mean ng/mL (SD)	*p* (Mann–Whitney)

Conclusion

In a comparative cross-sectional study in two agricultural communities with very similar characteristics in Mexico (a total of 281 children participated in the study), glyphosate was detected in more than 70% of the cases in both communities, having a higher prevalence rate along with malathion, metoxuron, compared to other pesticides analysed in the study. The mean urinary levels of glyphosate were 0.363 ± 0.3210 ng/mL in Agua Caliente and 0.606 ± 0.5435 ng/mL in Ahuacapán. In general, substantial differences in exposure and detection rate were also identified between the communities.

3. Assessment and conclusion

Assessment and conclusion by applicant:

In a comparative cross-sectional study using the urine of children living in two agricultural communities with very similar characteristics in Mexico (a total of 281 children participated in the study), glyphosate was detected in more than 70% of the cases in both communities. The mean urinary levels of glyphosate were 0.363 ± 0.3210 ng/mL in Agua Caliente and 0.606 ± 0.5435 ng/mL in Ahuacapán.

2. Full summary of the study according to OECD format

This study describes the validation and application of two independent analytical methods for the determination of glyphosate in breast milk. They are based on liquid chromatography − tandem mass spectrometry (LC-MS/MS) and gas chromatography − tandem mass spectrometry (GC-MS/MS), respectively. For LC-MS/MS, sample preparation involved an ultra filtration followed by chromatography on an anion exchange column. The analysis by GC-MS/MS involved an extraction step, clean-up on a cation exchange column, and derivatization with heptafluorobutanol and trifluoroacetic acid anhydride. Both methods were newly developed for breast milk and are able to quantify glyphosate residues at concentrations as low as 1 ng/mL. The methods were applied to quantify glyphosate levels in 114 breast milk samples, which had been collected from August to September of 2015 in Germany. The mothers participated at their own request and thus do not form a representative sample. In none of the investigated samples were glyphosate residues above the limit of detection found.

Materials and Methods

Chemicals – Glyphosate standard solution (10 µg/mL), reference glyphosate and internal standard ($^{13}C_2{}^{15}N$ labeled glyphosate) were purchased from LGC Standards, Wesel, Germany and from Dr. Ehrenstorfer, Augsburg, Germany.

Collection of breast milk samples - Breast milk samples were collected in August and September 2015 by the Governmental Institute of Public Health of Lower Saxony, Germany and by the Bavarian Authority for Health and Food Safety Germany for the analysis of glyphosate. All participants signed a declaration of consent concerning the use of their samples for scientific purposes. Participating mothers had not been selected by random sampling and thus do not form a representative sample. There were no restrictions relating to, for example, age and point of sampling during the lactation period for participating in the monitoring program. The milk samples for this study were collected and stored in polypropylene tubes which remained frozen during storage and shipment. In total, 114 milk samples were analysed and the participants completed a self-administered questionnaire. Information on sample collection, biometric data and self-reported pesticide exposure of the participants is given in Table 1.

Table 1: Biometric data of study participants

parameter	samples from Bavaria, Germany	samples from Lower Saxony, Germany
number of samples	17	97
age of mother (years)		
median	32.1	32.0
range	26–39	22–39
body weight of mother (kg)		
median	63.0	67.0
range	54–90	48–102
duration of lactating period (weeks)		
median	11.0	18
range	3–80	4–52
self-reported exposure to pesticides	6 participants	32 participants

The questionnaire also asked for the place of residence and the jobs practiced in the last 10 years. Thirty-eight participants declared the use of chemical insecticides, herbicides or wood preservatives. At least one participant has worked in a residue analytical laboratory and used pesticide standards regularly. Twenty of the 114 breast milk samples were divided each into two subsamples to allow the parallel analysis by LC-MS/MS and GC-MS/MS.

Fortification of breast milk samples for performance tests - A homogeneous sample of breast milk was prepared and spiked with different volumes of a glyphosate standard solution in water at 10 µg/mL. Twenty-eight stored breast milk samples from a previous study of the Governmental Institute of Public Health of Lower Saxony were pooled and 4 aliquots of 100 mL were spiked with glyphosate resulting in concentrations of 0.5, 1, 3, and 5 ng/mL. An additional aliquot of the pooled sample served as the control. All performance samples were divided into two subsamples and analysed in parallel with LC-MS/MS and GC-MS/MS. These samples served as independent quality control samples.

Sample Preparation for LC-MS/MS analysis - Removal of fat by centrifugation and removal of proteins by ultra-filtration in one step through centrifugal filtration using a molecular weight cutoff filter of 30 kDa was found to be suitable. To 3 mL of sample, 30 µL of internal standard solution containing 1000 ng $^{13}C_2{}^{15}N$ glyphosate/mL was added to obtain a concentration of 10 ng/mL. After mixing, the sample was transferred to the top part of the cutoff filter tube. The filter was centrifuged at 3500 rpm for 20 minutes and 500 µL of the filtrate was then transferred to the LC filter vial, the solution was filtered and the vial used for measurement. After this procedure, one mL of final extract contained the glyphosate residue of one mL breast milk.

LC-MS/MS analysis – The LC-MS/MS system used consisted of a Nexera UHPLC system from Shimadzu equipped with a 5500 Qtrap system (Sciex) in triple-quad mode. The LC system consisted of an anion exchange LC column (Dionex Ionpac AS 11 (2 × 250 mm) and a AG-11 guard column (2 × 50 mm) from Thermo Fischer Scientific). Twenty-five µL of standard solution or filtrate were injected into the LC system and glyphosate was eluted from the column using a gradient of water (A) and 1 mM citric acid solution brought to a pH of 11 by addition of a dimethyl amine solution (B). Gradient elution consisted of following steps: 100% A from 0 to 2 minutes, linear to 25% B in 5.5 minutes, and linear to 50% B in 2.5 minutes which was held for 4 minutes. After returning to 100% A in 0.5 minutes the system was re-equilibrated for 7.5 minutes before the next injection. The total run time (including injection) was 22.5 minutes with a flow rate of 0.4 mL/min. A column temperature of 40°C was maintained while the temperature of the samples in the autosampler was 12°C. All transitions were measured using a declustering potential of -75 V, an entrance potential of -10 V and a dwell time of 50 ms. The Turbospray source was used in negative

electrospray mode using the following parameters: Curtain gas 20 arbitrary units, collision gas medium, ion spray - 4000 V, temperature 400 °C, ion spray gas 1: 40 and ion spray gas 2: 50 arbitrary units. The mass transitions for evaluation [m/z] were 168.2 → 62.8 for quantification, 168.2 → 79.0 for confirmation and, 171.2 → 62.8 for $^{13}C_2$ ^{15}N glyphosate.

Sample Preparation for GC-MS/MS analysis - A 2 mL milk sample was extracted with 3.75 mL of 0.6% acetic acid and centrifuged for 5 minutes at 4000 rpm. Two mL of the supernatant liquid was extracted with 2 mL dichloromethane for 2 minutes and the two phases separated by centrifugation at 4000 rpm for 5 minutes. One mL of the supernatant liquid was filtered using a 0.45 µm Nylon filter and a cation exchange clean-up was performed using disposable Bio-Rad Poly-Prep columns filled with 1.72 g (equivalent to 2 mL filling volume) of AG 50W-X8 resin (H^+-form). A 0.55 mL aliquot of the filtered extract (corresponding to 0.2 mL breast milk) and 0.100 mL of internal standard solution (20 ng/mL) were added onto the cation exchange column and were eluted followed by 2.0 mL of CAX solution (800 mL HPLC grade water, 13.5 mL 10 N HCl solution and 200 mL methanol). Both eluates were discarded. Glyphosate residues were eluted from the column with 12.5 mL of CAX solution and evaporated to dryness. The residues were dissolved in 1.0 mL of CAX solution. Derivatization reagent (2,2,3,3,4,4,4-hepta fluoro-1-butanol and trifluoroacetic acid anhydride 1:1) was cooled to a temperature of - 20°C. 0.05 mL of the dissolved eluate (corresponding to 0.01 mL breast milk) was added to 1.5 mL of the chilled reagent and after 5 minutes derivatization is started by heating to 92-97°C for 1 hour. After cooling, the excess of derivatization reagent was removed by evaporation. The dry residue was dissolved in 0.2 mL of ethyl acetate containing 0.2 mL/L citral and then concentrated to a final volume of 20 µL. Citral was used to prevent adsorption of the analytes in the inlet and the GC column. Following this procedure, one mL of final extract contained the glyphosate residue of 0.5 mL breast milk.

GC-MS/MS analysis - The GC-MS/MS system consisted of a Thermo Trace GC Ultra equipped with a TriPlus liquid autosampler, split/splitless injector and MS detector TSQ Quantum with triple quadrupole (Thermo Fisher Scientific). The GC column was a Optima 5HT of 30 m length and 0.25 mm internal diameter coated with a 0.25 µm film (Macherey-Nagel). Four µL of the extracts were injected splitless with the injector temperature at 280 °C. The oven temperature was held at 80°C for 1.5 minutes, ramped up at 10 °C/minute to 180 °C, then ramped up at 30°C/minute to 300 °C and held at 300 °C for 2.8 minutes. The carrier gas was helium and the flow rate 1 mL/minute. The expected retention time for the glyphosate derivative was 9.1 minutes. The temperature of the ion source was 280 °C and the electron impact (EI) energy was 70 eV with an emission current of 50 µA. Mass transition for evaluation [m/z] was 612 → 213 for quantification, 611 → 261 for confirmation, and 615 → 213 for $^{13}C_2$ ^{15}N glyphosate. Calculations were performed using the ratio of the peak areas of the quantifier transition of glyphosate derivative and the internal standard derivative. Calibration solutions were prepared by volumetric dilution of a glyphosate stock solution in a solution containing 20 ng/mL internal standard. The dilutions were made in CAX solution. Aliquots of 0.05 mL of these calibration solutions were derivatized as described for the breast milk extracts. The concentration of the derivatized calibration solutions ranged from 0.01 to 10 ng/mL. The concentration of the internal standard in the final extract was always 5 ng/mL.

Results and Discussion

Since a very low transfer was observed of glyphosate into muscle, milk and fat in farm animal metabolism studies the LOQ should be as low as possible. The LC-MS/MS method was validated for glyphosate in accordance with the requirements of the EU guidance document for quality control and validation procedure. Recovery and precision of glyphosate were determined for 6 or 7 replicates at two fortification levels. The linearity of the system was tested by injecting 8 standards in water in a concentration range from 0 to 50 ng/mL. A linear relationship between concentration and the ratio of the peak area of glyphosate and its internal standard was observed with a coefficient of determination greater than 0.99. All calibration points were within 20% of the theoretical value. Quantification was performed using single-point calibration which is acceptable if the response of the analyte in the samples is close to the response in the standard. The average recovery of the LC-MS/MS method was 99% at 1 ng/mL and 91% at 5 ng/mL with a relative standard deviation of 16% and 7%, respectively. The LOQ of the LC-MS/MS method of 1 ng/mL

demonstrated sufficient recovery and precision. Possible matrix effects were corrected using the stable isotope labeled internal standard $^{13}C_2{}^{15}N$ glyphosate. At a concentration of 0.5 ng/mL, a signal-to-noise ratio of approximately 4 was obtained. This concentration is considered the LOD of the LC-MS/MS method.

For the analysis of glyphosate by GC-MS/MS, extraction with acidified water was combined with clean-up on a cation exchange column to remove interfering substances present in breast milk. To enable analysis by gas chromatography glyphosate was derivatized using heptafluoro-1-butanol and trifluoroacetic acid anhydride. Calibration was performed with freshly prepared derivatives of 8 glyphosate standard solutions in the concentration range from 0.01 to 10 ng/mL. All standard solutions contained the internal standard at 5 ng/mL and the coefficient of determination was always equal to or greater than 0.9980. The average recovery of the GC-MS/MS method was 84% at 1 ng/mL and 83% at 10 ng/mL with a relative standard deviation of 13% and 8%, respectively. All results obtained by GC-MS/MS had to be corrected for (derivatization reagent) blank interferences. A set of at least 4 reagent blanks were analysed within each set of breast milk samples. The average measured blank values ranged from 0.2 to 0.6 ng/mL. The relative standard deviations of blank values in the sample sets ranged from 19% to 33%. Considering the blank values from the derivatization reagent, the LOQ of the GC-MS/MS method was 1 ng/mL. Notwithstanding the interference problem of the GC-MS/MS method, both analytical methods were able to measure glyphosate residues in breast milk with an LOQ of 1 ng/mL.

In total, 114 different breast milk samples were analysed for glyphosate. Seventy-five samples were analysed by LC-MS/MS only. Because of the lower performance, only 19 samples were analysed exclusively by GC-MS/MS. Twenty milk samples were analysed by both methods. In addition to the 114 samples, 5 samples for performance testing were analysed by both LC-MS/MS and GC-MS/MS, 4 breast milk samples which were spiked in advance with glyphosate and one control sample. Glyphosate was identified by LC-MS/MS in all samples spiked with glyphosate. The recoveries for the LC-MS/MS method were 110%, 97% and 102% for the spiking levels of 1, 3, and 5 ng/mL, respectively. In the sample spiked at 0.5 ng/mL, glyphosate could still be detected by the LC-MS/MS method. Due to the interference problem in GC-MS/MS method, no clear detection of glyphosate was possible at this level.
The recoveries for the GC-MS/MS method were 70%, 70%, and 54% for the spiking levels of 1, 3, and 5 ng/mL, respectively. Generally, the GC-MS/MS method tended to result in lower concentrations, probably due to the correction for derivatization reagent blank values. The higher bias of the GC-MS/MS method might be due to dilution steps using very small volumes. The concentration step to yield the final volume might have resulted in a partial loss of the glyphosate derivative. Nevertheless, both methods are able to quantify glyphosate residues in breast milk at or above a concentration of 1 ng/mL. Because of the lack of significant blank values in the LC-MS/MS method, residues of glyphosate higher than 0.5 ng/mL are still detectable by this method. In none of the 114 breast milk samples obtained from German women glyphosate was detected.

Conclusion

A LC-MS/MS and a GC-MS/MS method were developed for the detection and quantification of glyphosate in human breast milk. Both methods have been fully validated and are suitable for the determination of glyphosate with an LOQ of 1 ng/mL. The LC-MS/MS method allows the detection of glyphosate at or above a level of 0.5 ng/mL. The LC-MS/MS method is much faster than the GC-MS/MS method, thus making it suitable for higher sample throughput. The positive findings of glyphosate in breast milk of American women could not be confirmed by the results of this study. In none of the 114 breast milk samples collected from German women in August and September 2015 glyphosate was found within the detection limitations of the analytical methods. Available data from farm animal studies on glyphosate with non-labeled material support these results. They provide no indication of a significant carry-over into fatty tissues or milk even at high dosing levels.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Two analytical methods were developed for the determination of glyphosate in human breast milk. In the first method fat was removed by centrifugation and the proteins by ultra-filtration using a molecular weight cutoff filter of 30 kDa. The final extract was then analysed by LC-MS/MS. In the second method the milk sample was acidified with acetic acid, centrifuged and the supernatant extracted with dichloromethane. The aqueous phase was filtered and cleaned-up using a cation exchange resin. The final extract was then analysed by GC-MS/MS after derivatization with heptafluoro-1-butanol and trifluoroacetic acid anhydride. $^{13}C_2{}^{15}N$ glyphosate was used as the internal standard in both methods. Both analytical methods were validated according to the EU guidance document on analytical quality control and validation procedures for pesticide residues in food and feed (SANCO/12571/2013) and were found suitable for the determination of glyphosate in human breast milk with an LOQ of 1 ng/mL. In August and September 2015, 114 breast milk samples were collected from German women and were analysed for glyphosate. In none of the samples analysed glyphosate concentrations were found at or beyond the LOQ.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the breast milk samples analysed were collected on a voluntary basis and there were no restrictions for participating in the monitoring program. As a consequence the samples cannot be considered representative of the German population. Both analytical methods developed were validated in accordance with the EU guidance on the procedures for the analysis of pesticide residues in food and feed.

Assessment and conclusion by RMS:

Guidelines followed in study	None
Deviations from current test guideline	Not applicable
Previous evaluation	None
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Yes/Reliable without restriction

2. Full summary of the study according to OECD format

The goal of this study was to assess biomarkers of exposure to glyphosate and assess potential associations with renal function in children. While previous studies have indicated that glyphosate may have nephrotoxic effects, few have examined potential effects on kidney function in children. In this study, three cohorts across different phases of child development and measured urinary levels of glyphosate. Associations of glyphosate with three biomarkers of kidney injury was evaluated: albuminuria (ACR), neutrophil gelatinase-associated lipocalin (NGAL), and kidney injury marker 1 (KIM-1). Multivariable regression analyses examined associations of glyphosate with kidney injury biomarkers controlling for covariates. Glyphosate was identified in 11.1% of the total participants. The herbicide was detected more frequently in the neonate population (30%). Multivariable regression models failed to identify significant associations of log-transformed glyphosate with any of the kidney injury biomarkers, controlling for covariates age, sex, and maternal education. While detectability of glyphosate in children's urine at various ages and stages of life was confirmed, there was no evidence for renal injury in children exposed to low levels of glyphosate.

Materials and methods

Study populations; We briefly describe a longitudinal birth cohort of children (Starting Early), in whom urine samples were measured at 10-19 months of age, as well as two cross-sectional studies Preventing Environmental Exposures in Pregnancy (PEEPS), and Bright Start which represent older children (ages 3-8) and newborns (<30 days), respectively. The three cohorts are comprised of chronologically ordered categories of age in children as follows: Bright Start (newborns), Starting Early, and PEEPS. Inclusion in the present study was determined if sufficient urine was available for the experimental testing. All research was performed in accordance with relevant guidelines/regulations. In particular, informed consent was obtained from participants' parents or their legal guardians for use of collected samples for use in future studies such as this one of glyphosate exposure.

Urine collection and storage; Urine samples for each cohort were obtained at study visits using age-appropriate methods (urine bags and cotton balls in untrained babies and infants, freshly voided urine in trained children) and immediately transferred to sterile polyethylene cups. Within 2 h after collection from the infants, urine was transferred to cryovials for storage at -80 °C prior to laboratory analysis. We measured urinary markers of kidney injury NGAL, and KIM1 using Luminex xMAP technology (see below). Urine albumin and creatinine were measured using standard methods of quantitative spectrophotometry at the ARUP National Reference Laboratory (Salt Lake City, Utah) and the results were used to calculate ACR (Albumin-to-Creatinine Ratio [mg:mg]).

Analysis of urine samples for glyphosate; 200 µL of urine sample was transferred into a 15 mL polypropylene (PP) tube and spiked with the labeled internal standard mixture (2-^{13}C, 99%; ^{15}N, 98+% Glyphosate), allowed to stand at room temperature for 30 min and then diluted to 1.0 mL (5-fold dilution) with 1% formic acid in water. The diluted sample was vortexed for 1 min, centrifuged and filtered through a nonsterile regenerated cellulose (RC) membrane filters (0.2 mm; Phenomenex, Inc., Torrance, CA, USA). The filtrate then transferred into an auto sampler vial for LC-MS/MS analysis. An Agilent 1260 Series HPLC system (Agilent Technologies Inc., Santa Clara, CA, USA) coupled with an ABSCIEX 4500 QTRAP mass spectrometer (Applied Biosystems, Foster City, CA, USA) running under negative mode electrospray ionization was used for the analysis. An anion-exchange column, Dionex IonPac AS 21 (2 mm x 250 mm, 7 µm) was employed for the separation of target chemicals under isocratic elution condition with a mobile phase consist of 1% formic acid in water and acetonitrile (95:5) mixture. Isotopic dilution mass spectrometry with MRM mode of analysis was used for selective quantification of the target chemicals. The QA/QC protocols included matrix spike (mean spike recoveries (n=5) for glyphosate was 109.5%) and procedural blanks (non-detected or < LOQ). Midpoint calibration standard and HPLC grade water were injected between every 20 samples analysed to check the instrument detection linearity and carry-over effects, respectively. The limit of detection (LOD) and the limit of quantification (LOQ) were calculated as three and ten times of signal to noise ratio, respectively. LOD for glyphosate was 0.1 ng/mL, and LOQ was 0.33 ng/mL.

Analysis of kidney injury biomarkers; NGAL was measured in human urine using the Luminex performance human kidney Biomarker kit (FCSTM16-01, R&D Systems). Urine samples were thawed and diluted 1:10 in calibrator diluent and protocol followed manufacturer's instructions. Data were captured on a Luminex MAGPIX instrument with xPonent 4.2 software. Standard curve R^2 values were 0.98 and high- and low-quality controls were within expected range. KIM-1 was measured in human urine using the Milliplex MAP Human Kidney Injury Magnetic Bead Panel Kit (HKI1MAG-99K, EMD Millipore). Urine samples were thawed and diluted 1:2 in assay buffer and protocol followed manufacturer's instructions. Data were captured on a Luminex MAGPIX instrument with xPonent 4.2 software. Standard curve R2 values were 0.97 and high- and low-quality controls were within the expected range.

Statistical analysis; We first described the demographics of our study population (N = 108), including age, sex, maternal education, race/ethnicity, BMI category, and intervention arm in the case of the Starting Early group. Body mass index (BMI), calculated as weight in kilograms divided by height in meters squared, was used to measure adiposity in the Starting Early group. We used standardized BMI *z* scores given that BMI varies widely by age and sex, following the Centers for Disease Control and Prevention year 2000 norms. Overweight and obese were categorized as BMI *z*-score of 1.036 or greater (85th percentile for age and sex) and 1.64 or greater (95th percentile), respectively. We calculated median glyphosate, albuminuria, KIM-1, and NGAL levels, as well as interquartile ranges for all biomarkers and percent detected for glyphosate levels by study group. We also described mean and standard deviation in each one of the mentioned biomarkers of interest in the total population. Univariate regressions examined log-transformed glyphosate concentrations and their detectability (using logistic regression) as dependent variables with covariates examined singly. We created dummy variables for maternal education with one category for those children whose mothers did not complete a high school education and another for those whose mothers at least completed high school, and created a dummy variable for missing values (N = 34) that we used as reference. We also created an ordinal variable reflecting the age of the children in increasing order from youngest to oldest type as follows: Healthy Start, Starting Early, and PEEPS (N ¼ 108). We also performed univariate analyses by study arm in the Starting Early sample (N = 66). Multivariable analyses of continuous log-transformed glyphosate exposure examined age, sex, and maternal education as predictors (N ¼ 108). We assessed differences in detectability of glyphosate using multivariable logistic regressions with age, sex, and maternal education as predictors. All regressions examining predictors of log-transformed glyphosate were retransformed from the logarithmic scale. We then examined associations of glyphosate with kidney injury. First, we calculated Pearson correlation coefficients for all log-transformed kidney injury markers KIM-1, NGAL, and ACR, as well as log-transformed glyphosate levels. For glyphosate levels below the limit of detection (LOD), we imputed values equal to LOD/square root of 2. We also performed univariate and multivariable regressions of urinary log-transformed glyphosate as predictor of log-transformed kidney injury markers KIM-1, NGAL, and ACR, controlling for age, sex and maternal education. Sensitivity analyses were also included; we performed univariate and multivariable regressions of creatinine-adjusted urinary log-transformed glyphosate as predictor of log-transformed kidney injury markers KIM-1, NGAL, and ACR. Statistical analysis was performed with Stata/IC Version 14 (StataCorp: College Station, TX).

Results

The population was largely Hispanic, and comprised roughly equal numbers of males and females (Table 1). Only 4% of our participants had a mother with a college degree but the majority of parents in our study population graduated from high school (62.1%). The mean urinary glyphosate concentration was 0.278 ± 0.228 µg/mL, with a range of 0.105-2.125 µg/mL. We identified glyphosate in 11.1% of the participants. The herbicide was detected in 7.6-30% of the three cohorts: 30% of neonates had glyphosate exposure above the LOD, followed by PEEPS cohort (12.5%) and Starting Early (7.6%). We also observed a wide detection range in NGAL biomarkers. We also noted that 40% of children in the Starting Early cohort were overweight or obese. Younger children had higher urinary levels of glyphosate in both univariate and multivariable regressions. Children with mothers without a high school diploma had slightly lower levels of urinary glyphosate relative to those with mothers who attained a high school education in our multivariable regression. However, we found no other significant associations of demographic covariates

with glyphosate in univariate or multivariable models. Similarly, we found no statistically significant associations of demographic factors in relationship to detectability of urinary glyphosate in children. No univariate regressions with urinary glyphosate identified a statistically significant association with increased renal biomarker injury (Fig. 1A-C respectively and Table 2). Multivariable regressions with urinary glyphosate failed to identify statistically significant associations of log-transformed glyphosate with KIM-1, NGAL, or ACR (Table 2). In sensitivity analyses of univariate and multivariable regressions with creatinine-adjusted log-transformed glyphosate, there was also no statistically significant evidence for increased levels of markers for renal injury (Table 2). In additional sensitivity analyses without the newborns similar results were reported with no statistically significant associations of log-transformed glyphosate with kidney injury biomarkers (Table 2).

Table 1: Study population (n=108)[a]

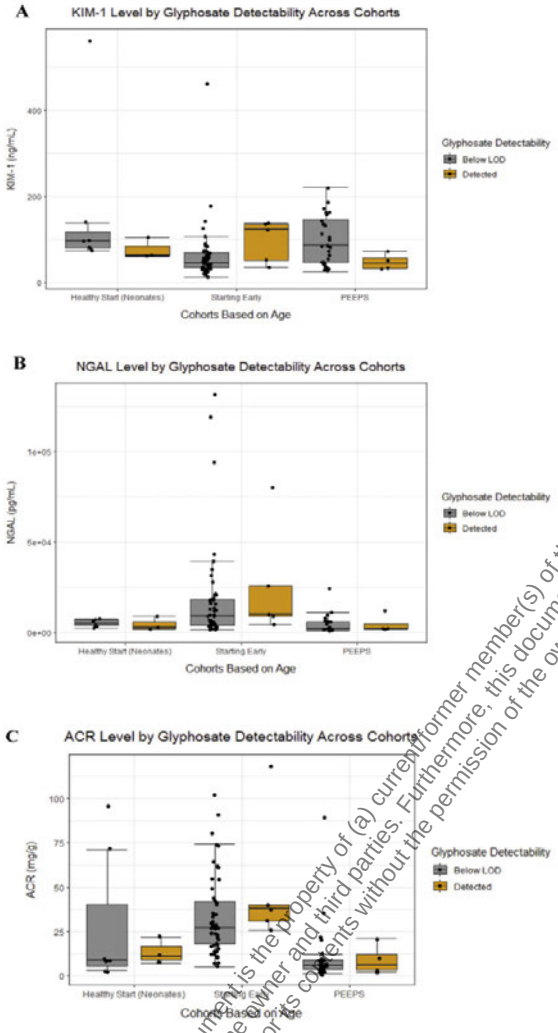
[c] KIM-1 N = 89; NGAL N = 86; ACR N = 86. Multivariable regression models controlling for demographic covariates age, sex, and maternal education, where maternal education missing observations were imputed as the majority category "Equal or Greater Than High School".
[d] Creatinine-adjusted regression models KIM-1 N = 85; NGAL N = 83; ACR N = 86.

Figure 1: A. The dot plot illustrates the urinary KIM-1 level in participants enrolled in the different studies, 1B. The dot plot illustrates the urinary NGAL level in participants enrolled in the different studies, 1C. The dot plot illustrates the urinary albumin:creatine ratio (ACR) in participants enrolled in the different studies.



Discussion

The main findings of this study are the substantial and frequent prevalence of glyphosate in children across the first decade of life in three independently assembled samples. We identified glyphosate in 11.1% of the total participants, and the herbicide was detected more frequently in the neonate population (30%). However, urinary concentrations detected in the neonates, toddlers, and young school age children was significantly lower than levels documented in adults with occupational or environmental exposure. No association of urinary glyphosate was found with any of the three renal biomarkers (KIM-1, NGAL or ACR). Urinary excretion of albumin and serum creatinine concentration are conventional biomarkers for renal dysfunction. Novel biomarkers such as urinary excretion of KIM-1 and NGAL have been developed and it has been that they have diagnostic utility for earlier detection of acute kidney injury (AKI) prior to significant loss of function. KIM-1 also predicted renal damage from acute exposures in animal studies. This study has a number of limitations.

We used maternal education as a proxy for family educational attainment or socioeconomic status (SES) which are well-known factors for different levels of chemical exposures in children or renal injury outcome. We emphasize that low sample size also limited us to perform analyses in the three cohorts in conjunction, in lieu of stratified analysis. We acknowledge that the strength of any conclusion about the frequency of detecting glyphosate in newborns is limited by the sample size. The source of the glyphosate in the newborns, which was detected more frequently than in the other groups but not at high levels, could be via lactation or infant formula. It is possible that immature or different metabolic pathways for glyphosate in neonates, kidney injury during delivery, or lactation may have affected the findings in this age group. However, the addition of neonates in our study evaluating the association of glyphosate and kidney injury biomarkers may have biased findings towards the null. Our results also suggest that glyphosate levels declined with increasing age. The differences by age may represent differences in dietary behavior and access to foods free of contamination or improved elimination of the herbicide, though further research is needed. Previous larger scale case-control studies have shown in the past changes in renal function, kidney injury, or chronic kidney disease of unknown etiology (CKDu) upon glyphosate exposure, especially of adult occupational exposures. Several strengths in this study are notable. Our study is the first to document the prevalence of glyphosate exposures in young children through age 8 years. Our frequent detection of glyphosate suggests the need for inclusion and biomonitoring of glyphosate exposures in national surveys or screenings in populations of interest, which could provide more information in regards to these exposures and outcomes. Glyphosate biomonitoring could be added into studies such as the National Health and Nutrition Examination Survey (NHANES). Our study is novel in that we examine specific renal biomarkers in relationship to glyphosate in a young population. The lack of evident renal toxicity in association with glyphosate exposure in young children does not exclude a potential adverse impact of longer term exposure to the pesticide. Problems during labor and delivery can compromise renal perfusion leading to increased excretion of tubular injury biomarkers in the neonatal period. This could interfere with the ability to detect an independent effect of glyphosate in this age group. In addition, the regenerative capacity of the renal tubular epithelium in infants and young children may mask an adverse effect of the pesticide on tubule integrity. Urinary biomarkers such as NGAL and KIM-1 have been demonstrated to be useful biomarkers of tubular injury even without reduced kidney function, highlighting their utility in detecting subclinical insults to the kidney. Further research could explore more in detail the association between glyphosate and kidney injury biomarker types across different age groups in larger cohorts, and assess whether more prolonged exposure could have progressive deleterious effects.

Conclusion

In this study, we identify frequent prevalence of levels of glyphosate (11.1%), present across all three age ranges, and particularly present in the youngest population of neonates. There is no evidence for renal injury in young children exposed to low levels of glyphosate. Further studies of larger sample size are indicated to better understand the potential deleterious effects of the herbicide after different levels, routes, and duration of exposure.

3. Assessment and conclusion

Assessment and conclusion by applicant:

This study evaluated three cohorts across different phases of child development and measured urinary levels of glyphosate. They evaluated associations of glyphosate with three biomarkers of kidney injury: ACR, NGAL, and KIM-1. Sample collection and analysis as well as statistical evaluation of data have been conducted using well described methodologies. Multivariable regression models failed to identify significant associations of log-transformed glyphosate with any of the kidney injury biomarkers, controlling for covariates age, sex, and maternal education. The authors confirm detectability of glyphosate in children's urine at various ages and stages of life, there is no evidence in this study for renal injury in children exposed to low levels of glyphosate.

This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions

because it complies with the quality criteria of a good monitoring study.

Assessment and conclusion by RMS:

Reliability criteria of exposure studies

Publication: Trasande et al., 2020.	**Criteria met? Y/N/?**	**Comments**
Guideline-specific		
Study in accordance to valid internationally accepted testing guidelines/practices.	Y	
Study performed according to GLP	N	
Study completely described and conducted following scientifically acceptable standards	Y	
Test substance		
Exposure to formulations with only glyphosate as a.s.	Y

Reference	Evaluation	Abstract
Bando, H., 2010, The Japanese journal of toxicology, (2010 Sep) Vol. 23, No. 3, pp. 246-9	This case report describes severe hyperkalemia in the setting of suicidal ingestion of potassium salt glyhoate formulations. This is not unexpected and since it describes a suicidal ingestion it should not impact re-registration	CASE REPORT: A 65-year-old female was transferred to our emergency and critical care center after taking two kinds of commercially available glyphosate herbicide products. On admission, her conscious level was depressed to Glasgow Coma Scale E3, V2, and M6. Vital signs were as follows ; blood pressure 83/33mmHg, pulse 59/min, and respiratory rate was 24/min. Arterial blood gas analysis showed metabolic acidosis and an extreme hyperkalemia of 9.22 mEq/L. Electrocardiogram showed absence of P wave and a tall, tapering T wave. On admission, gastric lavage was followed by an intragastric administration of activated charcoal together with cathartic. Immediately after recognition of hyperkalemia, sodium bicarbonate, glucose plus insulin, and calcium gluconate were also administered intravenously. Five hours later, plasma concentration of potassium decreased to 4.31 mEq/L, and the patient discharged on day 10. Later, it was disclosed that the new Roundup Maxload contains high concentration of glyphosate potassium. CONCLUSION: In case of Roundup poisoning, we have to take it consideration that the poisoning may results in a hyperkalemia.
Beswick, E. et al. (2011) Journal of the Intensive Care Society, (January 2011) Vol. 12, No. 1, pp. 37-39	This is a case report of a fatality after a formulated glyphosate suicidal overdose. Multiorgan failure is not uncommon in these overdoses. As this is a case report of a suicidal ingestion it should not impact re-registration decisions.	A 29-year-old man was admitted following deliberate ingestion of approximately 300 mL of 'Roundup Ace,' a herbicide containing glyphosate. On presentation, he was agitated and required intubation and admission to ICU. He developed severe and persistent lactic acidosis, hyperkalaemia, hypotension, torrential watery diarrhoea and abdominal distension in the first 24 hours. The patient was supported with a continuous noradrenaline infusion and continuous veno-venous haemodiafiltration. The clinical course was further complicated by cardiac arrhythmias and an episode of cardiac arrest. By day three, he had bone-marrow, liver and worsening respiratory failure. There was no hope of recovery; therefore, noradrenaline was discontinued, and the patient died 15 minutes later. Glyphosate-surfactant herbicide (GlySH) is a general-purpose herbicide with no anticholinesterase effect and no organophosphate-like CNS effects. GlySH intoxication has a case fatality rate of between 3.2% and 29.3%. There is no antidote and the mainstay of treatment for systemic toxicity is decontamination and aggressive supportive therapy. Early renal replacement therapy may improve prognosis but there is no evidence to support this. There is one published case of a patient who survived severe GlySH poisoning following administration of intravenous fat emulsion. Glyphosate-surfactant herbicide, commercially known as 'Roundup' is a widely available herbicide commonly used in both professional and domestic settings. This is a case of a young man who deliberately ingested GlySH at home and rapidly developed multi-organ failure, culminating in his death.© The Intensive Care Society 2011.
Bosak A. B. et al., 2014 Journal of Medical Toxicology (2014), Vol. 10, No. 1, pp. 72	This is a report about multi-organ failure after suicidal ingestion of formulated glyphosate and should not impact re-registration.	Background: Glyphosate is a commonly used herbicide associated with toxicity and death following large ingestions. Surfactants are implicated as the primary contributor. Hypothesis: Glyphosate herbicide preparations contain various surfactants and salts which may lead to diverse clinical toxicity. Methods: (Case 1) A 50-year-old man presented with N/V, abdominal pain, and somnolence 12 h after ingesting 6.5 oz of concentrated Roundup ® containing 50.2 %

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
		glyphosate as isopropylamine salt. Labs revealed metabolic acidosis (AG 40), lactate (9.2 mmol/L), creatinine (2.8 mg/dL), potassium (4.5 mmol/L), WBC (41.5 K/mm3), and lipase (2,528 IU/L). Electrocardiogram QRS was 142 ms and responsive to bicarbonate. Patient became hypoxic and hypotensive requiring intubation, vasopres-sors, and continuous veno-venous hemodialysis (CVVHD) for anuric renal failure. A CT scan showed multiple loops of dilated small bowel and possible pneumatosis with negative exploratory surgery on day 1. On day 5, he had peritonitis prompting the resection of the ischemic terminal ileum and cecum. Over the next 3 weeks, he developed recurrent GI bleeds unrelated to surgery, remained anuric on CVVHD, and ventilator dependent. (Case 2) A 48-year-old landscaper ingested 250- 350 mL of concentrated glyphosate herbicide and presented with AMS and N/V. Labs showed WBC (21.2 K/mm3), potassium (7.1 mmol/L), metabolic acidosis (AG 10), and creatinine of 1.2 mg/dL (0.60 baseline). Electrocardiogram QRS was 192 ms with wide complex rhythm, bradycardia, and responsive to bicarbonate. Persistent hyperkalemia continued despite medical treatment requiring high flux hemodialysis. He required ventilator support for hypoxia and had a negative EGD. Results: Case 1 developed anuric renal failure, QRS prolongation, ischemic bowel, and recurrent GI bleeds. Care was withdrawn on day 25. Case 2 had persistent hyperkalemia, non-anuric renal failure, QRS prolongation, and bradycardia. Discussion: We hypothesize that case 2 ingested a potassium salt preparation due to the persistent hyperkalemia that only resolved with hemodialysis. QRS prolongation was present in both cases responsive to bicarbonate. Conclusion: Glyphosate containing herbicides may have diverse clinical toxicity depending on surfactant and salt preparation.
Brunetti R. et al., 2019 HeartRhythm Case Rep. (2020), Vol. 6, pp. 63	This article claims that dermal exposure to a small amount of glyphosate led to cardiac arrhythmia and claims that the patient developed a Brugada syndrome & long Qt syndrome after exposure. The measured QTC in a wide-complex tracing is uninterpretable. Brugada syndrome is largely due to sodium channel block in cardiac myocytes, LQT syndrome is largely due to potassium channel block in the cardiac myoctyes. Glyphosate	Not available

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
	does neither. Moreover, glyphosate is not dermally absorbed and multiple GLP studies have shown that glyphosate is not cardiotoxic.	
Chan C-W. et al., 2016 Critical care medicine (2016), Vol. 44, No. 1, pp. E45	This paper looked at the use of ECMO in a critically ill patient after formulated glyphosate product overdose. ECMO is sometime of utility in treating overdose patients. This paper should not impact re-registration.	OBJECTIVE: To describe the experience of emergency extracorporeal membrane oxygenation in treating life-threatening glyphosate-surfactant intoxication. DESIGN: Case report. SETTING: Emergency department and ICU. PATIENT: A patient with cardiopulmonary failure after glyphosate-surfactant intoxication. INTERVENTION: Extracorporeal membrane oxygenation. CASE REPORT: A 47-year-old man presented with mildly decreased consciousness in our emergency department after ingesting approximately 100 mL of glyphosate-surfactant 1.5 hours previously. Respiratory failure, persistent ventricular tachycardia, profound shock refractory to inotropic agents, and metabolic acidosis developed in the patient within 2 hours. Extracorporeal membrane oxygenation was applied within 4 hours of cardiopulmonary failure. The patient's condition improved considerably. He was transferred to the general ward on the eighth day with stable hemodynamic status and complete neurological recovery. CONCLUSIONS: On the basis of our research, this was the first case in which extracorporeal membrane oxygenation was used to treat severe glyphosate-surfactant intoxication. We recommend early initiation of extracorporeal membrane oxygenation therapy to mitigate cardiopulmonary compromise in patients with glyphosate-surfactant intoxication.
Cho, Y. et al. (2019) AMERICAN JOURNAL OF EMERGENCY MEDICINE, (AUG 2019) Vol. 37, No. 8.	This case report describes the sucessful treatment of hyperkalemia and monitoring of blood glyphosate concentrations after a formulated glyphosate overdose. It is expected that the glyphosate level would be high on admission and then decrease rapidly. This is a case report of a suicidal ingestion and should not impact re-registration.	Introduction: This report describes changes in blood and urine concentrations of glyphosate potassium over Lime and their correlations with clinical symptoms in a patient with acute glyphosate potassium poisoning. Case report: A 67-year-old man visited the emergency center after ingesting 250 mL of a glyphosate potassium based herbicide 5 h before. He was alert but presented with nausea, vomiting, and bradyarrhythmia with atrial fibrillation (tall T waves). Laboratory findings revealed a serum potassium level of 6.52 mEg/L. After treatment with an injection of calcium gluconate, insulin with glucose, bicarbonate, and an enema with polystyrene sulfonate, the patient's serum potassium level normalized and the bradyarrhythmia converted to a normal sinus rhythm. During admission, the blood and urine concentration of glyphosate and urine aminomethylphosphonic acid (AMPA, a glyphosate metabolite) was measured at regular time intervals. The patient's glyphosate blood concentration on admission was 11.43 mg/L, and it had decreased rapidly by 16 h and maintained about 1 mgl/L by 70 h after admission. Urine glyphosate and AMPA levels had also decreased rapidly by 6 h after admission. Discussion: Glyphosate potassium poisoning causes hyperkalemia. Blood concentrations of glyphosate were decreased rapidly by 16 h after

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
		admission, and urine concentrations were also decreased by 6 h after admission. (C) 2019 Elsevier Inc. All rights reserved.
Choi B. et al., 2013 Toxicology Letters (2013), Vol. 221, Supp. 1, pp. S66	This is a report about measuring IMA rather than lactate as a marker of shock after suicidal ingestion of formulated glyphosate and should not impact re-registration.	Introduction: To date, plasma lactate level has been thought that the most important monitoring tool to measure systemic tissue hypoxia. However, the time lag and relatively low value in some cases are frequently encountered. Case: Sixty-seven year old female was admitted emergency room after 80 min from acute pesticide poisoning. She drank 500mL of glyphosate with intension of suicide. She was alert but her vital signs were unstable at admission; BP 84/37mm Hg, PR 97/min, SpO2 98%. After the initial resuscitation management including general decontamination treatment, she moved to the Acute Care Unit and continuous resuscitation due to her unstable hemodynamic status. During the hospital course, we daily measured the ischemic modified albumin (IMA) level using albumin-cobalt binding assay that its value could tell us the tissue hypoxia. Among the monitoring values, the trend of IMA and base deficit would be correlated with the clinical progress (Fig. 1). Conclusion: We experienced that IMA has a more sensitive monitoring value than lactate in critically ill patient in our acute pesticide poisoning patient. IMA could be measured in venous blood and may be an alternative monitoring laboratory value as base deficit. Also, further study is warranted.
De Raadt W. M. et al., 2015 Sarcoidosis, vasculitis, and diffuse lung diseases : official journal of WASOG (2015), Vol. 32, No. 2, pp. 172	This article is a case report of a smoker who developed eosinophilic pneumonia after glyphosate exposure. Glyphosate is not a sensitizer as established by multiple GLP regulatory studies. Nozzle application of formulated glyphosate producess aerosols of between 200-350 microns. In humans, it takes droplets of <100 microns to cause inhalational injury. The claim that formulated glyphosate can cause inhalational injury in a setting where it isn't aspirated is not biologically plausible.	We report a case of a female patient who developed acute eosinophilic pneumonia (AEP) after recent onset of smoking and exposure to glyphosate-surfactant.The additional exposure associated with the recent start of smoking may have contributed to the development and/or severity of AEP.A clinical relapse after re-challenge four years later both with smoking and glyphosate-surfactant made the association highly likely.Respiratory distress is a factor of poor outcome and mortality after ingestion of glyphosate-surfactant.This case highlights the importance of a thorough exposure history e.g., possible occupational and environmental exposures together with drug-intake.Genotyping should be considered in cases of severe unexplained pulmonary damage.

Reference	Evaluation	Abstract
Deo S. P. et al., 2012 Journal of the Nepal Medical Association (2012), Vol. 52, No. 185, pp. 40	Large ingestions of formulated glyphosate can often result in caustic injury secondary to the surfactant's detergent actions on the mucous membranes of in people who ingest them. That said, they shouldn't cause microstomia, which tends to result from much more corrosive and scarring chemicals. This should not impact re-registration.	Glyphosate (GlySH) is a broad spectrum, nonselective herbicide, widely used in agriculture. This case report describes a 25-year-old man presenting with extensive chemical burns and ulceration of the oral cavity as a result of accidental exposure to GlySH. This paper aims to illustrate the typical appearance of GlySH related chemical mucosal burn and to demonstrate the severity of the corrosive effect of GlySH which need team approach to prevent unfavorable sequelae such as microstomia.
Elsner, P. (2018) Journal der Deutschen Dermatologischen Gesellschaft = Journal of the German Society of Dermatology : JDDG, (2018 Jan) Vol. 16, No. 1, pp. 70-71	This paper describes a patient who spilled formulated glyphosate on her arms then washed it off. A week later she developed psoriasis which spread from her arms to her body. She filed a medicolegal claim which was then reported to this journal as a correspondence. The MD wrote that he reviewed the 1986 Maibach paper which evaluated >300 volunteers and showed no evidence of irritation or sensitization and countered this study with 2 case reports alleging sensitizatioin, that the psoriasis on the patient's hands and arms was related to glyphosate exposure, whereas the rest of the psoriasis on her body was not related to the exposure. There is	Not available

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
	not a mechanism for glyphosate to cause psoriasis, especially 1 week post exposure.	
Frappart, M. (2011) Vol. 30, No. 11, pp. 852-4.	This case report describes caustic injury to the GI tract and multiorgan failure after formulated glyphosate overdose. The clinical course is consistent with previous reports of overdose and should not impact re-registration.	Not available
Garlich F. M. et al., 2014 Clinical toxicology (2014), Vol. 52, No. 1, pp. 66	This article discusses the sucessful use of haemodialysis in a patient who was critically ill after a formulated glyphosate overdose.	CONTEXT: Ingestion of glyphosate-surfactant herbicides (GlySH) can result in acute kidney injury, electrolyte abnormalities, acidosis, cardiovascular collapse, and death. In severe toxicity, the use of hemodialysis is reported, but largely unsupported by kinetic analysis. We report the dialysis clearance of glyphosate following a suicidal ingestion of a glyphosate-containing herbicide. CASE DETAILS: A 62-year-old man was brought to the emergency department (ED) 8.5 h after drinking a bottle of commercial herbicide containing a 41% solution of glyphosate isopropylamine, in polyoxyethyleneamine (POEA) surfactant and water. He was bradycardic and obtunded with respiratory depression necessitating intubation and mechanical ventilation. Initial laboratory results were significant for the following: pH, 7.11; PCO2, 64 mmHg; PO2, 48 mmHg; potassium, 7.8 mEq/L; Cr 3.3, mg/dL; bicarbonate, 22 mEq/L; anion gap, 18 mEq/L; and lactate, 7.5 mmol/L. Acidosis and hyperkalemia persisted despite ventilation and fluid resuscitation. The patient underwent hemodialysis 16 h post ingestion, after which he demonstrated resolution of acidosis and hyperkalemia, and improvement in clinical status. Serum glyphosate concentrations were drawn prior to, during, and after hemodialysis. The extraction ratio and hemodialysis clearance were calculated to be 91.8% and 97.5 mL/min, respectively. DISCUSSION: We demonstrate the successful clearance of glyphosate using hemodialysis, with corresponding clinical improvement in a patient with several poor prognostic factors (advanced age, large volume ingested, and impaired consciousness). The effects of hemodialysis on the surfactant compound are unknown. Hemodialysis can be considered when severe acidosis and acute kidney injury complicate ingestion of glyphosate-containing products.
Han Sang Kyoon et al. (2010) Vol. 48, No. 6, pp. 566-8.	This is a case report of a suicidal ingestion of formulated glyphosate that was treated with lipid emulsion and	CONTEXT: Circulatory shock is a major cause of mortality in glyphosate-surfactant herbicide (GlySH) poisoning, and this condition responds poorly to conventional therapies. We report a case of GlySH poisoning with shock that was refractory to vasopressors but responsive to intravenous fat emulsion (IFE). CASE DETAILS: A 52-year-old man was brought to the emergency

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
	improved. Since this is a descriptionof medical management of a suicidal overdose, this should no impact re-registration	department by ambulance. He was found unconscious in his living room along with an empty bottle of GlySH herbicide, which contained glyphosate, polyoxyethyleneamine (POEA) surfactant, and water. He was drowsy at presentation. His heart rate was 44 beats/min, his blood pressure could not be measured with an arm cuff, but he had a palpable femoral pulse. After about 2.5 h of supportive care after admission, he remained hypotensive, and his systolic blood pressure was 80 mmHg. A 500 mL bottle of 20% IFE product was prepared. As a bolus, 100 mL of IFE was injected, and the remaining 400 mL was then infused. His blood pressure was 100/60 mmHg 1 h after the bolus injection. At 5 h after IFE injection, his blood pressure reached 160/100 mmHg and vasopressors were tapered. CONCLUSION: IFE should be considered in cases of refractory hemodynamic instability caused by GlySH after aggressive fluid and vasopressor support.
Hansen N. B. et al., 2013 Clinical Toxicology (2013), Vol. 51, No. 4, pp. 354	This is a case report of an accidental ingestion of formulated glyphosate resulting in mild corrosive injury to the GI tract in a small child and should not impact re-registration.	Objective: Glyphosate is a broad-spectrum systemic herbicide. Severe toxicity is rare. Case report: A 2.5 year-old boy ingested unknown amounts of concentrated glyphosate (Round-Up), decanted into a soda bottle. Immediately after ingestion the boy was crying, experienced excessive salivation, vomited several times, spontaneous and provoked. Fifteen minutes after ingestion the National Poison Center was contacted, and advised immediate emergency ward contact. The Poison Center alerted the hospital staff about the patient and treatment plan including activated charcoal and examination of oral and gastrointestinal mucosa. On emergency ward arrival the child was awake, crying, reacted adequately, was warm and dry, respiratory frequency (RF) 19/min, oxygen saturation 100%, heart rate 164 beats/min and blood pressure 104/71 mmHg. Activated charcoal 1 g/kg (body weight 14.5 kg) was dosed 1 hour after ingestion. Corrosive injury was suspected because of hypersalivation and red marks in the mouth and throat. Gastroscopy 3 hours after ingestion showed Grade 1b ulceration in the esophagus, pylorus and gastric mucosa. Antibiotic treatment (cefuroxime and metronidazole), with antiemetic (dexamethasone), and analgesics (diclofenac and paracetamol), was initiated. A gastric tube was placed for observation. Hemorrhage was not observed. Coagulation parameter deterioration with elevated international normalized ratio (INR 1.4) and decreased activated partial thromboplastin time (APTT 25 sec), was observed from 3 hours after ingestion and persisted to day 4. All other biochemical parameters were within normal range, and there was no sign of acute kidney injury. Three days after ingestion soft diet was initiated and the following day the patient was well and discharged. Conclusion: Typical symptoms from glyphosate ingestion include nausea, vomiting, abdominal pain, mouth and throat pain. In severe cases gastrointestinal ulceration and bleeding, renal and hepatic deterioration, and circulatory effects might be observed. There have been deaths after rapid onset of respiratory and circulatory collapse. In this case the ingested amount is unknown but is supposed to be a limited minor amount of a highly concentrated product. Immediate development of symptoms and gastric mucosa ulceration confirmed by gastroscopy support the suspicion of concentrated glyphosate

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
		ingestion. Unfortunately it was not possible to get a product sample for chemical analysis. The effect on coagulation parameters was unexpected and calls for increased attention in future glyphosate poisonings.
Iwai K. et al., 2014 Journal of Clinical Toxicology (2014), Vol. 4, No. 6, pp. 1	This article discusses the use of endoscopy to treat formulated glyphosate overdose and medical management of suicidal ingestions and therefore should not impact registration decisions.	Introduction: Roundup® is a herbicide widely used in Japan in gardening and agriculture. When ingested, Roundup is highly toxic, but gastrointestinal decontamination, including gastric lavage, is not routinely performed after ingestion. Endoscopy may be useful in managing individuals with liquid herbicide poisoning, by identifying gastric residual contents, assessing mucosal damage and retrieving herbicide directly by aspiration. Case report: A 73 year old, 40 kg female with a history of depression was transported to our emergency room by ambulance 1 h after attempting suicide by ingesting 100 ml Roundup, which contains 48% glyphosate-potassium, and 52% surfactant and water. This volume was below a fatal dose (<5000 mg/kg), but may have caused organ dysfunction and mucosal damage. After confirming respiratory and circulatory stability and after obtaining informed consent from the patient, endoscopy (XQ 260; Olympus, Tokyo, Japan) was performed in the emergency room to retrieve residual herbicide. About 80 ml of herbicide in the stomach were aspirated endoscopically with only mild erosion observed in the mucosa of the stomach. The patient was able to resume oral intake 2 days after endoscopy and was discharged without any complications on day 5. Conclusion: Endoscopy may be useful in cases of liquid poisoning including, Roundup, both to determine the amount of residual toxin and to remove it from the stomach.
Jovic-Stosic J. et al., 2013 Clinical Toxicology (2013), Vol. 51, No. 4, pp. 288.	This is a case series that included one patient with a formulated glyphosate overdose and treatment with ILE. This describes medical management of overdoses and should not impact re-registration.	Objective: To assess the efficacy and complications of intravenous lipid emulsion (ILE) antidotal use in acute human poisoning. Methods: Prospective clinical study on ILE (Intralipid 20%) effects given as fast intravenous infusion in total dose of 500- 1000 mL. The main criteria for administration were cardiocirculatory failure caused by liposoluble agents and poor response to vasopressors. Effects on blood pressure (BP), electrocardiogram (ECG), and central nervous system (CNS) depression were assessed. Pre- and post-lipid administration concentrations of drugs were obtained. Results: A total of nine patients were treated with ILE. Poisonings were caused by glyphosate/polyethyloxylated tallowamine (POEA) herbicide (1 patient), verapamil and benzodiazepines (3 patients), propranolol combined with alcohol or psychoactive drugs (2 patients) and mixed ingestion of various drugs including carbamazepine, lamotrigine, sertraline, risperidone, amitriptyline, clozapine, haloperidol, valproic acid/valproate and chlorpromazine (3 patients). Significant increase of BP leading to vasopressor therapy reduction was noted in all patients after the initial dose of 500 mL, but in some cases this effect was transient and an additional dose of Intralipid was necessary. The most prominent effect was on wide complex tachycardia which developed in two patients (ingested glyphosate/POEA or propranol/alcohol) as sinus rhythm was regained before the end of Intralipid infusion. ECG changes in others included slight widening of QRS or QT prolongation. There was no rapid normalisation that could be attributed to ILE. All patients were comatose (Glasgow Coma Sscale

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
		(GCS) 3-5). Improvement in GCS was noted in all except the cases with predominant carbamazepine and valproate. There were no significant changes in drug concentrations in blood after lipid administration. In cases of verapamil toxicity, analysis after lipid removal by ultracentrifugation revealed a decrease in concentration. The only complication which may be connected with ILE treatment was acute respiratory distress syndrome (ARDS) in a case of severe verapamil intoxication. Conclusion: Our results, though limited by the small number of patients, revealed that the most invariable effect of ILE was the increase of BP, and the most impressive was the fast reversal of wide complex tachycardia. Efficacy of ILE in case of poor response to other therapies indicated that the fear of adverse interactions with other conventional drugs for the treatment of cardiotoxicity may not be rational.
Jovic-Stosic J. et al., 2016 Vojnosanitetski pregled (2016), Vol. 73, No. 4, pp. 390	Medical case of intentional ingestion. ILE has been proposed as a possible therapy for formulated glyphosate overdoses. As this was a suicide attempt, this should not impact re-registration.	Introduction: Glyphosate is the first widely used herbicide against weed in genetically modified crops. Though glyphosate itself has a low toxicity, commercial products are more dangerous because of increased toxicity due to surfactants addition. There is no specific antidote for the poisoning with glyphosate-surfactant (Gly-SH). In recent times, the efficacy of intravenous lipid emulsion (ILE) administration for the treatment of acute poisoning caused by Gly- SH has been investigated. Case Report: A 50-year-old man was admitted 3 hours after self-poisoning with herbicide containing glyphosate and polyoxyethyleneamine, as a surfactant. On admission, the patient was in a coma, hypotensive (80/50 mmHg) and without spontaneous breathing. Electrocardiogram showed widecomplex tachycardia, and arterial blood gas (ABG) revealed acidosis (pH 7.07). Conventional treatment included mechanical ventilation, intravenous fluids, bicarbonate and dopamine. As there was no improvement, ILE was started. The patient received 100 mL of 20% Intralipid® bolus followed by infusion of 400 mL over 20 minutes. Prior to expiration of infusion, a gradual rise in blood pressure was noted, and within 2 hours sinus rhythm was restored. Conclusion: This case report suggests that the use of ILE may be an additional option for the treatment of cardiocirculatory disturbances caused by commercial products of glyphosate herbicide.
Jovic-Stosic J. et al., 2016 Clinical Toxicology (2016), Vol. 54, No. 4, pp. 476	This is a report about using ILE to treat overdoses with 1 patient who ingested formulated glyphosate. This paper should not impact re-registration.	Objective: Intravenous lipid emulsion (ILE) may successfully resuscitate patients with cardiotoxicity. However, the indications for its use, as well as its efficacy, are not sufficiently defined. Methods: An observational clinical study on the effects of lipid (Intralipid 20%) given as an intravenous infusion to a total dose of 500-1000 mL. The main criteria for administration of ILE were cardiocirculatory failure caused by liposoluble chemicals (drugs or pesticides) and poor response to conventional treatment which included dopamine, glucagon, bicarbonate and calcium chloride. Effects on blood pressure (BP), electrocardiogram (ECG) and survival of patients were assessed. Results: There were 31 patients (aged 28-83 years) treated with ILE, which comprised approximately 1% of the total number of patients hospitalized in the intensive care unit due to poisoning during 5-year follow up. ILE was most frequently used in calcium channel

Reference	Evaluation	Abstract
		blockers poisoning (15 patients). In 9 patients who had ingested verapamil, or a combination of verapamil and benzodiazepines or angiotensin converting enzyme (ACE) inhibitors (enalapril, cilazapril), ILE was effective in reversing hypotension and dysrhythmias. There were 5 cases of multi-drug poisoning including amlodipine. Lethal outcome occurred in a patient poisoned by a combination of amlodipine with cilazapril, metformin and gliclazide. Combination of nifedipine and metoprolol was fatal despite treatment including ILE and pace-maker administration. Beta-blockers, including propranolol, metoprolol and bisoprolol were among the ingested drugs in 7 cases. Metoprolol was also lethal in combination with gliclazide, mianserin and benzodiazepines. Administration of ILE rapidly improved conduction delay and increased BP in cases of propafenone (1 patient) and glyphosate herbicide (1 patient) toxicity. In two cases of organophosphate insecticide poisoning with cardiovascular collapse, only transient increase of BP was noted. The remaining cases involved psychoactive drugs. ILE was successful in the treatment of clomipramine, maprotiline, sertraline and risperidone overdoses, but failed to reverse cardiotoxicity in patients who ingested carbamazepine, lamotrigine or valproate. Conclusion: Although all our patients received multiple therapies, the improvement observed in most of them soon after administration ILE can be attributed to its beneficial effects. Our experience revealed that the most invariable result of ILE administration was an increase in BP. The most impressive effect was the fast reversal of wide complex tachycardia in 3 different cases (ingestion of propranolol, glyphosate and propafenone) which may suggest effectiveness of ILE in the treatment of sodium channel blockade. However, ILE was not effective in all cases in which it could be expected on the basis of the toxic agent's liposolubility.
Jyoti W. et al., 2014 Journal of postgraduate medicine (2014), Vol. 60, No. 3, pp. 346	Formulated glyphosate can cause caustic injury to the mucosa membrane after ingestion. The esophagus is especially prone to perforation. Due to the absence of a serosa, the esophagus is notoriously difficult to repair & heal. This is not an unusual feature of caustic injury. As this was a suicide attempt, this should not impact re-registration.	Not available

(2012), Vol. 50, No. 2, pp. 159	salt formulations can cause fatal hyperkalemia in overdose. This article discusses a feature of suicidal ingestions and therefore should not impact registration decisions.	
Kato Y., 2015 The Japanese journal of toxicology (2015), Vol. 28, No. 4, pp. 368	This article describes a case series of three patients who presented with extreme hyperkalemia after suicidal ingestion of formulated glyphosate. This is not unexpected in an ingestion involving glyphosate formulated product with potassium salts and should not affect re-registration.	Not available
Knezevic V. et al., 2012 Srpski arhiv za celokupno lekarstvo (2012), Vol. 140, No. 9-10, pp. 648	Glyphosate based formulations can cause renal injury in overdose, and the K+ formulations may result in hyperkalemia. It is therefore reasonable to start hemodialysis or hemofiltration in critically ill patients with kidney failure or hyperkalemia. As this was a suicide attempt, this should not impact re-registration.	INTRODUCTION: Treating severe acute glyphosate-surfactant poisoning requires intensive therapy including dialysis. Cases of hemoperfusion and hemodialysis use in renal failure induced by herbicide ingestion have been reported in the current medical literature. We present a case report of successful patient treatment with continuous venovenous hemodiafiltration in acute glyphosate-surfactant poisoning. CASE OUTLINE: A 36-year-old male patient attempted suicide by drinking approximately 300 ml of glyphosate-surfactant about an hour before coming to our Clinic. On admittance the patient was somnolent, normotensive, acidotic and hyperkalemic. Six hours after poison ingestion there was no positive response to symptomatic and supportive therapy measures. The patient became hypotensive, hypoxic with oliguric acute renal failure, so that post-dilution continuous veno-venous hemodiafiltration was started. During the treatment the patient became hemodinamically stabile, diuresis was established along with electrolyte and acid-base status correction and a gradual decrease of blood urea nitrogen and creatinine levels. After a single 27.5-hour treatment, clinical condition and renal function parameters did not require further dialysis. Complete recovery of renal function was achieved on the fifth day. CONCLUSION: Early introduction of continuous veno-venous hemodiafiltration with other intensive therapy measures led to complete recovery in a hemodinamically instable patient.

Reference	Evaluation	Abstract
Lee, G. (2018) Journal of Veterinary Clinics (2018), Volume 35, Number 4, pp. 144-145, 10	Multiple GLP studies have been conducted to evaluate whether glyphosate is neurotoxic. There is no mechanism by which glyphosate can cross the Blood Brain Barrier or enter the bundles of neurons in the cauda equina to cause a lower motor neuron lesion. Given the clinical description, this sounds more like a Guillan-Barre syndrome which has been reported in dogs.	A 4-year-old Yorkshire terrier was presented with hindlimb paresis and urinary incontinence after accidental ingestion of an herbicide. Based on neurologic examinations, decreased hindlimb proprioception with flaccid paresis were revealed. Other possible causes of the clinical signs were excluded. The clinical signs gradually improved after administration of anti-inflammatory and antioxidant therapy. This case report is the first to describe the long-term outcome of hindlimb paresis and urinary incontinence induced by glyphosate surfactant herbicide (GPSH) poisoning in a dog.
Lee B. K. et al., 2012 hong Kong Journal of Emergency Medicine (2012), Vol. 19, No. 3, pp. 214	This is a report about multi-organ failure and the use of CVVHD after suicidal ingestion of formulated glyphosate and should not impact re-registration.	Intractable hypotension is a major cause of death after glyphosate-surfactant herbicide poisoning. However, there is no specific treatment besides conservative care. Herein, we report a patient poisoned by glyphosatesurfactant herbicide experiencing cardiac arrest but was successfully resuscitated and treated with continuous venovenous haemodiafiltration (CVVHDF). The 60-year-old patient was brought to our emergency department after ingesting glyphosate-surfactant herbicide. He developed pulmonary oedema, severe metabolic acidosis (pH 6.960), and hyperkalaemia (serum potassium 8.8 mmol/L). Although he experienced cardiac arrest for about 12 minutes, the use of CVVHDF improved the metabolic acidosis and hyperkalaemia, and finally stabilised his vital signs. He regained an alert mental state after therapeutic hypothermia. CVVHDF, which is a better tolerated renal replacement therapy than haemodialysis in haemodynamically unstable patients, should be considered in glyphosate-surfactant poisoned patients of intractable hypotension with severe metabolic acidosis or hyperkalaemia. © 2006 Hong Kong College of Emergency Medicine.
Lee D. H. et al., 2017 Hong Kong Journal of Emergency Medicine (2017), Vol. 24, No. 1, pp. 40	This is a report about multi-organ failure and the use of dialysis after suicidal ingestion of formulated glyphosate and should not impact re-registration.	Glyphosate-surfactant is one of the most commonly used herbicides in the world. Its key component, glyphosate, is a competitive inhibitor of the shikimate pathway, a metabolic pathway found only in plants. However, severe intoxication, including lethal cases by ingestion of, glyphosate-surfactant has been reported. We describe the full recovery of two patients from glyphosate-polyoxyethyleneamine surfactant intoxication and multi-organ system failure following continuous renal replacement therapy. Both patients developed persistent shock, acute kidney injury, lactic acidosis, hyperkalaemia and multi-organ failure despite of resuscitation. We believe that continuous renal replacement therapy should be initiated immediately for removal of glyphosate-polyoxyethyleneamine surfactant in patients with signs of cardiopulmonary compromise, lactic acidosis, and renal failure. We propose the addition of glyphosate-

		polyoxyethyleneamine surfactant to the list of toxins for which early haemodialysis should be indicated.
Luo W. et al., 2019 Medicine (2019), Vol. 98, No. 30, pp. e16590	This article describes a case report of gastric ulceration and swelling causing pyloric obstruction in a patient who ingested formulated glyphosate. This is not unexpected as formulations contain surfactants which can cause caustic injury to the GI tract with suicidal ingestions. This should not impact re-registration.	RATIONALE: Oral ingestion of glyphosate can induce gastrointestinal symptoms such as vomiting, abdominal pain, and hematochezia. Timely and effective treatment of pyloric stenosis caused by glyphosate poisoning is important. PATIENT CONCERNS: The patient had a poor appetite, accompanied by nausea and vomiting of a small amount of dark brown material that resembled blood clots several times a day. Gastroscopy revealed gastric ulcer, a large pyloric antrum ulcer, and a deformed stomach cavity. DIAGNOSIS: Pyloric stenosis due to glyphosate poisoning in a 36-year-old man. INTERVENTIONS: The patients received distal gastrectomy and subsequently transferred to the ICU for further treatment. A mechanical ventilator was used to assist breathing. OUTCOMES: Follow-up was conducted 3 years after surgery. The patient had no problem with food ingestion and experienced no discomfort, such as vomiting, nausea, coughing, or expectoration. LESSONS: Gastrectomy is necessary to treat pyloric stenosis caused by glyphosate poisoning.
Mahendrakar K. et al., 2014 Indian journal of critical care medicine (2014), Vol. 18, No. 5, pp. 328	ILE has been proposed as a possible therapy for formulated glyphosate overdoses.	Glyphosate is a widely used herbicide in agriculture, forestry, industrial weed control and aquatic environments. Glyphosate potential as herbicide was first reported in 1971. It is a non-selective herbicide. It can cause a wide range of clinical manifestations in human beings like skin and throat irritation to hypotension, oliguria and death. We are reporting a case of a 35-year-old male patient who was admitted to our tertiary care hospital following intentional ingestion of around 200 ml of herbicide containing glyphosate. Initially, gastric lavage done and the patient was managed with intubation and mechanical ventilation, noradrenaline and vasopressin infusion, continuous veno-venous hemodiafiltration and intravenous (IV) lipid emulsion (20% intralipid 100 ml), patient was successfully treated and discharged home. This case report emphasizes on timely systemic supportive measure as a sole method of treatment since this poison has no known specific antidote and the use of IV lipid emulsion for a successful outcome.
Malhotra, R.C. (2010)	This paper describes prolonged encephalopathy in a suicidal glyphosate ingestion. There is no mention of the medication that was used for sedation while the patient was intubated in the ICU. Accumulations of lorazepam and other	Glyphosate-surfactant (GlySH) is a commonly used herbicide that has been used in attempted suicide. Most reports of GlySH toxicity in patients have followed ingestion of the commercial product "Round-up" (Monsanto Ltd; Melbourne, Victoria, Australia), which consists of a mixture of glyphosate (as a isopropylanine salt) and a surfactant (polyoxyethyleneamine). Ingestion of Round-up is reported to cause significant toxicity including nausea, vomiting, oral and abdominal pain. Renal and hepatic impairment and pulmonary oedema may also occur. Impaired consciousness and encephalopathy have been reported as sequelae but there are limited data on the central nervous system (CNS) effects of Round-up toxicity. We report a 71-year-old male who attempted suicide with GlySH and developed a prolonged

Reference	Evaluation	Abstract
	sedatives may result in prolonged coma. In formualted glyphosate overdose with multiorgan failure it is common to sedate patients until their hemodynamics improve. In the setting of suicidal overdose, this paper should not impact re-registration.	but reversible encephalopathy suggestive of acute CNS toxicity.
Nakae H. et al., 2015 Acute medicine & surgery (2015), Vol. 2, No. 3, pp. 214	This article describes alternative medicine therapies that were used to treat a Japanese woman with a paralytic ileus after glyphosate ingestion. It is not uncommon for patients in a critical care setting to develop an ileus. These tend to resolve on their own without intervention. I cannot be commented on whether this intervention increases GI motility.	Case: A 65-year-old woman ingested glyphosate-surfactant herbicide in an attempt to commit suicide. She experienced glyphosate intoxication associated with multiple organ failure and developed a paralytic ileus. Daijokito, a traditional Japanese Kampo medicine was given to the patient to improve constipation and psychological symptoms. Next, rikkunshito was given to increase her gastric motility. Finally, daikenchuto was given to improve overall digestive peristalsis. Outcome: All abdominal symptoms ultimately improved after treatment with daikenchuto. Conclusion: Kampo medicines may help improve abdominal symptoms associated with glyphosate intoxication in cases where modern medical treatment alone proves inadequate.
Nakayama T. et al., 2019 Clinical and experimental nephrology (2019), Vol. 23, No. 6, pp. 865	This was a suicidal ingestion of formulated glyphosate that resulted in poor renal perfusion & multiorgan failure. Since this was a suicidal ingestion, the outcome is not unexpected and should not impact the re-egistration.	A 70-year-old woman presented with abdominal pain 2 h after ingesting 500 ml of glyphosate–surfactant herbicide (GPSH). As her abdominal pain worsened, contrast-enhanced computed tomography was performed 12 h after the admission, demonstrating renal blood flow shunting through the medulla which is called “reverse rim sign” (Fig. 1). She had been anuric since hospitalization with sufficient mean artery pressure and negative blood culture. Despite intensive care, she died of multiple organ failure on the 6th day of hospitalization. [No abstract was available; this is copied from article. MSB]
Ozaki T. et al., 2017 Therapeutic apheresis and dialysis (2017), Vol. 21, No. 3,	This article discusses the use of haemodialysis and haemofiltration in formulated glyphosate	INTRODUCTION: In our case report we describe the case of a patient who experienced a stroke in her left hippocampus that was found following an attempted suicide via glyphosate overdose. To the best of our knowledge this is the first case report to describe a hippocampal infarction associated with a drug overdose.

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
pp. 296	overdoses.This article discusses medical management of suicidal ingestions and therefore should not impact registration decisions.	CASE PRESENTATION: A 64-year-old Japanese woman was brought to our emergency department after ingestion of an unknown dose of glyphosate surfactant herbicide in order to attempt suicide. On admission, she was assumed to be presenting with depression or psychiatric illness, however, sudden-onset memory deficit became apparent. The patient manifested delirium, confusion, and severe anxiety. In addition, short-term memory loss was prominent, with the patient forgetting her attempted suicide. Following an array of standard tests and a brain computed tomography scan (which only showed an old infraction), we performed a magnetic resonance imaging scan and neuropsychological evaluations. The brain magnetic resonance image revealed a small high-intensity lesion in the dorsal part of the left hippocampal body, and memory tests demonstrated severe short-term recall deficits. We diagnosed her with a left hippocampal infarction and administered a course of 75mg of clopidogrel. She gradually became less confused over the course of a week, and a follow-up memory test revealed partial improvement in some domains. No abnormalities were found on a follow-up brain scan. However, despite rehabilitation, memory impairments remain. CONCLUSIONS: It is important to note that had the symptom of short-term memory been absent or less severe, she might have been misdiagnosed with depression or another psychiatric illness. Although a computed tomography scan failed to detect hippocampal lesions, a diffusion-weighted magnetic resonance imaging scan clearly revealed a lesion within the left hippocampus. Therefore, in addition to assessments focusing on psychiatric illnesses that might be the root cause of an attempted suicide, organic factors should be considered along with radiological examination and precise memory assessments for diagnosing similar cases.
Picetti E. et al., 2017 Acta Biomedica (2017), Vol. 88, No. 4, pp. 533	This is a report about multi-organ failure after suicidal ingestion of formulated glyphosate and should not impact re-registration.	Not available
Thakur D. S. et al., 2014 Toxicology international (2014), Vol. 21, No. 3, pp. 328	This is a case report of the clinical manifestations of glyphosate-based herbicide ingestions and discusses predictors of mortality in suicidal ingestions and therefore should not impact registration decisions.	Background: Water soluble and insoluble chemicals in the pesticide formulation may be eliminated more effectively in time if hemodialysis (HD) and hemoperfusion (HP) are performed concurrently. Aim: This study is aimed at evaluating the efficacy of concurrent HP and HD in patients with acute pesticide intoxication. Methods: Between January 2011 and December 2012, we used HP and HD consecutively (HP-HD group, 347 cases), and then during the next 2 years (January 2013 to December 2014), we used concurrent HP and HD (HPD group, 383 cases). We compared the clinical outcomes between the 2 groups. Results: The mortality was higher in the HP-HD group than in the HPD group: (48.1 vs. 20.9%) for the overall mortality and (81.8 vs. 57.9%) for the paraquat (bipyridylium) mortality ($p < 0.001$). In multiple logistic analyses, age ($p = 0.013$), ingested volume ($p < 0.001$), and HP-HD ($p = 0.014$) were significant risk factors for mortality in the paraquat ingested group. Conclusion:

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
		Concurrent HP and HD would be an effective and safe treatment for patients with acute pesticide intoxication, in particular, paraquat intoxication.
Veale D. J. H. et al., 2013 SAMJ (2013), Vol. 103, No. 5, pp. 293	This article summarises the chemicals used in South Africa for suicide. Glyphosate is only mentioned in a table in the article as being involved in 23 cases over a 1 year period accounting for 0.9% of the overall cases reported.	A 55 years old man self-presented to our Emergency Department (ED) reporting an attempted suicide by cutting the left forearm veins and ingesting approximately 200 mL of an herbicide (Myrtos®, containing 36% of glyphosate as isopropylamine salt). Laboratory tests showed metabolic acidosis. Hydration with normal saline and alkalinization with sodium bicarbonate was started according to suggestion of the poison control center, since an antidote was unavailable. Cardiorespiratory condition gradually worsened, so that non-invasive positive pressure ventilation (NIPPV) was applied and infusion of fluids was established. Nevertheless, the patient deteriorated and he needed to be transferred to the Intensive Care Unit (ICU), where he underwent orotracheal intubation and invasive mechanical ventilation. Noradrenaline and adrenaline were infused and fluid resuscitation with crystalloids was incremented. An esophagogastroduodenoscopy (EGD) showed diffuse mucosal erosions of upper digestive tract. No signs of visceral perforation were found during ICU stay. In the following days, the clinical conditions improved and a new EGD showed marked improvement of erosive lesions. After 12 days of ICU stay, the patient was extubated and then transferred to the Psychiatric Unit, in good clinical conditions. Gliphosate ingestion is associated with rapid development of multiple organ failure (MOF). Since an effective antidote is unavailable, major attention should be placed to aggressive life-support care and careful monitoring of complications.
Vidyadhara et al., 2014 Indian Journal of Critical Care Medicine (2014), Vol. 18, Suppl. 1, pp. S36.	This is a report about multiorgan failure after suicidal ingestion of formulated glyphosate and should not impact re-registration.	A 55 years old man self-presented to our Emergency Department (ED) reporting an attempted suicide by cutting the left forearm veins and ingesting approximately 200 mL of an herbicide (Myrtos®, containing 36% of glyphosate as isopropylamine salt). Wang D. et al., 2019 Medicine (2019), Vol. 98, No. 6., pp. e14414	This article describes using ECMO to manage a patient with multiorgan failure after formulated glyphosate and diquat ingestion. Since this is describing medical management of suicidal overdoses, it should not impact re-registration	This article requires a subscription to view the full text. If you have a subscription you may use the login form below to view the article. Access to this article can also be purchased. A 66-year-old man, with a history of Wolff-Parkinson-White syndrome, coronary artery disease, left partial colectomy for polyps, and alcohol abuse (50 g/d), attempted suicide by ingestion of commercially available glyphosate (Round-Up, 200 mL). He was admitted to the emergency ward for monitoring and hyperhydration. First clinical and biological workup and gastric endoscopic examinations were normal.
Wu M-H. et al., 2015 Clinical Toxicology (2015), Vol. 53, No. 4, pp. 330	This is a report about renal failure and haemodialysis after suicidal ingestion of formulated glyphosate and should not impact re-registration.	INTRODUCTION: The mechanisms underlying early central nervous system (CNS) signs and symptoms of glyphosate-surfactant herbicide (GlySH) poisoning are unclear. CASE PRESENTATION: A 58-year-old woman ingested approximately 150 mL of GlySH containing 41% glyphosate and 15% polyoxyethyleneamine. Two days later, she was admitted in the Emergency Center in a semicomatose state. Acute respiratory distress syndrome, circulatory collapse, acute renal failure, and disseminated intravascular coagulopathy were diagnosed. Meningitis was also suspected as she demonstrated Kernig's sign and significant neck stiffness with rigidity of the extremities as well as consciousness disturbance and fever (38.4°C). Investigations of cerebrospinal fluid (CSF) revealed the presence of glyphosate (122.5 µg/mL), significant elevation of IL-6 (394 µg/mL), and pleocytosis (32 cells/µL) with monocyte dominance. All bacteriological and virological tests were later found to be negative. She recovered completely after responding to aggressive supportive care in the intensive care unit. All signs and symptoms suggesting meningitis resolved as the concentration of glyphosate in CSF decreased. She was discharged on day 39 of hospitalization. DISCUSSION: These findings suggest that the present case involved aseptic meningitis in association with GlySH poisoning. CONCLUSION: CNS signs and symptoms induced by aseptic meningitis should be considered in cases of glyphosate-surfactant herbicide poisoning.
You Y. et al., 2012 The American journal of emergency medicine (2012), Vol. 30, No. 9, pp. 2097.e1	This article is discussing the efficacy of intravenous fat emulsion as therapy for formulated glyphosate overdose. This report contributes to the evidence that intravenous fat emulsion may be a useful treatment for glyphosate overdose	Glyphosate herbicide is promoted by the manufacturer as having no risks to human health, with acute toxicity being very low in normal use. In Thailand, however, poisoning from glyphosate agricultural herbicides has been increasing. A case of rapid lethal intoxication from glyphosate-surfactant herbicide involved a 37-year-old woman, who deliberately ingested approximately 500 mL of concentrated Roundup formulation (41% glyphosate as the isopropylamine salt and 15% polyoxyethylene amine; Mosanto Company). The postmortem examination revealed that the stomach contained 550 mL of yellow fluid. The gastric mucosa of anterior fundus revealed hemorrhage and the small intestines had marked dilatation and thin walls. We used the high-performance liquid chromatography method for determination of serum and gastric content levels of glyphosate. The glyphosate levels of serum and gastric content were 3.05 and 59.72 mg/mL,

Appendix 1: Overview on case reports. No review information or epidemiologic information is listed in this table. The complete references on any kind of medical data are available in the literature search report, CA 9-01.

Reference	Evaluation	Abstract
	as it may limit the toxicity associated with large surfactant ingestions. There are no RCTs for this as it is a suicidal overdose situation.	respectively. Toxic effects of polyoxyethylene amine and Roundup were caused by their ability to erode tissues including mucous membranes and linings of the gastrointestinal and respiratory tracts. A mild degree of pulmonary congestion and edema was observed in both lungs. We proposed that the characteristic picture of microvesicular steatosis of the hepatocytes, seen predominantly in centrilobular zones of the liver, resembled drug-induced hepatic toxicity or secondary hypoxic stress.
Yu G. C. et al., 2017 Chinese journal of industrial hygiene and occupational diseases (2017), Vol. 35, No. 5, pp. 382	This is a case study describing the clinical course of 10 patients who drank formulated glyphosate. There were no long-term sequelae of ingestion, and all 10 patients survived. These were suicdal ingestions and should not impact re-registration.	The literature, particularly from India, is scarce on the renal effects of glyphosate poisoning. Glyphosate causes toxicity not only after its ingestion but also after dermal exposure by inhalation route and on eye exposure. We present a patient report of glyphosate consumption which resulted in toxic epidermal necrolysis - the first report after glyphosate consumption and acute kidney injury.
Zouaoui K. et al., 2013 Forensic science international (2013), Vol. 226, No. 1-3, pp. E20	This report demonstrates a link between higher blood and urine concentrations with formulated glyphosate overdoses and a poorer outcome. This is unsurprising as it reflects that patients drank a larger volume. Larger volumes of formulated product are associated with more toxicity due to the caustic nature of the surfactant, not the amount of active ingredient. All of the laboratory parameters are expected in critically ill patients. As these were suicidal ingestions, this paper should not impact re-registration.	An 86-year-old woman intentionally drank approximately 300 mL of a glyphosate-surfactant. She was found with consciousness disturbance and experienced several vomiting episodes. On arrival, serum biochemistry revealed a decreased level of butyrylcholinesterase (B-CHE) [11 (normal range: 180-450) IU/L]. Later, her B-CHE level further decreased to single-digit values, and she became comatose with involuntary movement and an increase in muscle tone. Her consciousness level and muscle tone improved with the recovery of her B-CHE level. Physicians should be alert for the occurrence of intermediate syndrome when the B-CHE levels of patients who have consumed a massive amount of glyphosate-surfactant show a prolonged decrease.

Glyphosate

ANNEX to the Documen M of the technical section[46]:

TOXICOLOGY AND METABOLISM

[46] Annex to the Doc ID: 110054-MCA5_GRG_Jun_2020

AIR 5 introduction

During the AIR 2 evaluation process of glyphosate, in the Renewal Assessment Report 2015 version[47], the RMS Germany included public literature articles as part of the Annex B.6. **All articles** included in this version of the RAR Vol 3 2015 have been included in this annex for the sake of completeness, with the aim of providing the EU authorities during the AIR 5 EU process with all information available for glyphosate from previous EU evaluations.

All information presented in this Annex, is an exact copy of the literature information included in the RAR Vol 3 2015 version. When reading the present annex, please note:

- This annex only present articles and not regulatory studies.
- Some references are made to the former Monograph glyphosate 1998.
- If text was strickethrough in the RAR Vol 3 2015, then those sentences were not included in the present annex.
- The numbering of tables in the present annex have not been changed and remain as original presented in the RAR Vol 3 2015 version.
- If text was highlighted in the RAR Vol 3 2015, then those sentences are also highlighted in the present annex.
- If text was given in italic style in the RAR Vol 3 2015, then those sentences are also given in italic in the present annex.

[47] Renewal Assessment Report, Revised 2015 Vol 3

Renewal Assessment Report, Revised 29 January 2015 Vol 3, annex B.6.4 Background

General introduction and explanation of the approach taken by RMS

This health evaluation of glyphosate is based on the following sources:

- Toxicological and ADME studies that were submitted by the GTF for this re- evaluation.
- Toxicological studies and ADME studies that had been reported in the previous DAR (1998, ASB2010-10302) already and, thus, were part of previous EU evaluation. However, they were subject to re-assessment by the RMS according to current quality standards and were used only when regarded as acceptable or at least supplementary. In very few cases, NOAELs/LOAELs were revised. Unacceptable (old or new) studies were usually deleted with justifications given in the respective sections of Volume 3. In exceptional cases, such studies are still mentioned, i.e., if they were formerly taken into consideration for, e.g., ADI setting.
- Scientific publications and other relevant information that were submitted either by the GTF or by third parties or of which the RMS was aware before. It must be emphasised that a large part of the publications was on formulations different from the representative one and, thus, is of limited value for the toxicological evaluation of the active ingredient. With rather few exceptions in the areas of genotoxicity and human data, mainly scientific literature published since 2000 was assessed.

Due to the large numer of submitted toxicological studies, the RMS was not able to report the original studies in detail and an alternative approach was taken instead. The study descriptions and assessments as provided by GTF were amended by deletion of redundant parts (such as the so-called ”executive summaries”) and new enumeration of tables. Obvious errors were corrected. Each new study was commented by the RMS. These remarks are clearly distinguished from the original submission by a caption, are always written in italics and may be found on the bottom of the individual study summaries.

Furthermore, in Volume 3, assessment was performed on the individual study level. Overall evaluation of the diverse toxicological endpoints was transferred into Volume 1 (section 2.6).

The technical databases that have been used for the literature search include: Web of ScienceSM, BIOSIS Previews®, CAB Abstracts® (CABI), MEDLINE®, and CA Plus (Chemical Abstracts Plus). The searches were made on glyphosate acid, glyphosate salts (including isopropyl amine, potassium, ammonium, and methylamine), and AMPA, and their related chemical names and CAS numbers. Searches based on these search terms were also found suitable to identify publications that consider glyphosate and surfactants (such as polyoxyethylenealkylamines, or POEA) in the context of glyphosate formulations.

Additional publications cited in a recent document prepared by the NGO ”Earth Open Source” (Antoniou M, *et al.*, 2011, ASB2011-7202) have also been included in the literature review.

The peer-reviewed publications identified for inclusion during the literature search were reviewed and classified into one of the categories listed below.

- Category 0 publications: These are publications in which glyphosate is only mentioned as an example substance or is discussed/studied in a context that is not relevant or related to any of the regulatory sections or the exposure/hazard assessments within this submission; the publication is therefore outside of the scope of this submission.
- Category 1 publications: These are publications which discuss glyphosate in a context relevant or related to the regulatory dossier sections and the conclusions fall within the conclusions of the exposure/hazard assessment. The publication is submitted with minimal or no comment or discussion.
- Category 2 publications: These are publications which discuss glyphosate in a context relevant or related to the regulatory dossier sections and have conclusions that call into question the

endpoints/conclusions in the exposure/hazard assessment. Additionally, Category 2 also includes publications with conclusions that support the risk/hazard assessment, and may be included in discussion of other relevant publications. For selected Category 2 publications, an OECD Tier-II type summary is provided in addition to a reliability assessment (Klimisch rating, see Klimisch *et al.*, 1997, ASB2010-14388); limited comments and critical remarks are provided, as appropriate.

- Category 3 publications: These are publications that discuss glyphosate in a context relevant or related to (1) non-regulatory endpoints that need to be addressed as per new Regulation (EC) 1107/2009; or (2) in a context relevant to sensitive allegations that have emerged or could emerge in the media; or (3) in a context relevant to the regulatory dossier sections and have conclusions that are in disagreement with endpoints/conclusions in the exposure/hazard assessment (although the experimental design seems relevant at first glance). An OECD Tier-II type summary is provided and a Klimisch rating assigned, and supplemented with critical review and discussion.
- Category 'E' publications: These are peer-reviewed publications that were cited in the Earth Open Source document. This category includes publications that were already captured by the literature search and are addressed within the appropriate discipline, as well as publications that were out of scope of the search (primarily as a result of being published prior to 2001). Publications already captured in the literature search were assigned a Category 1, 2 or 3 rating (as appropriate) in addition to a Category 'E' rating. An OECD Tier-II type summary has been prepared and a Klimisch rating assigned for each of the Category E publications. All Category 'E' publications are reviewed within the appropriate discipline, with most of the reviews provided within the toxicology dossier under Section IIA 5.10.

A full description of the literature search methodology was provided by the GTF in a separate document (Carr and Bleeke, 2012, ASB2012-11583).
Five separate publication subject areas are addressed in the literature review.

1. Developmental and Reproductive Toxicity (DART) and Endocrine Disruption (ED)
2. Neurotoxicity
3. Carcinogenicity
4. Genotoxicity
5. Category E and other publications

The publications on subject areas 1-4 are presented in the chapters on Genotoxicity, Long term toxicicity and carcinogenicity, Reproductive Toxicity and Neurotoxicity of the report.
Furthermore, publications are presented in the chapters "Further toxicological studies" and "Medical data". Important publications are presented in summaries as quoted from the articles followed by Klimisch ratings and by RMS comments on the paper.

In the process of public consultation after the submission of the first draft of this RAR PAN-Europe, PAN-Germany and PAN-UK conducted a PubMed literature search on the keywords 'glyphosate' and 'toxicity' and stated they got significant differences in comparison conducted by the notifier. The GTF repeated the PubMed search on June 11, 2014, using the same keywords (Glyphosate Task Force 2014, ASB2014-9624). Overall, a total of 504 articles were identified in the search. Of those, 349 were from the time period of 2001 to 2012, and thus were considered relevant to the glyphosate submission, and were further evaluated as the whether or not they were included in either the original literature search, included in the May 2012 submission, or as part of the ongoing update of the search. As of the time of June 11 PubMed search. There were 266 reviewed for the submission (222 were included), with an additional 34 reviewed after the submission (29 selected for submission). Of the 49 remaining articles, 43 were considered to tbe not relevant based on the subject of the article (the majority were either on GM crops, efficacy or weed resistance). The remaining 6 were added to the literature review, and of those 4 were considered to be relevan and were selected for submission in the update.

Thus, of the 349 articles identified in the search, only 4 were determined to be relevant and were not already identified in the GTF literature search process.

B.6.1 Absorption, distribution, excretion and metabolism (toxicokinetics) (Annex IIA 5.1)

B.6.1.1 Toxicokinetic and metabolism studies in rats that were not previously evaluated in the EU

B.6.1.2 Re-evaluation of previously known studies (mentioned in the 1998 DAR, ASB2010-10302) by the RMS

B.6.1.3 Published information

Toxicokinetics and metabolism of glyphosate were seldom subject to investigations of industry-indpendent researchers and, thus, experimental data in open literature is scarce. The following paragraphs were transferred from the original DAR (1998, ASB2010-10302) and slightly amended for purposes of the RAR:

Brewster et al. (1991, TOX9551791) reported an absorption rate from the gastrointestina tract of 35 - 40% of the total dose following the single oral administration of 10 mg of a mixture of ^{12}C- and ^{14}C-glyphosate per kg bw to male Sprague-Dawley rats. Urine and faeces were considered equally important routes of elimination. 7 days after application, total body burden was approximately 1% of the administered dose and was primarily associated with the bone. Two hours following a single dose of the mixed test material, traces of a minor metabolite (<0.1% of the dose applied) were detected beside the predominating parent in the colon tissue. This compound was also found in the gastrointestinal tract content of one rat at 28 hours post dosing and was considered likely to be aminomethyl phosphonic acid (AMPA) although the retention time for this metabolite was not identical to that for AMPA. The authors reported AMPA to be a product of metabolic activity of intestinal microbes.

Chan and Mahler (1992, TOX9551954) investigated (with contributions of Duerson and Sipes who are mentioned above) the elimination and tissue distribution of ^{14}C-glyphosate in male F344/N rats following oral and intravenous administration. After single low (5.6 mg/kg bw) or high (56 mg/kg bw) oral doses, more than 90% of the applied radioactivity was eliminated within 72 hours. During the first 24 hours, approximately 50% had been excreted in the faeces and nearly 30% via the urine. It was assumed that the urinary radioactivity represented the amount of glyphosate absorbed. The peak blood levels occurred at 1 (low dose) or 2 (high dose) hours after dosing. Following an i.v. dose of 5.6 mg/kg bw, 90% of the radioactivity was excreted in urine within the first 6 hours already. Glyphosate did not accumulate in the body. In a further group of rats receiving 5.6 mg/kg bw by oral gavage, only 1% of the dose remained in the tissues after 24 hour. It is also stated that pretreatment with Roundup® via drinking water did not change the elimination pattern of glyphosate.

In a more recent paper that was included in the GTF dossier submitted for current evaluation, Anadon *et al.* (2009, ASB2012-11542) reported some parts of toxicokinetics of glyphosate (obtained from SIGMA CHEMICALS) in rats after single intravenous (i.v.) administration of 100 mg/kg bw or a single oral dose of 400 mg/kg bw. The focus was on plasma characteristics and distribution to the different compartments: "Serial blood samples were obtained after i.v. and oral administration. Plasma concentrations of glyphosate and its metabolite amiomethyl phosphonic acid (AMPA) were determined by HPLC method. After i.v. and oral administration, plasma concentration-time curves were best described by a two-compartment open model. For glyphosate, the elimination half-lives ($T_{1/2ß}$) from plasma were 9.99 h after i.v. and 14.38 h after oral administration. The total plasma clearance was not influenced by dose concentration or route and reached a value of 0.995 l $h^{-1}kg^{-1}$. After i.v. administration, the apparent volume of distribution in the second

compartment (V_2) and volume of distribution at steady state (V_{ss}) were 2.39 and 2.99 l kg^{-1}, respectively, suggesting a considerable diffusion of the herbicide into tissues. After oral administration, glyphosate was partially and slowly absorbed with a T_{max} of 5.16 h. The oral bioavailability of glyphosate was found to be 23.21%. Glyphosate was converted to AMPA. The metabolite AMPA represented 6.49% of the parent drug plasma concentrations. The maximum plasma concentrations of glyphosate and AMPA were 4.62 and 0.416 µml^{-1}, respectively. The maximum plasma concentration of AMPA was achieved at 2.42 h. For AMPA, the elimination half-life ($T_{1/2ß}$) was 15.08 h after oral administration of glyphosate parent compound (*quoted from original article*)."

The RMS is not aware of any further scientific publications dealing with toxicokinetics and metabolism of glyphosate in laboratory animals or man. However, information on urinary excretion of glyphosate in humans was provided. In the original draft, this data was reported here but, for the revised version, the information was substantially amended (because more data had become available in the meantime) and transferred to section B.6.9.3 where a new sub-section on human biomonitoring was created[48].

B.6.3.2.1 90-day studies in rats

Published information

Glyphosate was tested in the 1980ies in U.S. National Toxicology Program (NTP) for oral subchronic toxicity (Chan and Mahler, 1992, TOX9551954). The following paragraph was partly copied from the previous DAR (1998, ASB2010-10302):

20 F344/N rats per sex and dose were fed glyphosate (supplied by Monsanto, approximately 99% pure) for 13 weeks at dietary levels of 0, 3125, 6250, 12500, 25000 or 50000 ppm. Ten rats/sex and group were used for evaluation of haematological and clinical chemistry parameters. All rats survived until the end of the study and there were no clinical signs of toxicity apart from diarrhea at the top dose level in both sexes. Body weight gain was markedly reduced in high dose males and slightly decreased in high dose females. There were some minor alterations in haematological and clinical chemistry parameters at least at the upper dose levels. Morphologic changes at necropsy were confined to parotid and submandibular (submaxillary) salivary glands in both sexes. This "cytoplasmatic alteration"consisted of basophilic change and hypertrophy of acinar cells. The parotid gland was more affected. Here, the normal granular, eosinophilic staining cytoplasm of the acinar epithelial cells was replaced by basophilic and finely vacuolated cytoplasm. A NOEL could not be established since these lesions were observed already at the lowest dose level but not in the control groups. The degree of change showed a clear dose response. The outcome of this study shows that glyphosate is of low toxicity when administered orally over a period of 3 months to rats since the animals tolerated daily doses as high as 50000 ppm (more than 3000 mg/kg bw/day) without mortality or clinical signs of overt toxicity and without pathological changes other than the rather equivocal salivary gland findings.

B.6.3.2.1 90-day studies in mice

[48] Text which was strickethrough in the RAR was not copied into this Annex 1

Published information

Glyphosate was tested in the 1980ies in U.S. National Toxicology Program (NTP) for oral subchronic toxicity (Chan and Mahler, 1992, TOX9551954). The following paragraph was partly copied from the previous DAR (1998, ASB2010-10302):

Groups of ten B6C3F1 mice per sex and dose were fed glyphosate (supplied by Monsanto, approximately 99% pure) for 13 weeks at dietary levels of 0, 3125, 6250, 12500, 25000 or 50000 ppm. Clinical pathology investigations were not performed but all animals were necropsied at study termination. Mice of the highest dose group and of the control group were subjected to complete histopathological examination. In addition, salivary glands were examined microscopically in all dose groups. There were no clinical signs of toxicity. However, one high dose female died from undetermined causes. Body weight gain was depressed at the two upper dose levels in both sexes. From the dose level of 6250 ppm onwards, a dose-related increase in occurrence and severity of cellular alteration of the parotid salivary gland was noted. This change consisted of basophilia of the acinar cells and in more severely affected glands, the cells and acini also appeared enlarged with an associated relative reduction in the number of ducts. A dose of 3125 ppm (ca 507 mg/kg bw/day seems to represent the NOEL for substance-related effects. However, the extent of investigations performed was rather limited.

B.6.1.4 Genotoxicity of formulations (taking into account published data that were released before 2000)

Published literature (before 2000)

During the past few years, a number of studies was published dealing with possible mutagenic effects of glyphosate formulations in different test systems. Scientific assessment of these data is very difficult for at least two reasons.

One main deficiency is the lack of precise description of the test material. Usually, source, composition and/or purity neither of the formulations nor, if tested, of the active ingredient are not stated at all or, at least, not sufficiently reported in the publications. It should be also taken into consideration that different formulations may be marketed in different countries under the same trademark, e.g. Roundup®. Further confusion comes from the fact that sometimes by- products in formulations (e.g. surfactants) were replaced by others but the name of the product was not changed. On request, data on the ingredients were submitted by the manufacturer Monsanto but even this information was not sufficient to clarify all uncertainties about the test substances. However, on the basis of the information available so far, it can be be stated that the Roundup products used in the different published studies were not identical. Thus, it is questionable whether results obtained with one product will apply to others containing different non-active ingredients in different concentrations.

A second point of concern is the frequent use of less validated test systems with no proven relevance of the findings for human health risk assessment even if such systems may be well accepted to predict special environmental hazards. With regard to health effects, there are no current guidelines for these test methods and there is no actual experience how to assess positive findings in such test systems. For other test methods used, OECD guidelines do exist but the experiments were not carried out in compliance with these recommendations.

To facilitate presentation of data, it was decided to start with those experiments for which, in principle, widely agreed guidelines are available. Because of the large background database, the SCE assays were also included here. In the subsequent part of this section, investigations in test systems less frequently used for examination of plant protection products and with no guidelines existing are reported. As a result of this approach, one and the same publication may be referred to repeatedly on different sites.

It should be mentioned that in some publications also experiments are reported which were carried out with glyphosate active substance (i.e., the acid or one of its salts) being the test material. These data were not included in the monograph since the respective publications, for different reasons, were considered unacceptable for evaluation purposes (for justification, see description of experimental conditions below) in particular when the current OECD criteria for assessment of published data were applied. However, the findings are reported in this addendum since a direct comparison between active ingredient and formulation data may be of particular interest.
Although various test systems measuring different endpoints were used, it was tried to summarize the available studies in Table B.6.4-26 (see next pages) to facilitate general overview before the individual publications were discussed in greater detail below. For practical reasons, in particular to facilitate direct comparison, the studies were divided into sections according to the test systems and methods and the experiments separately tabulated.

Table B.6.4-26: Overview on published studies on mutagenicity of glyphosate, its salts and formulations

Test method/ test system	Test material	Dose levels/ Dose range	Results	Remarks	Reference
Ames test in S.typhimurium strains TA98 and TA100 (+/- S9 mix)	Roundup (48% glyphosate IPA; polyoxyethylene tallowamine surfactant)	0 - 1440 µg/plate (calculated as glyphosate IPA salt)	Equivocal. Occasional increase in mutation rate but no clear dose response. Marked cytotoxicity from 360 or 720 µg/plate onwards.	Study not acceptable for evaluation purposes due to serious deficiencies. Reliable assessment avoided by cytotoxicity.	Rank *et al.*, 1993 Z82234
Micronucleus test in mouse bone marrow; single i.p. administration; sampling after 24 or 48 h	Glyphosate IPA salt (1:1 mixture) and Roundup (48% glyphosate IPA; tallowamine surfactant)	0, 100, 150, 200 mg/kg bw (glyphosate IPA); 0, 133, 200 mg/kg bw (Roundup, calculated as IPA salt)	Negative. Indication of dose-related bone marrow cytotoxicity with the Roundup formulation but not with glyphosate IPA.	Supplementary study confirming previous results.	Rank *et al.*, 1993 Z82234
Micronucleus test in mouse bone marrow; two i.p. administrations with a 24-h interval between; sampling after 6 and 24 h after the final dose	Glyphosate a.i. (99.9% pure) and Roundup (IPA salt with 30.4% glyphosate a.e.; alkyle sulfate surfactant)	0, 300 mg/kg bw (2X150 mg/kg bw/d) for glyphosate; 0, 450 mg/kg bw (2x225 mg/kg bw/d) for Roundup	Weakly positive for glyposate after 24 h and for Roundup at both sampling times. Some evidence of bone marrow cytotoxicity of Roundup.	Supplementary study (methodical deficiencies) revealing an increase in micronucleus frequency, data in contrast to previous results.	Bolognesi *et al.*, 1997 Z59299
SCE assay in human lymphocytes	Glyphosate a.i. (99.9% pure)and Roundup (IPA salt with 30.4% glyphosate a.e.; alkyle sulfate surfactant)	0 - 6 mg/ml for glyphosate; 0, 0.1, 0.33 mg/ml for Roundup	Positive for glyphosate from 1 mg/ml onwards and for Roundup at both concentrations. With Roundup, complete cytotoxicity at concentrations >0.33 mg/ml.	Insufficient data. In addition, a positive result in this assay is of equivocal biological significance against the background of more appropriate mutagenicity studies.	Bolognesi *et al.*, 1997 Z59299
SCE assay in human lymphocytes	Roundup (not specified)	0, 250, 2500, 25000 µg/ml	Weakly positive at the low and mid dose level (for one of two donors). Cytotoxic at the high dose.	see comment above	Vigfusson and Vyse, 1980 TOX9700576 / ASB2012-12044
Alkaline elution assay for DNA single-strand breaks and formation of alkali labile sites in DNA obtained from liver and kidneys of mice following single i.p.administration	Glyphosate a.i. (99.9% pure)and Roundup (IPA salt with 30.4% glyphosate a.e.; alkyle sulfate surfactant)	0, 300 (glyphosate a.i.), 900 (Roundup) mg/kg bw; sampling after 4 and 24 h	Weakly positive after 4 h in both organs suggesting possible transient DNA damage.	Supplementary study (methodical deficiencies). Biological significance equivocal. Results in contrast to the negative outcome of the UDS assay. Effects might be also due to toxicity.	Bolognesi *et al.*, 1997 Z59299

Table B.6.4-26: Overview on published studies on mutagenicity of glyphosate, its salts and formulations (continued)

Test method/ test system	Test material	Dose levels/ Dose range	Results	Remarks	Reference
Investigations for oxida-tive damage in liver and kidney of i.p. treated mice by measuring the number of 8-OHdG (hydroxydesoxyguanosine) adducts	Glyphosate a.i. (99.9% pure)and Roundup (IPA salt with 30.4% glyphosate a.e.; alkyle sulfate surfactant)	0, 300 (glyphosate a.i.), 900 (Roundup) mg/kg bw (single i.p. administra-tion); sampling after 4 and 24 h	Evidence of stimulation of oxidative metabolism in the liver (only glyphosate) or kidney (only Roundup) after 24 h.	Finding not indicative of mutagenicity but could indicate one possible mechanism of toxicity.	Bolognesi *et al.*, 1997 Z59299
Measuring of DNA adducts by means of ^{32}P-postla-beling technique in the liver and kidney of mice following single i.p. administration	Glyphosate IPA salt and Roundup (IPA salt with 30.4% glyphosate a.e.; alkyle sulfate surfactant)	0, 130, 270 mg/kg bw (glyphosate IPA); 0, 400, 500, 600 mg/kg bw (Roundup)	Weak dose-related increase in adducts with Roundup; n adducts seen with the IPA salt alone and in the control group.	Indication of possible DNA damage, however, biolo-gical significance of this finding equivocal. Further characterization of ad-ducts needed. Toxicity not adressed. However, non-mutagenic toxic effects can also cause DNA adducts.	Peluso *et al.*, 1998 TOX1999-318
Comet assay for single-strand DNA breaks in tadpole erythrocytes	Roundup (41% glyphosate IPA; tallowamine surfactant)	0-1.69-6.75-27-108 mg/L water	Dose-related effect on DNA at 6.75 and 27 mg/l; completely lethal at 108 mg/l.	Impact of this formulation on tadpole DNA under environmental conditions indicated. Effect could be also due to toxicity. No relevance for human health risk evaluation.	Clements *et al.*, 1997 Z101728
Test for lethal mutations in Drosophila melanogaster after treatment of larvae	Roundup (assumed to contain 41% glyphosate IPA and tallowamine surfactant); Pondmaster (probably made from 41% glyphosate IPA; alkyle sulfate surfactant)	Not specified but indicated to be around LC_{50} concentration.	Positive.	Not predictive for mutagenicity in mammals. Concentrations used were expected to exhibit high toxicity making evaluation of results very difficult.	Kale *et al.*, 1995 Z73986
Anaphase-telophase allium test for chromosome aberrations in onion root cells	Glyphosate IPA salt (1:1 mixture) and Roundup (48% glyphosate IPA; tallowamine surfactant)	0-720-1440-2880 µg/L (for Roundup calculated as IPA salt)	Roundup: increase in chro-mosome aberrations at the two upper levels indicating rather polyploidy than clastogenicity, no clear dose response Glyphosate IPA: negative	Effects in plant cells not predictive for mutagenicity in mammals. Testing a herbicide for genotoxic effects in plants generally doubtful since cytotoxicity may be expected.	Rank *et al.*, 1993 Z82234
Chromosome aberration (CA) and Sister chromatid exchange (SCE) in human lymphocytes	Glyphosate (purity ≥ 98 %)	0-5.0-8.5-17.0-51.0 µM	Increase in CA and SCE frequency	Increase of SCE not dose related in highest dose group	Lioi et al, 1998a ASB2013-9836

Table B.6.4-26: Overview on published studies on mutagenicity of glyphosate, its salts and formulations (continued)

Test method/ test system	Test material	Dose levels/ Dose range	Results	Remarks	Reference
CA and SCE in bovine lymphocytes	Glyphosate (purity ≥ 98 %)	0-17-85-170 µM	Increase in CA and SCE frequency	Increase of SCE not dose related in highest dose group	Lioi et al, 1998b ASB2013-9837

a.e. = acid equivalents

Studies in test systems for which guidelines exist and/or much experience is available (i.e. Ames test, micronucleus test, SCE assay)

Rank *et al.* (1993, Z82234) studied the mutagenic potential of the herbicide Roundup and of glyphosate isopropylamine salt in different test systems *in vitro* as well as *in vivo*. An Ames test (plate incorporation test) was performed with Roundup only in the *Salmonella typhimurium* strains TA 98 and TA 100 with and without S9 mix for metabolic activation. Evidence of mutagenicity was confined to the strain TA 98 under non-activation conditions as indicated by a slight but significant increase in the mean number of revertants at a concentration level of 360 µg/plate (calculated as IPA salt) which was also confirmed in the repeat experiment. With activation, however, no increase in mutation rate was seen up to this dose level. From the next higher concentration (720 µg/plate) onwards, cytotoxicity became apparent with and without metabolic activation avoiding meaningful evaluation. The study authors also reported a positive result for TA 100 in the presence of S9 mix at a concentation of 720 µg/plate but already the next lower dose of 360 µg had markedly reduced the number of revertants as compared to the control suggesting a cytotoxic effect. Furthermore, a dose response was lacking. Thus, the marked increase in mutation frequency at 720 µg/plate is not reliable. In the second experiment, this dose level was not included. Without activation, concentrations from 720 µg/plate onwards appeared cytotoxic. At lower concentrations, no increase in mutation rate was noted with strain TA 100.
In a micronucleus test in mouse bone marrow erythrocytes following single i.p. administration, Roundup as well as the IPA salt (i.e., a 1:1 mixture of glyphosate technical and isoproplyamine) proved negative up to the highest dose of 200 mg/kg bw. However, with Roundup but not with the glyphosate IPA salt alone, there was evidence of bone marrow cytotoxicity at this top dose level as indicated by a significantly lower percentage of polychromatic erythrocytes.

Comment: According to the publication and to further information submitted by Monsanto, it is assumed that the Roundup formulation used was made of 48% IPA salt, tallowamine surfactant, and water. The study design of the Ames test does not comply with current guideline requirements, e.g. the plate number scored was inconsistent throughout the study. The data obtained are so controversial that a reliable interpretation is not possible. Unfortunately, a complete confirmatory experiment was not performed since repeated testing was confined to the dose of 360 µg/plate and an additional concentration of 180 µg/plate was included. A more extensive study by [redacted] (1992, TOX1999-242, see above in section I) using four S. typhimurium strains including also TA 98 and TA 100 failed to elicit any indications of mutagenicity. This latter trial was conducted in compliance with OECD guideline 471 requirements and is of higher reliability, therefore. Of course the Roundup formulations tested by Rank and her group and by [redacted] were not identical but similar since both contained only the active substance formulated as IPA salt, tallowamine surfactant, and water. The cytotoxicity of Roundup was described by both groups but the respective concentrations were different.

The design of the micronucleus test was also not in compliance with guideline requirements. A direct comparison between results obtained with the IPA salt and Roundup is not feasible since not exactly the same dose levels were used and since there was a difference in sampling time (24 and 48 h post dosing for the IPA experiment versus only at 24 h after administration of Roundup). The negative outcome of previous micronucleus studies with the IPA salt (Rodeo® formulation, [redacted], 1992, TOX9552376) and with a similar Roundup formulation in mice ([redacted], 1992, TOX1999-242) was confirmed. The reported weak bone marrow cytotoxicity occurring already after single i.p. administration of 200 mg Roundup/kg bw (amount calculated as the IPA salt to facilitate comparison) may be considered a possible formulation-related effect when the observations in other micronucleus studies (see section I) are taken into consideration.

In contrast, Bolognesi *et al.* (1997, Z59299) reported positive results from a micronucleus test in mouse bone marrow erythrocytes. Either glyphosate a.i. (declared as 99.9% pure) or a Roundup formulation were administered to Swiss mice once daily by the i.p. route on two consecutive days. Cell samples were harvested at 6 and 24 hours following the final dose. A weak positive effect was observed at total dose levels of 300 mg/kg bw (2 x 150 mg/kg bw/day) after 24 hours for glyphosate and of 450 mg/kg bw (2 x

225 mg/kg bw/day) at both sampling times for Roundup.
Further data in this publication indicated for high purity glyphosate a significant and dose- dependent increase in SCE frequency in human lymphocyte cultures obtained from two female donors from a concentration of 1000 µg/mL onwards. For Roundup, this effect became apparent even at lower concentrations of 100 and 330 µg/mL.

<u>Comment:</u> The outcome of the micronucleus test with glyphosate a.i. is at least surprising since much higher doses of this compound had been tested before and did not reveal indications of clastogenicity (see section B.5.4.2.1 in the monograph). A direct comparison is not possible since the only available test using the i.p. route in which the highest dose of 1000 mg/kg bw proved negative [redacted], 1983, TOX9552369) was performed in rats. The respective study by Rank et al. (1993, Z82234, see above) was conducted in mice but the test material was glyphosate IPA salt and the dose administered was probably too low for meaningful evaluation. However, a number of well-performed micronucleus tests with oral administration to mice is available. Even when the low oral absorption rate of glyphosate (about 30%) is taken into account, the dose levels (up to 5000 mg/kg bw nominal) are much higher than those given by Bolognesi and her co-workers but no convincing evidence of a potential to cause chromosome aberrations in vivo was obtained. It should be emphasized that the increase in the incidence of micronucleated polychromatic erythrocytes as reported in this publication was rather weak only. The test was not performed according to the current OECD guideline. In particular, the number of animals used (three male mice per dose group) was too low since a group size of at least five is recommended. A dose response cannot be assessed since only one dose level was included. The basis for statistical comparison is questionable since it is not clear when the six control animals were sacrificed because only one group mean value was indicated. Due to these deficiencies, this isolated positive finding is not considered to provide sufficient evidence to contravene the previously obtained negative results regarding the active substance.
The same methodical shortcomings apply to the experiment with the Roundup fomulation. The formulation tested is reported to contain 30.4% glyphosate acid equivalents. The a.i. is formulated as the IPA salt. Alkyl sulfate surfactant (MON 8080) is also contained (source of information: Monsanto). The weak positive response is in contrast to the beforementioned GLP-like study by [redacted]. (1992, TOX1999-242) in which Roundup® proved negative. However, these two Roundup formulations were not identical since the glyphosate concentrations were nearly the same but the surfactants contained were different making a direct comparison of the study results difficult. Little is known on mutagenicity of alkyle sulfate itself, however, MON 8080 proved negative in the Ames test but was clearly cytotoxic at relatively low concentrations (see section III of this addendum). Some evidence of bone marrow cytotoxicity was obtained with both Roundup products as indicated by a decrease in the ratio between polychromatic and normochromatic erythrocytes. Cytotoxicity could have also an impact on chromosome aberration frequency. An overall, unequivocal conclusion from the experiment of Bolognesi and her group cannot be drawn, however an actual clastogenic response is not very likely. Even if a positive result could be confirmed, it would not be applicable to products containing other surfactants. A higher SCE frequency is not considered to provide evidence of mutagenicity against the large number of studies in which glyphosate proved clearly negative. The two other studies of this type which have been submitted for purposes of toxicological evaluation of glyphosate ([redacted], 1990, TOX9500269 and [redacted], 1993, TOX9500381, the latter using the IPA salt) did not reveal an increase in sister chromatid exchange frequency but, unfortunately, did not include the high concentrations as tested by the group of Bolognesi (see section B.5.4.1.3 of the monograph). Apart from general doubts about biological significance of a positive result in an SCE assay, some methodical deficiencies became obviously in this publication. For statistical reasons, the number of only two subjects to be included in the study appears too low for meaningful evaluation. Furthermore, the data from two experiments were pooled for the two donors and individual values were not given. Therefore, a possible influence of interindividual variation could not be sufficiently assessed by the reviewer. As shown below, this variation may well reach a considerable level. Again, the positive result obtained with Roundup at least might be also due to cytotoxicity of the formulation avoiding further testing at dose levels exceeding 330 µg/ml since no mitotic cells were present anymore.

Vigfusson and Vyse (1980, TOX9700576) also reported a weak but statistically significant increase in SCE frequency in human lymphocytes obtained from two donors when the cultures were exposed to Roundup

(not specified) at concentrations of 250 and 2500 µg/mL. At the next higher concentration of 25000 µg/mL, the test substance was absolutelycytotoxic.

Comment: The reported increase is doubtful since a dose response was seen in the cultures from one of the two donors only. Furthermore, this increase in SCE frequency over the control was weak only and the statistically increased values in the cultures provided from donor 1 were below the control value from donor 2. Furthermore, possible cytotoxicity was not adressed in this paper. Generally, the SCE assay is not accepted to provide convincing evidence of mutagenicity but is rather a screening test. For clarification, the study authors themselves recommended further mutagenicity tests to be conducted.

Lioi *et al.* (1998a, ASB2013-9836 and 1998b, ASB2013-9837) reported an increase in CA and SCE frequency in human lymphocytes of 3 donors in concetrations between 5 and 51 µM and in bovine lymphocytes between 17 and 170 µM.

Comment: The results are questionable because a number of well performed and validated studies in vitro im mammalian cells and in vivo in mammals did not register comparable effects even in dose levels more than 10 times higher than the doses used in the studies described by Lioi et al. (1998a and 1998b, ASB2013-9836 and 1998b, ASB2013-9837). A replication would be needed to confirm such aberrant results.

Other test systems (Comet assay in tadpole erythrocytes, tests for DNA adducts in rats and mice, *Drosophila melanogaster*, plant cells)

Clements *et al.* (1997, *Z101728*) investigated the genotoxicity of selected herbicides in *Rana catesbeiana* (bullfrog) tadpoles using the single-cell gel DNA electrophoresis test (`Comet´ assay). After a previous study had shown a higher amount of DNA damage in bullfrog tadpoles inhabiting small bodies of water in agricultural areas as compared to non-agricultural regions, the impact of Roundup and some other commonly used herbicides on the DNA of tadpole erythrocytes was investigated in this test system under alkaline conditions. This modification allows the detection of single-stranded DNA breaks which are indicated by an increase in length: width ratio of the DNA mass following electrophoresis. DNA was obtained from tadpole erythrocytes (nucleated cells in amphibians) after the animals had been exposed to different concentrations of Roundup in the surrounding water for 24 hours. Whereas the low dose of 1.69 mg/L did not cause evidence of DNA damage, a clear and dose-dependent effect became apparent at the following concentrations of 6.75 mg/L and 27 mg/L. At 27 mg/L, the effect level caused by the positive control substance methylmethanesulphonate (MMS) was already approached. The intended top dose level of 108 mg/L could not be evaluated since all tadpoles died during the exposure period. According to the study authors, the concentrations tested were well below the recommended application levels suggesting an environmental mutagenic hazard in particular for organisms living in small adjacent bodies of water that are usually the first to be affected by pesticide runoff.

Comment: Generally, information on genotoxic effects of pesticides under natural conditions is scarce and, thus, this test system may provide important information regarding environmental effects. In this special case, however, it appears equivocal whether the observed impact on the DNA was indicative of a true mutagenic effect or rather caused by cytotoxicity. It is known that a positive response in the Comet assay may be not only the result of direct interaction with cellular DNA but can be also mediated by toxic and other effects causing apoptosis or necrosis. Cytotoxicity is not addressed in the publication because it is not directly measured in this test system. A certain degree of general toxicity can be assumed since the highest dose was completely lethal to the tadpoles. This effect could be well in line with the toxicity of certain glyphosate formulations to aquatic organisms as reported in the monograph. The Roundup product tested by Clements et al. was made of 41% glyphosate IPA salt and MON 0818, i.e. the tallowamine surfactant which is already known to cause toxic effects in different test systems in vitro as well as in vivo. Of course, although there is some evidence of a cytotoxic mechanism behind the positive result in the Comet assay, a direct impact of the test compound on the DNA cannot be completely excluded.
At this time, it is not clear whether a positive result of this test obtained in tadpole erythrocytes, even if it was actually due to mutagenicity, would be of any relevance to human beings exposed. In particular, this

is doubtful when the strong body of evidence that neither glyphosate nor its formulations are mutagenic as coming from many studies in various test systems is taken into consideration. Thus, the outcome of the Comet assay should be rather used for environmental hazard evaluation only. Again, the application of results obtained with one formulation to others must be critically regarded.

A possible impact on the DNA was also investigated by Bolognesi *et al.* (1997, Z59299) in further experiments. A transient but significant effect towards DNA damage in liver and kidney was noted in the alkaline elution assay after glyphosate (300 mg/kg bw) or Roundup (900 mg/kg bw) had been administered once by the i.p. route to mice. This assay may indicate the induction of DNA single-strand breaks and alkali labile sites. A test for DNA oxidative damage suggested glyphosate and the formulation Roundup to stimulate oxidative metabolism in the liver (glyphosate) or in the kidney (Roundup) at 24 hours after application.
In a subsequent study from the same institute (Peluso *et al.*, 1998, TOX1999-318), a low incidence of DNA adducts was found by means of the very sensitive ^{32}P-postlabeling technique in the liver and kidney of mice following single intraperitoneal administration of Roundup. All tested concentrations (400, 500 and 600 mg Roundup/kg bw, corresponding to 122, 152, and 182 mg glyphosate salt/kg bw) caused DNA adducts in both organs. A dose response was to be seen. In contrast, treatment with the vehicle (i.e., a DMSO/olive oil mixture) and with doses of 130 and 270 mg glyphosate IPA salt/kg bw did not result in DNA adduct formation.

Comment: The data from the tests for DNA damage and stimulation of oxidative metabolism (Bolognesi et al., 1997, Z59299) are hardly to interpret since the results are given in summary figures only which are based on pooled individual data. There are reporting inconsistencies, e.g. it is not clear how many animals were actually used for testing. A positive control substance was not included. Taking into account that glyphosate proved negative in the UDS assay which is generally accepted to indicate a more frequent occurrence of DNA damage and repair (see section B.5.4.1.3 in the monograph), the published findings are not considered to provide convincing evidence of an interaction with the DNA. Positive results in the alkaline elution assay may also occur as a result of toxic but not-mutagenic effects. Stimulation of oxidative metabolism is not a sign of mutagenicity but may elucidate a possible mechanism behind toxic effects.
The results of Peluso (1998, TOX1999-318) and his group suggest a direct effect on the DNA. It has been shown that the observed effects were related to administration of the formulation only but not to glyphosate IPA salt. Biological significance of the results is equivocal. Generally, it is questionable whether findings after i.p. administration can be applied to more realistic exposure conditions. Of course, the occurrence of such effects also after oral intake would be much more relevant for human health evaluation. Furthermore, some deficiencies of this study make a definitive assessment difficult. It is rather equivocal what a low incidence of DNA adducts per animal as compared to no adducts in the control group actually means since a positive control substance was not included. The degree of variation between the animals is not known because only mean values for the groups' comprizing of 3 to 6 mice were reported and individual values are not given but would be helpful for interpretation of the results. Another point of concern is the lacking information on toxicity. At least with Roundup, one could expect marked general toxicity when the observations reported from the micronucleus tests (see section I of this addendum) and from the acute intraperitonal toxicity studies (see section B.5.2.4 in the monograph) were taken into account. It is known that DNA adducts may be formed not only as a result of direct interaction of cellular DNA with chemicals but also occur naturally or can be even related to a treatment-dependent increase in endogenous metabolites. Thus, further characterisation of these adducts and clarification of their nature would be desirable.

Kale *et al.* (1995, Z73986) examined nine agricultural chemicals in the sex-linked recessive lethal test in *Drosphila melanogaster* for their ability to cause genotoxic damage to the germ cells leading to lethal mutations in the subsequent generations. The group of test compounds included two insecticides and seven herbicides among those were the glyphosate formulations Roundup and Pondmaster. Unlike the generally used method of feeding the test substance to adult males only, larvae were treated in this experiment. This modification was expected by the study scientists to improve the sensitivity of the test system. All products tested proved positive.

Comment: This test system is not considered predictive for mutagenicity in mammals. Generally, tests in Drosophila are considered helpful for screening purposes. For glyphosate, however, a large database on the basis of much more reliable test systems does exist. Furthermore, since lethal changes in spermatogonia and spermatocytes were the relevant endpoint, it appears difficult to distinguish between mutagenicity and general toxicity. The dose level tested was not specified but it is stated in the publication that concentrations around the LC_{50} were used. At such a high dosage, some toxicity must be expected.

An anaphase-telophase allium test in onion root cells was conducted by Rank *et al.* (1993, Z82234) to detect a possible induction of chromosome aberrations. The exposure period was 24 hours. In this plant system, a significant increase in the occurrence of chromosome aberrations was noted at the two upper dose levels when Roundup was tested. However, there was no dose response, since the total incidence of aberrations at 1440 µg/L was twice that seen at 2880 µg/L. The authors attributed this lack of a clear dose response to cytotoxicity, however, mitotic index was not dramatically reduced (24.2 in the mean at 2880 µg/L versus 28.2 at 1440 µg/L). According to the investigators, the type and pattern of aberrations suggest rather spindle disturbances than clastogenicity in particular when compared to the effects caused by the positive control substance MMS. In contrast, the glyphosate IPA salt did not increase the frequency of chromosome aberrations in this experiment.

Comment: The Roundup product tested was made of the IPA salt, tallowamine surfactant, and water (for details see description of the Ames test and the micronucleus test portions of this study above). The more pronounced effect of the formulation as compared to the IPA salt could be explained by an improved uptake by the onion root cells as mediated by the surfactant. However, genotoxic or aneugenic effects in a plant system are generally not accepted to be indicative of mutagenicity in mammals. For glyphosate and its formulations, a number of well-performed studies in mammals is available for this purpose. Generally, it appears questionable whether an herbicide should be tested for mutagenicity in a plant cell system since at least a certain degree of cytotoxicity must be expected.

Assessment

In the whole, the published data are not sufficient to provide convincing evidence of mutagenic effects caused by glyphosate or its formulations. Of cours, the effects observed in different test systems cannot be totally ignored. Looking for an explanation, the data obtained in the mutagenicity studies with formulations (see section I) must be also considered. Taking all the findings together, the effects reported in the literature appear rather due to cytotoxic properties of the formulations than to a genotoxic mode of action. The same conclusion was also reached by the Danish EPA in an assessment (Rasmussen, 1997, ASB2013-9671) which was made available to the Rapporteur. It has been already known before, that cytotoxicity is much more pronounced with glyphosate formulations than with the active substance and, therefore, is probably due to by-products or impurities. In particular, surfactants are the agents to be suspected for causing such effects.

There are even data suggesting the possiblity of a direct interaction of glyphosate formulations with cellular DNA in some test systems. This is evidenced by a higher frequency of DNA adducts in mouse liver and kidneys following i.p. administration (Peluso *et al.*, 1998, TOX1999-318) as well as from the Comet assay in tadpole erythrocytes (Clements *et al.*, 1997, Z101728). Since glyphosate active ingredient is apparently devoid of a DNA damaging potential (see monograph), these effects, if occurring, can be certainly assumed to be related to co-formulants. Damage to the DNA is not essentially indicative of mutagenicity but could also result from cytotoxicity. Irrespective of the origin of these effects on DNA level, they appear to be confined to very special exposure situations only and not to represent a health hazard to human beings.

B.6.1.5 Published data (released since 2000)

B.6.4.8.1 Introduction

An earlier review of the toxicity of glyphosate and the original Roundup™ formulation concluded that neither glyphosate nor the formulation pose a risk for the production of heritable/somatic mutations in

humans (Williams *et al.*, 2000, ASB2012-12053). This review of subsequent glyphosate genotoxicity publications includes analysis of study methodology and incorporation of all the findings into a weight of evidence for genotoxicity. Two publications provided limited additional support for the conclusion that glyphosate and glyphosate based formulations (GBFs) are not active in the gene mutation assay category. The weight of evidence from *in vitro* and *in vivo* mammalian chromosome effects studies supports the earlier conclusion that glyphosate and GBFs are predominantly negative for this end point category. Exceptions are mostly for unusual test systems but there are also some unexplained discordant positive results in mammalian systems. Several reports of positive results for the SCE and comet DNA damage endpoints have been published for glyphosate and GBFs. The data suggest that these DNA damage effects are likely due to cytotoxic effects rather than DNA reactivity. This weight of evidence review concludes that there is no significant *in vivo* genotoxicity and mutagenicity potential of glyphosate or GBFs that would be expected under normal exposure scenarios.

B.6.4.8.1 General review and analysis considerations

The published studies for review consideration were identified by literature searches for published reports containing references to glyphosate or glyphosate based formulations (GBFs) that also contained searchable terms which indicated that genotoxicity studies were performed. Literature search utilised Chemical Abstracts (provided by Chemical Abstracts Service, a division of the American Chemical Society) and Web of Knowledge (Thompson Reuters), using the following modules: Web of ScienceSM, BIOSIS Previews®, MEDLINE®, and CAB Abstracts® (CABI) abstracting services. Search criteria were as follows (glyphosate acid and the various salts): glyphosat* OR glifosat* OR glyfosat* OR 1071-83-6 OR 38641- 94-0 OR 70901-12-1 OR 39600-42-5 OR 69200-57-3 OR 34494-04-7 OR 114370-14-8 OR 40465-66-5 OR 69254-40-6 OR (aminomethyl w phosphonic*) OR 1066-51-9. Each identified publication was evaluated to verify that it contained original results of one or more genotoxicity studies on glyphosate or GBFs. Emphasis was placed on publications in peer- reviewed journals and abstracts or other sources with incomplete information were not considered. Reviews without original data were not considered for evaluation; however, these reviews were examined to determine if there were any cited publications that had not been detected in the literature searches.

Each relevant publication was examined using several criteria to characterize the scientific quality of the reported genetic toxicology studies. Useful, objective criteria for this purpose were international guidelines for genetic toxicology studies developed by expert groups. These include principles for conducting studies, reporting results and analyzing and interpreting data. Some of the principles of the guidelines are generally applicable to categories of studies or all studies while others are specific for a particular type of test system and end point. Some of the specific types of studies encountered in the review do not yet have international guidelines; however, some of the guideline elements should be generically applicable to these studies. The guidelines for genetic toxicology tests developed for the Organisation for Economic Cooperation and Development (OECD) are a pre-eminent source of internationally agreed and expert guidelines. Other regulatory international and national regulatory genetic toxicology testing guidance are usually concordant with the OECD guidelines. Table B.6.4-28 presents some key OECD guideline criteria that were found to be relevant to analysis of the studies considered in this review.

Comparison of the published studies to the criteria in guidelines used for regulatory purposes does not represent an absolute judgment standard but it does serve to provide one means of characterization of the various published studies. Some of the criteria are rarely met in scientific publications. For example, data for individual cultures and individual animals are not commonly included in publications in scientific journals. These data are presumably collected but are usually summarised as means with a measure of variance for the treatment and control groups. This is not considered to be a significant omission in a scientific publication. However, other guideline features are more essential in demonstrating scientific quality standards and should be considered as having greater weight in evaluating a study. For example, there are consistent recommendations that assays involving visual scoring (e.g. chromosome aberration, micronucleus and sister chromatid exchange) should use slides that are independently coded so that scoring is performed without knowledge of the treatment or control group being scored. This guidance is good scientific practice and studies that do not include a description of coding or "blind" scoring in the methodology would appear to have a deficiency either in the methodology or the description of the methodology used. Other examples of guideline features that have clear experimental scientific value are

the use of concurrent negative and positive controls and concurrent measurement and reporting of toxicity endpoints in main experiments, especially in in vitro mammalian cell assays.
Test materials, as described in the publications, were reviewed by industry experts to identify any publicly available and useful information on composition for the reported formulations to assist in interpreting the relevance of findings to glyphosate and/or formulation components. It should be noted that a common problem encountered in the published literature is the use of the terms "glyphosate", "glyphosate salt" or "Roundup" to indicate what may be any GBF that contains additional components such as surfactants. Published results from studies with different formulations have sometimes been incorrectly or inappropriately attributed to the active ingredient. The original Roundup formulation (MON 2139), containing 41% isopropyl amine glyphosate salt and 15.4% MON 0818 (a polyethoxylated tallowamine based surfactant blend), is no longer sold in many markets. However, other glyphosate based formulations are sold under the Roundup brand name with varying glyphosate forms, concentrations and surfactant systems. Clear identification of the test material is very important in toxicology studies because toxicity of formulations can be dramatically different than the active ingredient. The fact that test materials identified as Roundup formulations may actually have different compositions should be considered when comparing results of different studies. A major consideration, especially for DNA damage endpoints and for in vitro mammalian cell assays, is an assessment of whether observed effects might be due to toxicity or extreme culture conditions rather than indicating DNA-reactive mediated processes. Relevant considerations include control of medium pH and osmolality for in vitro mammalian cell studies and whether effects are observed only at cytotoxic doses or in association with severe toxicity to the test system. Other important generic considerations in evaluating experimental results of each published study are evidence of experimental reproducibility and whether a biologically plausible dose response has been demonstrated.

Table B.6.4-28: Genetic Toxicology Test Guideline Criteria

Area	Guidance	Reference
All studies	Test material purity and stability should be reported	OECD 471 (1997)
	Concurrent negative and positive controls should be included with each assay	OECD 473 (1997)
Assays with visual scoring	All slides should be independently coded before analysis (i.e. scored without knowledge of the treatment or control group)	OECD 473 (1997) OECD 479 (1986)
In vitro mammalian cell assays	Assay should be usually be conducted in the presence and absence of an appropriate exogenous metabolic activation system	OECD 473 (1997)
	Cytotoxicity should be determined in the main experiment	
	At least three analyzable concentrations should be used	
	Maximum dose determined by toxicity or 5 µg/mL, 5 mg/mL or 10 mM for soluble non-toxic test materials	
	Individual culture data should be provided	
In vivo mammalian assays	Five analyzable animals per group. Single sex may be used if there are no substantial difference in toxicity between sexes	OECD 475 (1997) OECD 474 (1997)
	Limit dose for non-toxic substances of 2000 mg/kg for treatments up to 14 days and 1000 mg/kg for treatments longer than 14 days	
In vitro chromosome aberration	Treatment for 3-6 hours in one experiment and harvest at 1.5 cell cycles. If negative a second experiment with continuous treatment for 1.5 cell cycles	OECD 473 (1997)
	Scoring of at least 200 metaphases ideally divided between duplicate cultures	
In vitro sister chromatid exchange	Treatment for 1-2 hours up to two cell cycles with harvest after two cell cycles in the presence of bromodeoxyuridine	OECD 479 (1986)
	Scoring of 25 metaphases per culture (50 per treatment group)	
In vitro micronucleus	Most active agents detected by treatment for 3-6 hours with harvest at 1.5-2 cell cycles after treatment. An extended treatment for 1.5-2 cycles in the absence of metabolic activation is also used	OECD 487 (2010)
	Scoring of at least 2000 binucleated cells or cells for micronuclei for each treatment or control group	

In vivo bone marrow chromosome aberration	Single treatment with first harvest at 1.5 cell cycles after treatment and second harvest 24 hour later or single harvest 1.5 cycles after last treatment for multiple daily treatments	OECD 475 (1997)
	Three dose levels usually recommended except when limit dose produces no toxicity	
	Concurrent measures of animal toxicity and toxicity to target cells	
	At least 100 cells analyzed per animal	
	Individual animal data should be reported	
In vivo erythrocyte micronucleus	Three dose levels for first sampling time	OECD 474 (1997)
	Treatment once with at least 2 harvests usually at 24 and 48 h after treatment or one harvest 18-24 h after final treatment if two or more daily treatments are used	
	Scoring of 2000 immature erythrocytes per animal or 2000 mature erythrocytes for treatments of 4 weeks or longer	

Table B.6.4-29 presents a summary of genotoxicity test results for glyphosate and GBFs published subsequent to Williams *et al.* (2000, ASB2012-12053). Test results are organised by the major genotoxicity assay categories of gene mutation, chromosome effects and DNA damage and other end points. Major features presented for each publication are the assay endpoint, the test system, the test material, the maximum dose tested and comments relevant to the reported conduct and results of the assay. For brevity, earlier reviewed individual publications of genotoxicity study results are referred to by citation of (Williams *et al.*, 2000, ASB2012-12053) rather than the original references reviewed in (Williams *et al.*, 2000, ASB2012-12053).

Genetic toxicology studies of glyphosate and glyphosate formulations published on or after 2000

End point	Test System	Test Material	Maximum Dose	Result	Comment[a]	Reference
In Vitro Gene Mutation						
Point mutation	Ames strains	Perzocyd 10 SL formulation	2 µg/plate (toxic)	Negative	TA1535 not used	Chrusciels ka *et al.*, 2000, (ASB2013-9830)
Wing spot test	Drosophila	Glyphosate (96%)	10 mM in larval stage	Negative/ inconclusive[c]	Negative or inconclusive in crosses not sensitive to recombination events	Kaya *et al.*, 2000, (ASB2013-9832)
In Vitro Chromosome Effects—Mammalian Systems						
Cytokinesis block micronucleus	Bovine lymphocytes	Glyphosate formulation (62% glyphosate Monsanto source)	560 µM 48 h –S9	Positive?	PH, MA, SC, TO	Piesova, 2004 (ASB2012-12001)
Cytokinesis block micronucleus	Bovine lymphocytes	Glyphosate formulation (62% glyphosate Monsanto source)	560 µM 48 h –S9 2 h –S9 2 h +S9	Positive? Negative Negative	PH, SC, TO	Piesova, 2005 (ASB2012-12000)
Chromosome aberration	Mouse spleen cells	herbazed formulation	50 µM?	Positive	Concentrations used not clear. PH, MA, SC, TO, RE	Amer *et al.*, 2006 (ASB2012-11539)

Genetic toxicology studies of glyphosate and glyphosate formulations published on or after 2000

Chromosome aberration	Bovine lymphocytes	Glyphosate formulation (62% glyphosate) Monsanto source	1.12 mM (toxic) (24 h)	Negative	Chromosome 1 FISH analysis. PH, MA, PC, SC, TO, RE	Holeckova, 2006 (ASB2012-11847)
Chromosome aberration	Bovine lymphocytes	Glyphosate formulation (62% glyphosate) Monsanto source	1.12 mM (toxic) (24 h)	Negative	PH, MA, SC, RE	Sivikova and Dianovsky, 2006 (ASB2012-12029)
Chromosome aberration	Human lymphocytes	Glyphosate (96%)	6 mM (not toxic)	Negative	MA, IC, RE	Manas *et al.*, (2009 ASB2012-11892)
Cytokinesis block micronucleus	Human lymphocytes	Glyphosate (technical, 96%)	580 µg/mL (toxic) (est. 3.43 mM)	Negative (-S9) Positive (+S9)	SC, RE	Mladinic *et al.*, 2009 (ASB2012-11906)
Cytokinesis block micronucleus	Human lymphocytes	Glyphosate (technical, 96%)	580 µg/mL (toxic) (est. 3.43 mM)	Negative (-S9) Positive (+S9)	SC, RE	Mladinic *et al.*, 2009 (ASB2012-11907)
In Vitro Chromosome Effects— Non Mammalian Systems						
Chromosome aberration	Onion root tip meristem	Roundup formulation (Bulgaria)	1% active ingredient (estimated 4.4-5.9 mM)	Negative	TO, IC, RE	Dimitrov *et al.*, 2006 (SB2012-11607)
Micronucleus	Onion root tip meristem	Roundup formulation (Bulgaria)	1% active ingredient (estimated 4.4-5.9 mM)	Negative	TO, RE	Dimitrov *et al.*, 2006 (SB2012-11607)
In Vivo Chromosome Effects—Mammalian Systems						
Bone marrow erythrocyte micronucleus	Mouse	Glyphosate	300 mg/kg i.p. Perzocyd 10 SL formulatio n	Negative Negative	DL, TO, SC, IM, RE DL, TO, SC, IM, RE	Chrusciels ka *et al.*, 2000, (ASB2013-9830)
Bone marrow erythrocyte micronucleus	Mouse	Roundup 69 formulation	2 x 200 mg/kg i.p.	Negative	TO, SC, IE, RE	Coutinho do Nasciment o and Grisolia, 2000 (ASB2013-11477)

[a] MA, Mammalian metabolic activation system not used and short exposure not used; PH, no indication of pH or osmolality control;
DL, less than three dose levels used; PC, no concurrent positive control;
TO, no concurrent measurement of toxicity reported or toxicity not observed for highest dose level;
SC, independent coding of slides for scoring not indicated for visually scored slides;
IC, less than 200 cells scored per treatment or less than 100 metaphases scored per animal for chromosome aberrations;
IE, less than 2000 erythrocytes scored per animal;
RE, results not reported separately for replicate cultures or individual animals;

[b] Positive for small wing spots only in one cross. Negative or inconclusive for all spot categories for three other crosses.

[c] Statistically significant increase in micronucleated PCE frequency only at mid dose level but overall result judged negative.

A new comprehensive review on genotoxicity studies of glyphosate and glyphosate-based formulations was submitted by Kier and Kirkland (2013, ASB2014-9587). The authors concluded that an overwhelming preponderance of negative results in well-conducted bacterial reversion and *in vivo* mammalian micronucleus and chromosomal aberration assays indicates that glyphosate and typical GBFs are not genotoxic in these core assays. Negative results for *in vitro* gene mutation and a majority of negative results for chromosomal effect assays in mammalian cells add to the weight of evidence that glyphosate is not typically genotoxic for these endpoints in mammalian systems. Mixed results were observed for micronucleus assays of GBFs in non-mammalian systems. Reports of positive results for DNA damage

endpoints indicate that glyphosate and GBFs tend to elicit DNA damage effects at high or toxic dose levels, but the data suggest that this is due to cytotoxicity rather than DNA interaction with GBF activity perhaps associated with the surfactants present in many GBFs. Glyphosate and typical GBFs do not appear to present significant genotoxic risk under normal conditions of human or environmental exposures.

B.6.4.8.1 Structure Activity Analysis

B.6.4.8.1 Gene Mutation

As reviewed by Williams *et al.*, (2000, ASB2012-12053), most gene mutation studies for glyphosate and GBFs were negative. Gene mutation assays included numerous Ames/*Salmonella* and *E. coli* WP2 bacterial reversion assays, *Drosophila* sex-linked recessive lethal assays and a CHO/HGPRT *in vitro* mammalian cell assay. Of fifteen gene mutation assays reported, there were only two positive observations. A reported positive Ames/*Salmonella* result for Roundup formulation was not replicated in numerous other studies. There was one report of a positive result for a GBF in the *Drosophila* sex-linked recessive lethal assay but this was contradicted by a negative result for the same GBF in this assay reported by another laboratory. Further, the positive study had some features that hampered interpretation, including the lack of concurrent negative controls (Williams *et al.*, 2000).

Subsequent to the Williams *et al.* (2000, ASB2012-12053) review only two gene mutation studies have been reported (Table B.6.4-29). One negative Ames/*Salmonella* assay result was reported for a GBF of undefined composition, Percozyd 10 SL (Chruscielska *et al.*, 2000, ASB2013-9820). Although this result is consistent with a large number of negative Ames/*Salmonella* results for glyphosate and GBFs, the reported study results have significant limitations. One of the recommended test strains, TA1535, was not used and results were only presented as "-" without presentation of revertant/plate data. A positive result for glyphosate was reported in the *Drosophila* wing spot assay which can indicate both gene mutation and mitotic recombination endpoints (Kaya *et al.*, 2000, ASB2013-9832). Small increases in small wing spot frequencies were observed in one of four crosses of larvae treated with up to 10 mM glyphosate. The lack of a positive response in the balancer-heterozygous cross offspring, which are insensitive to mitotic recombination events, suggests that there is no evidence for effects on gene mutation endpoint events such as intragenic mutations or deletions in this publication.

These gene-mutation publications add very limited data to the weight of evidence conclusion that glyphosate and GBFs do not pose significant risk for gene mutation

B.6.4.8.1 Chromosome effects

Assays to detect chromosome effects such as structural chromosome aberrations and micronucleus incidence constitute a second major genotoxicity end point category. A large number of publications with chromosome effects endpoints have been reported since the Williams *et al.* (2000, ASB2012-12053) review. These are described in Table B.6.4-29 and are separated into various test system categories which include *in vitro* cultured mammalian cell assays, *in vitro* tests in non-mammalian systems, *in vivo* mammalian assays and *in vivo* assays in non-mammalian systems. A *Drosophila* wing spot test (discussed previously) is also included in this category because results are relevant to somatic recombination.

B.6.4.8.1.1 *In vitro* chromosome effects

Two human and one bovine *in vitro* peripheral lymphocyte chromosome aberration studies of glyphosate were considered in the earlier review (Williams *et al.*, 2000, ASB2012-12053). One human lymphocyte *in vitro* study had negative results for glyphosate tested up to approximately 2-3 mM (calculated from reported mg/ml) in the absence and presence of an exogenous mammalian activation system. The other two studies with human and bovine lymphocytes and no metabolic activation system reported positive results at concentrations more than two orders of magnitude lower. The earlier review noted several other unusual features about the positive result studies including an unusual exposure protocol and discordant positive results for another chemical found negative in other laboratories.

As indicated in Table B.6.4-29 both positive and negative results have been reported for glyphosate and GBFs in the nine *in vitro* chromosome effects assays published after the Williams *et al.* (2000, ASB2012-12053) review. It is noteworthy that many of these studies have various deficiencies in conduct or reporting

compared to internationally accepted guidelines for conduct of *in vitro* chromosome aberration or micronucleus studies (see Table B.6.4-28). Perhaps the most significant deficiency was that coding and scoring of slides without knowledge of the treatment or control group was not indicated in seven of nine publications. This could be a deficiency in conducting the studies or perhaps a deficiency in describing methodology in the publications. Other common deficiencies included failure to indicate control of exposure medium pH, no use of exogenous metabolic activation and no reporting of concurrent measures of toxicity.

Results for glyphosate active ingredient

Three publications reported testing of technical glyphosate for micronucleus or chromosome aberration endpoints in cultured human lymphocytes (Manas *et al.*, 2009, ASB2012-11892; Mladinic *et al.*, 2009, ASB2012-11906; Mladinic *et al.*, 2009, ASB2012-11907). Negative results for the micronucleus or chromosome aberration end points were observed in the absence of exogenous metabolic activation (S9) in all three publications. The maximum exposure concentration in the absence of S9 was in the range of 3-6 mM in these studies.

Two publications by one author reported cytokinesis block micronucleus results for cultured bovine lymphocytes treated with what was reported as 62% by weight isopropyl amine salt of glyphosate from a Monsanto Belgium source (Piesova, 2004, ASB2012-12001; Piesova, 2005, ASB2012-12000). This test material appears to be a manufacturing batch of the isopropylamine salt of glyphosate in water without surfactants, which is not sold as a GBF. In one publication no statistically significant increases in binucleated cell micronucleus frequency were observed with 24 hours of treatment (Piesova, 2004, ASB2012-12001). For 48 hours of treatment a statistically significant increase in micronucleus frequency was observed in one donor at 280 µM but not at 560 µM and in a second donor at 560 µM but not 280 µM. The second publication reported negative results for the cytokinesis block micronucleus assay in bovine lymphocytes incubated with glyphosate formulation up to 560 µM for two hours in the absence and presence of a mammalian metabolic activation system (Piesova, 2005, ASB2012-12000). This publication also reported positive results for 48 hours of treatment without S9. Curiously, in this second publication the same inconsistent dose response pattern was observed in which a statistically significant increase in micronucleus frequency was observed in one donor at 280 µM but not at 560 µM and in a second donor at 560 µM but not 280 µM. The lack of a consistent dose response pattern between donors suggests that the results with 48 hours of treatment are questionably positive.

Two other publications found negative results for the chromosome aberration endpoint in cultured bovine lymphocytes treated with what appears to be the same test material of 62% by weight isopropylamine salt of glyphosate from a Monsanto Belgium source, (Holeckova, 2006, ASB2012-11847; Sivikova and Dianovsky, 2006, ASB2012-12029). Both the studies used a maximum concentration of 1.12 mM which was reported to cause a decrease in mitotic inhibition of >50%. These two studies have several limitations including that an exogenous mammalian metabolic activation system was not used for chromosome aberration and scoring was not reported to be on coded slides. In addition, Holeckova (2006, ASB2012-11847) only examined effects detectable by staining of chromosome 1 and did not report positive control results (Holeckova, 2006, ASB2012-11847). Despite these limitations and the variable donor results, the results from these two studies are generally consistent with a lack of chromosome aberration effects of the isopropylamine salt of glyphosate on *in vitro* cultured mammalian cells in several experiments using high, toxic dose levels and exposures of 2-24 hours in the absence of S9.

One laboratory reported increases in cytokinesis-blocked micronucleus frequency in cultured human lymphocytes exposed to glyphosate for 4 hours in the presence of an exogenous human liver metabolic activation system (S9) in two publications (Mladinic *et al.*, 2009a; Mladinic *et al.*, 2009b). In both publications a statistically significant increase in micronuclei was observed with S9 at the highest dose level of glyphosate tested (580 µg/mL, ≈ 3.4 mM). Increased proportions of centromere- and DAPI-positive micronuclei were observed for the high dose with S9 suggesting that the induced micronuclei were derived from chromosomes rather than chromosome fragments. Statistically significant increases in the frequency of nuclear abnormalities (buds and bridges) and DNA strand breakage were also observed at the highest dose tested in both publications. In parallel experiments cytotoxic effects such as early apoptosis, late apoptosis and necrosis were observed and these effects were uniquely or preferentially observed in the presence of S9 and at the highest dose level tested (Mladinic *et al.*, 2009, ASB2012-11906). Also, the

negative control level of such end points as necrosis and alkaline SCGE tail moment was significantly increased in the presence of S9 (Mladinic *et al.*, 2009, ASB2012-11906). It should be noted that glyphosate is mostly excreted unmetabolised *in vivo* in mammals with only very small levels of aminomethylphosphonic acid (AMPA) or an AMPA-related structure observed (Anadon *et al.*, 2009, ASB2012-11542; Brewster *et al.*, 1991, TOX9551791). These observations suggest that the observations of S9 mediated effects by Mladinic *et al.* are not likely to be due to *in vivo* relevant metabolites. The preponderance of *in vitro* genotoxicity studies conducted with exogenous mammalian metabolic activation systems has been negative, including a previously reviewed chromosome aberration study in human lymphocytes conducted up to a similar dose level (Williams *et al.*, 2000, ASB2012-12053) and a bovine lymphocyte cytokinesis block micronucleus study (Piesova, 2005, ASB2012-12000). Overall these results suggest the possibility of a weak aneugenic rather than clastogenic (chromosome breaking) effect occurring in the presence of S9 at high dose levels of glyphosate. The pattern of activity as well as the failure to observe activity in several other *in vitro* genotoxicity assays conducted with S9 suggests that the activity observed in the Mladinic *et al.* studies does not have a significant weight of evidence for *in vitro* genotoxicity and is not likely to be relevant to *in vivo* genotoxicity.

The recently published results for mammalian *in vitro* chromosome aberration and micronucleus assays demonstrate a weight of evidence that technical glyphosate and glyphosate salt concentrates are negative for these end points in cultured mammalian cells in the absence of an exogenous mammalian metabolic activation system. Five publications from four laboratories report negative *in vitro* mammalian cell chromosome or micronucleus results in the absence of exogenous activation while three publications from two laboratories report positive results. These results reinforce the Williams *et al.* (2000, ASB2012-12053) conclusion that positive chromosome aberration results reported for glyphosate in cultured human lymphocytes in the absence of an exogenous metabolic activation system are aberrant. Recent reports of positive chromosome aberration and micronucleus results for glyphosate in the presence of an exogenous mammalian activation system in cultured human lymphocytes in one laboratory (Mladinic *et al.*, 2009, ASB2012-11906; Mladinic *et al.*, 2009, ASB2012-11907) have no substantial reproducibility verification from other laboratories in the recent *in vitro* chromosome effects studies considered in this review because most of the studies performed by other laboratories (Table B.6.4-29) did not employ an exogenous mammalian activation system. These results are discordant with one previously reviewed result demonstrating a negative result for glyphosate in cultured human lymphocytes with mammalian metabolic activation using the chromosome aberration endpoint (Williams et al 2000, ASB2012-12053) and a negative result in the presence of S9 for the micronucleus endpoint in bovine lymphocytes (Piesova, 2005, ASB2012-12000). The numerous consistent negative results for glyphosate and GBFs in gene mutation studies which employed exogenous mammalian metabolic activation and careful examination of the data suggests that the positive results indicate a possible threshold aneugenic effect associated with cytotoxicity rather than a DNA-reactive mechanism resulting in chromosome breakage. Thus, the weight evidence for the *in vitro* chromosome effect assays indicates a lack of DNA-reactive clastogenic chromosome effects.

Results for GBFs

Amer *et al.* (2006, ASB2012-11539) reported positive *in vitro* chromosome aberration effects in mouse spleen cells for a formulation described as herbazed, which was reported to contain 84% glyphosate and 16% solvent, an unusually high glyphosate concentration for a formulation. The test material is not further characterised, lacking description of the glyphosate salt form and inert ingredients. The glyphosate concentrations used in the study are not clear because there are different descriptions of the concentration units (M or M glyphosate/ml medium) in the publication. Thus, the maximum concentration might have been 5×10^{-5} M (50 µM) or 5×10^{-5} M glyphosate/mL medium (50 mM). The former concentration, which was reported as toxic, would indicate effects at concentrations well below those typically found toxic for GBFs in cultured mammalian cells. The latter level of 50 mM would be well in excess of the limit level of 10 mM recommended in OECD guidelines (OECD473, 1997). In addition to a question about the concentration used there are several other limitations to the reported study including no indication that pH of treatment solutions was controlled, no use of a mammalian metabolic activation system, no reported concurrent toxicity measurements and no reported use of coded slides for scoring. Given these limitations,

the uncertainty about the concentrations used and the nature of the test material, these results should not be considered to have significant relevance or reliability with respect to glyphosate or GBFs.
In addition to *in vitro* mammalian cell studies there is also a report of negative results for the chromosome aberration and micronucleus endpoints in onion root tips incubated with a Roundup formulation (Dimitrov *et al.*, 2006, ASB2012-11607). The maximum exposure concentration (stated as 1% active ingredient) is estimated to be on the order of 4-6 mM. This study did not employ an exogenous mammalian metabolic activation system; however, it does provide evidence for a lack of chromosome effects for glyphosate and a GBF in a non- mammalian *in vitro* system. The result agrees with earlier reported negative onion root tip chromosome aberration results for glyphosate but is discordant with earlier reported positive results for a Roundup GBF in this system (Williams *et al.*, 2000, ASB2012-12053).

B.6.4.8.1.2 In vivo Chromosome Effects—Mammalian Systems

The Williams *et al.* (2000, ASB2012-12053) glyphosate toxicityreview presented results from *in vivo* mammalian chromosome effect assays. Results from several mouse bone marrow erythrocyte micronucleus studies of glyphosate and GBFs (e.g. Roundup, Rodeo and Direct) were negative for micronucleus induction. These included studies from different laboratories mostly following modern guidelines. The intraperitoneal (i.p.) route was used for most of the negative studies and maximum doses for many of the studies were toxic or appropriately close to LD_{50} values. In addition to i.p. studies a 13 week mouse feeding study was also negative for the micronucleus endpoint with an estimated maximum daily glyphosate dose of over 11,000 mg/kg/day. There was one published report of a weak positive mouse bone marrow micronucleus response observed for glyphosate and Roundup GBF. This study, which employed a smaller number of animals per group than other negative studies, was clearly aberrant from the numerous other negative studies not only in micronucleated cell frequency finding but also the finding of altered polychromatic erythrocyte to normochromatic erythrocyte (PCE/NCE) ratios. The overall weight of evidence from the earlier reviewed studies was that glyphosate and GBFs were negative in the mouse bone marrow erythrocyte micronucleus assay. The earlier review also noted a negative mouse dominant lethal result for glyphosate administered by gavage at a maximum dose level of 2000 mg/kg.
As indicated in Table B.6.4-29, there are numerous subsequent publications of *in vivo* mammalian chromosome effects assays. With one exception, all of the *in vivo* mammalian studies were conducted in the mouse using either the bone marrow chromosome aberration or micronucleus endpoints. It should be noted that there are some fairly consistent limitations in the reported conduct of these studies compared to OECD guidelines. In most studies concurrent indications of toxicity (other than effects on the bone marrow) are not reported, coding of slides for scoring is not reported, individual animal data are not reported and fewer than recommended cells or metaphases per animal were scored. Other limitations encountered include use of only a single or two dose levels rather than three dose levels.

Results for glyphosate active ingredient

Two publications reported results for glyphosate in the mouse bone marrow erythrocyte micronucleus assay. Negative results were reported in one study which used a dose of 300 mg/kg of glyphosate administered once i.p. with sacrifices at 24, 48 and 74 hours after dosing (Chruscielska *et al.*, 2000, ASB2013-9820). This study had some limitations including the use of only one dose level, no reporting of toxicity other than PCE/NCE ratio, no reported coding of slides for scoring and scoring of 1000 PCE's per animal (scoring of 2000 PCE's per animal is recommended by OECD guidelines). A second publication reported positive results for glyphosate administered at 50, 100 and 200 mg/kg via i.p. injections repeated at 24 hours apart with sacrifice 24 hours after the second dose (Manas *et al.*, 2009, ASB2012-11892). A statistically significant increase in micronucleated erythrocytes was observed in the high dose group. This study had limitations comparable to the negative study. A more significant potential difficulty with this second publication is that "erythrocytes" rather than polychromatic erythrocytes were indicated as scored for micronuclei. This does not appear to be a case of using "erythrocytes" to mean polychromatic erythrocytes because the term "polychromatic erythrocytes" is used elsewhere in the publication describing measurements of PCE/NCE ratios. Scoring of total erythrocytes instead of immature polychromatic erythrocytes for micronuclei would be inappropriate in an assay with the stated treatment and harvest times because of the transient nature of micronucleated PCE's in bone marrow (OECD474, 1997).
There is no definitive explanation for the discrepancy between the two publications. Although one study

used a single dose with multiple harvest times and the second used two doses and a single harvest time, both are acceptable protocols and would not be expected to lead to such discordant results (OECD474, 1997). The negative result reported for the 13 week feeding study in the earlier review (Williams *et al.*, 2000, ASB2012-12053) confirms that positive results are not simply due to repeat dosing. The reported negative result (Chruscielska *et al.*, 2000, ASB2013-9820) seems to be in accord with a majority of earlier reviewed mouse bone marrow micronucleus studies of glyphosate using similar doses and the i.p. or feeding routes (Williams *et al.*, 2000, ASB2012-12053). Also, the apparent scoring of micronuclei in erythrocytes rather than just polychromatic erythrocytes raises a significant methodological question for the reported positive study.

Results for GBFs

There are several publications reporting *in vivo* mammalian bone marrow chromosome aberration and micronucleus endpoint results for Roundup GBFs. Three publications report negative results for Roundup branded GBF in mouse chromosome aberration or micronucleus assays. Negative results were reported for two different Roundup branded GBFs administered at 2 x 200 mg/kg i.p. in mouse bone marrow erythrocyte micronucleus assays (Coutinho do Nascimento and Grisolia, 2000, ASB2013-11477; Grisolia, 2002, ASB2012-11834). The second study did not report coding of slides for scoring. Another publication reported negative results in mouse bone marrow studies for both the chromosome aberration and erythrocyte micronucleus endpoints (Dimitrov *et al.*, 2006, ASB2012-11607) using a dose of 1080 mg/kg administered orally (p.o.). In contrast, one publication reported positive results for Roundup GBF in mouse bone marrow for the chromosome aberration and erythrocyte micronucleus endpoints using a single maximum dose of 50 mg/kg i.p. (Prasad *et al.*, 2009, ASB2012-12005). Both the positive results and the magnitude of the increases in the chromosome aberration and micronucleus endpoint reported in this study are remarkably discordant with other reported results for Roundup and other GBFs in mouse bone marrow chromosome aberration and erythrocyte studies in a number of laboratories and publications (Table B.6.4-29 and Williams *et al.*, 2000, ASB2012-12053). The reasons for this discordance are not clear. One unusual feature of the positive study is that the Roundup GBF was administered in dimethylsulfoxide. This is an unusual vehicle to use in *in vivo* genotoxicity studies, particularly for glyphosate which is water soluble and especially so in a formulated product. A published toxicity study found that use of a dimethylsulfoxide/olive oil vehicle by the i.p. route produced dramatically enhanced toxicity of glyphosate formulation or the formulation without glyphosate compared to saline vehicle and that the enhanced toxicity observed with this vehicle was not observed when the oral route was used (Heydens *et al.*, 2008, ASB2012- 11845). These observations suggest that use of DMSO as a vehicle for administration of formulation components by the i.p. route might produce unusual toxic effects that are not relevant to normally encountered exposures. Regardless of the reasons for the discordant positive results it is clear that a large preponderance of evidence indicates that GBFs are typically negative in mouse bone marrow chromosome aberration and erythrocyte assays. One publication reported positive results for bone marrow chromosome aberration in rabbits administered Roundup GBF in drinking water at 750 ppm for 60 days (Helal and Moussa, 2005, ASB2012-11841). This study is relatively unique in terms of species and route of administration. The results do not report water intake in the test and control groups. Given the potential for water palatability issues with a formulated product, this is a significant shortcoming, as any effects noted may be attributable to dehydration. This study had further limitations including the use of only a single dose level and not coding slides for scoring. Examination of the chromosome aberration scoring results showed that large increases for the treated group were observed for gaps and "centromeric attenuation" which were included in the summation and evaluation of structural chromosome aberration effects. Ordinarily gaps are scored but are not recommended for inclusion in total aberration frequency and centromeric attenuation is not included in ordinary structural aberrations (OECD475, 1997). These unusual scoring and interpretive features raise significant questions about using this study to make conclusions about clastogenicity of the GBF tested.

Two other publications report *in vivo* mammalian chromosome aberration or micronucleus results for GBFs. An uncharacterisd GBF, Percozyd 10L, was reported to be negative in a mouse bone marrow erythrocyte micronucleus assay (Chruscielska *et al.*, 2000, ASB2013- 8929 and ASB2013-8931). The maximum dose level tested, 90 mg/kg i.p., was reported to be 70 of the i.p LD_{50} as determined experimentally by the authors. This study had several limitations including use of less than three dose levels

and no reported coding of slides for scoring. Positive results were reported for another uncharacterized GBF, herbazed, in mouse bone marrow and spermatocyte chromosome aberration studies (Amer *et al.*, 2006, ASB2012- 11539). No statistically significant increases in aberrant cells were observed in bone marrow cells for i.p. treatment of 50 mg/kg for 1, 3 or 5 days or in spermatocytes for 1 or 3 days treatment. Statistically significant increases in frequency of spermatocytes with aberrations were reported for 5 days of treatment with 50 mg/kg (i.p.). Oral treatment of 50 mg/kg and 100 mg/kg were reported to produce increases in aberrant cell frequency in bone marrow cells after extended treatments (14 and 21 days) but not after shorter 1 and 7 day treatments. Similarly, significant increases in aberrant cell frequencies of spermatocytes were reported at 14 and 21 days of 50 mg/kg oral treatment (negative for 1 and 7 days treatment) and at 7, 14 and 21 days of 100 mg/kg treatment (negative for 1 day treatment). Although not a genotoxic endpoint per se, it should be noted that statistically significant increases in frequency of sperm with abnormal morphology were also observed in mice treated with 100 and 200 mg/kg p.o. for 5 days. The positive results for the uncharacterized herbazed GBF were only observed after extended oral treatments (bone marrow and spermatocytes) and extended i.p. treatments (spermatocytes). The fact that positive results were not observed in an erythrocyte micronucleus test of mice treated with glyphosate up to 50,000 ppm in feed for 13 weeks (Williams *et al.*, 2000, ASB2012-12053) provides direct evidence that extended glyphosate treatment by the oral route does not induce detectable chromosome effects. This treatment was longer and up to much higher glyphosate exposures than those used for the Amer *et al.* (2006, ASB2012-11539) studies. Thus, it appears likely that these effects were due to some component(s) of the specific herbazed GBF tested rather than glyphosate. *In vivo* mammalian assays for chromosome effects are an important category for characterisng genotoxicity that complements the gene mutation category. While some positive results have been reported the preponderance of evidence and published results are negative for glyphosate and GBFs.

B.6.4.8.1.3 In vivo Chromosome Effects – Non-Mammalian Systems

The Williams *et al.* (2000, ASB2012-12053) review reported a few *in vivo* plant assays for chromosome effects in non-mammalian systems. These included negative results for glyphosate and positive results for Roundup GBFs for chromosome aberrations in an onion root tip assay and negative results for glyphosate with the micronucleus end point in a *Vicia faba* root tip assay. Subsequent to the earlier review a number of publications reported results for erythrocyte micronucleus assays conducted on GBFs in several non-mammalian fish and reptile species with discordant results. One publication reported apparently negative results for the erythrocyte micronucleus test in *Oreochromis niloticus* (Nile tilapia) administered a test material described as Roundup 69 GBF at an upper dose of 170 mg/kg i.p. (Coutinho do Nascimento and Grisolia, 2000, ASB2013-11477). Although there was an increase in micronucleated erythrocyte frequency at the mid-dose level this was not observed at the high dose level and considerable variability in frequencies in different groups was noted. Negative results were also reported in another fish species (*Prochilodus lineatus*) exposed to 10 mg/liter Roundup branded GBF for 6, 24 and 96 hours (Cavalcante *et al.*, 2008, ASB2012- 11586). This concentration was reported to be 96% of a 96 hour LC_{50}. Positive results were reported for the erythrocyte micronucleus assay conducted in the fish *Tilapia rendalii* exposed to 170 mg/kg i.p. of another Roundup GBF (Grisolia, 2002, ASB2012-11834). Examination of the micronucleus frequencies in this publication indicated that the negative control micronucleus frequency was considerably lower than the frequencies for all but one of 21 treatment groups for 7 different test materials. This suggests an unusually low control frequency and at least one treatment group was statistically significantly elevated for each of the 7 test materials, including many instances where the statistically significant increases were not consistent with a biologically plausible dose response. The possibility that the apparently significant increases were due to a low negative control value should be considered for this publication. Another publication reported positive erythrocyte micronucleus results in goldfish (*Carassius auratus*) exposed to 5 to 15 ppm of a Roundup GBF for 2 to 6 days (Cavas and Konen, 2007, ASB2012-11587). The reasons for the discordant results are not clear for these fish erythrocyte micronucleus assays of Roundup GBFs. Although different species and GBF's were used in the different studies there were pairs of studies with positive and negative results that used similar treatment conditions (170 mg/kg i.p. or 10-15 mg/litre in water).

Results for an unusual test system of exposed caiman eggs are reported by Poletta *et al.*, 2009, ASB2012-12002. Eggs were topically exposed in a laboratory setting to Roundup Full II GBF, and erythrocyte

micronucleus formation was measured in hatchlings (Poletta *et al.*, 2009, ASB2012-12002). The GBF tested was reported to contain the potassium salt of glyphosate and alkoxylated alkylamine derivatives as surfactants. Statistically significant increases in micronucleated erythrocytes were observed in hatchlings from eggs treated with 500-1750 µg/egg. This system is quite unusual in the species tested and even more so in using an egg application with measurement of effects in hatchlings. Although there is some experience with a hen's egg erythrocyte micronucleus assay using *in ovo* exposure the erythrocytes are evaluated in embryos with only a few days between treatment and the erythrocyte micronucleus end point. In the reported caiman egg assay there was presumably a single topical exposure followed by an egg incubation period of about 10 weeks before hatching. Biological plausibility raises questions whether genotoxic events *in ovo* can produce elevated micronucleated erythrocyte frequencies detectable after 10 weeks, given the number of cell divisions occurring in development of a hatchling.

One published study reported a weak positive result in a *Drosophila* wing spot assay (Kaya *et al.*, 2000, ASB2013-9832). Statistically significant positive increases were only in one of four crosses for small twin spots and not for the two other wing spot categories (large wing spots and twin wing spots). As discussed above, only negative or inconclusive results were observed for crosses that were not subject to mitotic recombination effects. If the result was actually treatment related it only would indicate an increase in recombination events and not in somatic mutations.

The above *in vivo* chromosome effect assays in non-mammalian systems give discordant results for reasons that aren't precisely defined. Typically these results would be given lower weight than mammalian systems in being predictive of mammalian effects, especially since there is little or practically no assay experience with these systems in comparison with *in vivo* mammalian chromosome effects assays, such as the rat or mouse bone marrow chromosome aberration or erythrocyte micronucleus assays.

B.6.4.8.2 DNA damage and other end points

A number of studies of glyphosate and GBFs have been published since 2000 which used various DNA damage end points in a variety of *in vitro* and *in vivo* systems. The DNA damage category includes end points such as sister chromatid exchange and DNA repair response in bacteria, but the most common DNA damage end point encountered was the alkaline single cell gel electrophoresis end point (alkaline SCGE) also commonly referred to as the "comet" assay. The alkaline SCGE end point has been applied to both *in vitro* and *in vivo* test systems.

In addition to DNA damage there are a few reports of other types of studies which can be associated with genotoxic effects even though the end points are not specific indicators of genotoxicity per se. These include sperm morphology and carcinogenicity studies.

In vitro DNA Damage Studies

Some positive results for glyphosate or GBFs in the SCE end point were reported in cultured human and bovine lymphocytes in the earlier review (Williams *et al.*, 2000,ASB2012-12053). These results tended to be weak, inconsistent and with limited evidence for dose response. A number of limitations were observed for the studies such as the failure to control pH and abnormally low control values. Additional *in vitro* DNA damage end point results described in the earlier review included negative results for glyphosate in the *B. subtilis* rec-assay and in the primary hepatocyte rat hepatocyte unscheduled DNA synthesis assay.

There are two subsequent publications using *in vitro* cultured mammalian cells and the SCE endpoint. Positive SCE results were reported for the uncharacterised herbazed GBF in mouse spleen cells (Amer *et al.*, 2006, ASB2012-11539). The dose response pattern for SCE response in this study was similar to the response for chromosome aberrations in this publication. Limitations of this study are in common to those described above for the chromosome aberration end point portion of the study; no indication that pH of treatment solutions was controlled, no use of a mammalian metabolic activation system, no reported concurrent toxicity measurements and no reported use of coded slides for scoring. Positive SCE results were also reported for cultured bovine lymphocytes treated with up to 1.12 mM glyphosate for 24 and 48 hours without exogenous mammalian metabolic activation (Sivikova and Dianovsky, 2006, ASB2012-12029). The highest dose of 1.12 mM significantly delayed cell cycle progression with 48 hour treatment. These same concentrations for 24 h exposures did not induce statistically significant increases in chromosome aberrations which provides a clear example of a differential response of the SCE endpoint

(Sivikova and Dianovsky, 2006, ASB2012-12029). This is an important consideration in these publications, as chromosome effects are considered more relevant to genotoxicity than DNA damage.
Positive results for glyphosate are reported for the alkaline SCGE end point in three publications. Positive SCGE results were observed for two mammalian cell lines exposed to glyphosate for 4 hours at concentrations of 4.5-6.5 mM (GM39 cells) and 4.75-6.5 mM (HT1080 cells) (Monroy *et al.*, 2005, ASB2012-11910). These concentrations are close to the upper limit dose of 10 mM generally recommended for *in vitro* mammalian cell assays and control of medium pH is not indicated. Characterisation of nuclear damage was done by visual scoring without coding of slides being indicated. Positive alkaline SCGE results were also reported in Hep-2 cells exposed for 4 hours to 3.5-7.5 mM glyphosate (Manas *et al.*, 2009, ASB2012-11892). Higher concentrations of glyphosate were reported to result in viability of <80% as determined by dye exclusion. As noted for the preceding publication, the concentrations employed were reasonably close to a limit dose of 10 mM and control of medium pH was not reported. This publication reported negative results for the chromosome aberration endpoint in cultured human lymphocytes exposed to up to 6 mM glyphosate for 48 hours and it should be noted that in this case an appropriate control of medium pH was reported for this human lymphocyte experiment. Positive alkaline SCGE results have also been reported for cultured human lymphocytes exposed to glyphosate at concentrations up to 580 µg/mL (estimated 3.4 mM) for 4 hours (Mladinic *et al.*, 2009, ASB2012-11906). Effects were observed both in the presence and absence of S9 with statistically significant increases in tail intensity at 3.5, 92.8 and 580 µg/mL without S9 and at 580 µg/mL with S9. A modification of the alkaline SCGE assay employing human 8-hydroxyguanine DNA-glycosylase (hOGG1) to detect oxidative damage only indicated statistically significant effects on tail length for treatment with 580 µg/mL with S9. Increases in nuclear abnormalities (nuclear buds and/or nucleoplasmic bridges) were also observed at 580 µg/mL with and without S9 and in micronucleus frequency at 580 µg/ml with S9. Measurements of total antioxidant capacity and thiobarbituric acid reactive substances showed statistically significant increases at 580 µg/ml in the presence or absence of S9. Interpretation of the significance of metabolic activation effects is complicated by the observation that several of the end points (alkaline SCGE tail intensity and nuclear abnormalities) tended to show increases in the presence of S9 in negative controls or at the very lowest concentrations of glyphosate. A reasonable summation of the results in this publication is that alkaline SCGE effects and other effects such as nuclear abnormalities, early apoptosis, necrosis and oxidative damage were consistently observed at 580 µg/mL.
In addition to mammalian cell studies there are publications reporting positive alkaline SCGE effects for glyphosate in *Tradescantia* flowers and nuclei exposed to up to 700 µM glyphosate (Alvarez-Moya *et al.*, 2011, ASB2012-11538) and in the *E. coli* SOS chromotest for DNA damage conducted on a Roundup BIO GBF (Raipulis *et al.*, 2009, ASB2012-12008). Observations of DNA damage in plants exposed to glyphosate are of questionable significance because of the herbicidal nature of glyphosate and the SOS chromotest provides only indirect evidence of DNA damage in a bacterial system.

Overall there appear to be a number of studies in which glyphosate or GBFs have been reported to produce positive responses in DNA damage endpoints of SCE or alkaline SCGE *in vitro* in mammalian cells. Most of these have occurred with exposures to mM concentrations of glyphosate. Although this dose level range is lower than the limit dose of 10 mM recommended for several *in vitro* mammalian cell culture assays (OECD473, 1997; OECD476, 1997; OECD487, 2010), an even lower limit dose of 1 mM was recently recommended for human pharmaceuticals, particularly because of concerns about relevance of positive *in vitro* findings observed at higher dose levels. In addition, many of the studies have limitations such as not indicating control of medium pH and not coding slides for visual scoring.
Concerns over the possibility of effects induced by toxicity have led to several suggestions for experimental and interpretive criteria to distinguish between genotoxic DNA-reactive mechanisms for induction of alkaline SCGE effects and cytotoxic or apoptotic mechanisms. One recommendation for the *in vitro* alkaline SCGE assay is to limit toxicity to no more than a 30% reduction in viability compared to controls. Importantly, dye exclusion measurements of cell membrane integrity, such as those reported in some of the above publications may significantly underestimate cytotoxicity that could lead to alkaline SCGE effects. Other recommendations include conducting experiments to measure DNA double strand breaks to determine if apoptotic process might be responsible for alkaline SCGE effects. Measurement of apoptotic and necrotic incidence were only performed in one publication (Mladinic *et al.*, 2009, ASB2012-11906)

and these measurements indicated both apoptotic and necrotic processes occurring in parallel with observations of alkaline SCGE effects. These direct observations as well as the reported dose responses, consistently suggest that biological effects and cytotoxicity accompany the observations of DNA damage *in vitro* in mammalian cells and therefore confirm the likelihood that the observed effects are secondary to cytotoxicity and are thresholded.

In vivo DNA damage studies

In the earlier review positive results for DNA strand breakage were reported for mice treated by the i.p. route with glyphosate and GBFs and for the alkaline SCGE endpoint in tadpoles of the frog *Rana catesbiana* exposed to a GBF (Williams *et al.*, 2000, ASB2012-12053).

Amer *et al.* (2006, ASB2012-11539) reporten an increase in SCE frequency in bone marrow cells of mice treated with uncharacterised herbazed GBF. Statistically significant positive effects were only observed at the highest dose level tested (200 mg/kg administered p.o.).

Several recent publications report alkaline SCGE results for GBFs in aquatic species. Three publications reported positive alkaline SCGE results in aquatic vertebrates exposed to Roundup GBFs in water. These publications have a common feature that alkaline SCGE results were reported as visually scored damage category incidence rather than instrumental measurements of properties such as the tail length or tail intensity. In one publication increases in nuclei exhibiting alkaline SCGE visual damage effects were observed in erythrocytes and gill cells of the tropical fish *Prochilodus lineatus* exposed to 10 mg/litre of a Roundup GBF in water (Cavalcante *et al.*, 2008, ASB2012-11586). Results were variable with cell type and incubation; statistically significant positive responses were observed for erythrocytes at 6 hours and 96 hours, but not 24 hours or for branchial cells from the gills at 6 hours and 24 hours. Measurement of erythrocyte micronucleus frequency and nuclear abnormalities did not show statistically significant increases in these endpoints. The concentration used was reported to be 75% od the 96 hour LC_{50} trypan blue dye measurements apparently indicated >80% viability of cells used in the alkaline SCGE assays. A second publication reported positive alkaline SCGE results in erythrocytes of the goldfish, *Carasseus auratus*, exposed to 5, 10 and 15 ppm of a Roundup GBF for 2, 4 or 6 days (Cavas and Konen, 2007, ASB2012-11587). Similar effects were observed for other end points (micronucleus and nuclear abnormalities). In general, effects increased with concentration and time. This publication did not report toxicity measurements or, more specifically, measurements of cell viability in the population studied. Positive results were also reported in erythrocytes of the European eel, *Anguilla anguilla*, exposed to 58 and 116 µg/L of a Roundup GBF in water for 1 or 3 days (Guilherme *et al.*, 2010, ASB2012-11836). Increasesin nuclear abnormalities were also observed in erythrocytes from animals exposed for 3 days. Measurement of toxicity was not reported for the animals or erythrocytes; however, several endpoints relevant to antioxidant responses and oxidant effects were made in whole blood samples. No statistically significant effects were observed for catalase, glutathione transferase, glutathione peroxidase, glutathione reductase or reduced glutathione content. A large statistically significant increase for thiobarbituric acid reactive substances (TBARS, a measure of lipid peroxidation) was observed for the 115 µg/L concentration group at 1 day. Statistically significant TBARS increases were not observed at 3 days, but, the 3-day negative control value appeared to be several fold higher than the 1-day value.

Significance of DNA damage end point results

DNA damage end points such as SCE or alkaline SCGE are generally regarded as supplementary to the gene mutation and chromosome effects end point categories. DNA damage endpoints do not directly measure effects on heritable mutations or events closely associated with chromosome mutations. *In vitro* DNA damage endpoints such as the SCE or alkaline SCGE can be induced by cytotoxicity and cell death processes rather than from DNA- reactive mechanisms.

The observation of effects of sodium dodecyl sulfate is also interesting because it suggests responses to surfactants which are typically components of GBFs. As a more specific example, polyoxyethylenealkalylmine (POEA), a surfactant component of some GBFs has been shown to elicit

cytotoxic effects such as perturbation of the mitochondrial membrane and disruption of mitochondrial membrane potential in cultured mammalian cells (Levine *et al.*, 2007, ASB2009-9030). Surfactant effects provide a plausible mechanism for observations of GBFs inducing DNA damage responses. Such responses would be expected to be associated with cytotoxicity-inducing exposures and exhibit a threshold.

B.6.4.8.3 Human and environmental studies

A number of human and environmental studies have been published in or after 2000 where some exposures to GBFs in the studied populations were postulated. These publications are summarised in Table B.6.4-30.

Table B.6.4-30: Studies of Human and Environmental Populations with Reported or Assumed Glyphosate Exposure

Exposed Population	End point	Exposures	Result	Reference
Human Studies				
Open field and fruit farmers	Bulky DNA adducts	glyphosate formulation use reported in only 1 of 29 fruit farmers	No effects attributed to glyphosate formulation exposure	Andre *et al.*, 2007 (ASB2012-11543)
Humans in areas where glyphosate formulation is applied	Lymphocyte cytokinesis block micronucleus (CB MN)	Aerial or manual spraying of glyphosate formulation for illicit crop control and sugar cane maturation	Increase in CB MN but no clear relationship to assumed or reported exposures	Bolognesi *et al.*, 2009 (ASB2012-11570)
Floriculturists	Lymphocyte CB MN	Glyphosate formulation use reported in 21/51 workers with average of 106.5 kg applied	Increase in CB MN but not statistically significant	Bolognesi *et al.*, 2004 (ASB2012-11572)
Floriculturists	Lymphocyte CB MN	Glyphosate formulation use reported in 57/107 workers. Numerous other pesticides reported as used by a similar number or more of workers	Statistically significant increase in CB MN	Bolognesi *et al.*, 2002 (ASB2012-11573)
Agricultural workers	Buccal cell micronucleus	Glyphosate formulation use reported along with numerous other pesticides	Statistically significant increase in MN	Bolognesi *et al.*, 2009 (ASB2012-11570)
Fruit growers	Lymphocyte Alkaline SCGE; Ames test on urine	Glyphosate use reported in 2/19 1 day before captan spraying and 1/19 on the day of captan spraying	No effects attributable to glyphosate formulation exposure	Lebailly *et al.*, 2003 (ASB2012-11878)
Agricultural workers	Lymphocyte CB MN; buccal cell micronucleus	Glyphosate formulation use reported in 16% of one of four populations studied (Hungary)	No statistically significant increases in CB MN or buccal cell micronucleus frequencies	Pastor *et al.*, 2003 (ASB2012-11991)
Individuals on or near glyphosate spraying	Lymphocyte alkaline SCGE	Glyphosate formulation aerially sprayed within 3 km	Statistically significant increases in damaged cells	Paz-y-Mino C, 2007 (ASB2012-11992)
Greenhouse Farmers	Lymphocyte SCE	Glyphosate formulation use reported in 99/102 workers; numerous other	Statistically significant increases in SCE	Shaham *et al.*, 2001 (ASB2012-12025)

		pesticides used		
Farmers	Lymphocyte CB MN	Glyphosate formulation use reported in 3/11 farmers	Statistically significant increase in micronucleus frequency but not in frequency of binucleated cells with micronuclei	Vlastos *et al.*, 2006 (ASB2012-12045)
Environmental Studies				
Meadow voles living on golf cousres	Blood cell alkaline SCGE; erythrocyte micronucleus	Glyphosate formulation use reported along with numerous other pesticides	Some effects judged possibly related to Daconil® fungicide	Knopper and Lean., 2004 (ASB2012-11871)

Many of the human studies either found no effects attributable to GBFs or the reported GBF usage by the studied population was too low to be associated with observed population effects (Andre *et al.*, 2007, ASB2012-11543; Bolognesi *et al.*, 2004, ASB2012-11572; Lebailly *et al.*, 2003, ASB2012-11878; Pastor *et al.*, 2003, ASB2012-11991; Vlastos *et al.*, 2006, ASB2012-12045).

In some studies, incidence of GBF use by the population studied was significant but high incidence of use of other pesticides was also reported (Bolognesi *et al.*, 2002, ASB2012- 11573; Shaham *et al.*, 2001, ASB2012-12025). Even though positive effects were observed in these populations, ascribing these effects to any particular environmental exposure is not scientifically justifiable and such results certainly cannot be considered as definitive evidence for GBF-induced human genotoxic effects.

Two published studies focused on populations believed to be exposed to GBFs by their presence at or near aerial or manual spraying operations. One publication reported induction of alkaline SCGE effects in blood lymphocytes of populations living within 3 km of areas sprayed with glyphosate formulation for illicit crop eradication (Paz-y-Mino C, 2007, ASB2012-11992). The populations studied were relatively small (24 exposed individuals and 21 non-exposed individuals). The sprayed material was reported to be Roundup Ultra, a GBF containing 43.9% glyphosate, polyethoxylated tallowamine surfactant and a proprietary component, Cosmoflux 411F. Specific methods for collection, storage, and transport of blood samples are not described for either the exposed population or control group. The publication also does not indicate that slides were coded for scoring which consisted of visual classification into damage categories and measurement of DNA migration (tail length). There were fairly large differences in ages and sex distribution of the exposed and control populations but these did not appear to be statistically significant. The study reported increases in damaged cell categories and statistically significant increases in DNA migration (tail length) in the presumably exposed population. Interpretation of the results of this study should consider numerous reported signs of toxicity in the exposed population and the reported application rate of 24.3 litres/ha which was stated to be 20 times the maximum recommended application rate. Some of the reported human health effects described by Paz-y- Mino (2007, ASB2012-11992) appear to be consistent with severe exposures noted in clinical reports of acute poisoning incidents with GBFs and other pesticide formulations (often self- administered) rather than typical bystander exposures. Given the considerably favorable general toxicology profile of glyphosate as reported by the WHO/FAO Joint Meeting on Pesticide Residues (WHO/FAO, 2004, ASB2008-6266) and in Williams *et al.* (2000, ASB2012-12053), factors related to either high surfactant exposure, unusual GBF components in this formulation or other undocumented variables appear to be confounding factors in this study. It appears that the reported alkaline SCGE effects could well have been secondary to the ailments reported in this study population.

A second publication reported results for a blood lymphocyte cytokinesis-block micronucleus study of individuals in areas treated with glyphosate formulation by aerial spraying or manual application (Bolognesi *et al.*, 2009, ASB2012-11570). Although the title of the publication contains the term "agricultural workers", most of the populations studied do not appear to be agricultural workers who are involved in application of GBFs. The human lymphocyte culture and scoring methodology employed in the Bolognesi *et al.* (2009, ASB2012-11570) study appear to be generally consistent with commonly used

and recommended practices for this assay. However, there is a significant question as to how long the blood samples used in the study were stored prior to initiating cultures and this may have affected the micronucleus numbers observed in the different sets of samples and populations. Also, the populations in the aerially sprayed regions had a second sampling a few days after the first sampling and this second sampling was not performed in the control populations. The publication reported a small increase in the frequency of binucleated cells with micronuclei and micronuclei per cell in samples collected from people living in three regions after spraying of GBFs compared with control values of samples collected just before spraying. However, the pattern of the increases did not correlate either with the application rate or with self-reported exposure. The largest post-spraying increase in binuclated cell micronucleus frequency was reported for a population with a much lower glyphosate active ingredient application rate and only 1 of 25 people in this region reported contact with sprayed glyphosate formulation. Increases in binucleated cell micronucleus frequency did not have a statistically significant relationship with self-reported exposure for two other populations. Some interpretative statements in Bolognesi *et al.* (2009, ASB2012-11570) suggest a small transient genotoxic effect of glyphosate formulation spraying on frequencies of binucleated cells with micronuclei, but other statements indicate that causality of the observed effects could not be determined using reasonable criteria and that lack of exposure data precluded conclusions. This study has a combination of uncontrolled or inadequately characterized variables, such as uncharacterisd exposure to ”genotoxic pesticides”, that would appear to preclude using the data to support any conclusion that exposure to GBFs affects binucleated micronucleus frequencies. Actually, the available data, while certainly limited in nature, support a conclusion that the observed effects do not appear to be attributable to glyphosate formulation exposure. This conclusion is reinforced by Acquavella *et al.* (2004, ASB2012-11528), where biomonitoring of agricultural workers applying GBFs reports systemic exposures orders of magnitude below *in vivo* model chromosome aberration and micronucleus study doses, the majority of which were negative for glyphosate and GBFs.

There are two publications related to environmental monitoring for genotoxic endpoints. One study using blood cell alkaline SCGE and micronucleus endpoints was conducted on samples from meadow voles living on or near golf courses where pesticides had been applied (Knopper & Lean, 2004, ASB2012-11871). Results were significantly inconsistent between two seasons. Although some suggestions of effects were reported, glyphosate was only one of a number of applied pesticides and the effects observed were considered as possibly attributable to exposure to Daconil® fungicide. A second publication reported results for the erythrocyte micronucleus assay applied to fish collected from several dams in Brazil (Salvagni *et al.*, 2011, ASB2012-12017). Glyphosate formulation was one of a number of pesticides reported to be used in the area of the dams. No efforts appear to have been made to measure glyphosate or other pesticide concentrations in any of the ten dams from which fish were sampled. This study reported what were considered to be high levels of micronucleated cell frequency but there were no concurrent negative controls. In the absence of these controls the results cannot be interpretted as indicating any effect of pesticide exposure.

Although there have been a fairly large number of human genotoxicity studies reported where there was some exposure to GBFs, the large majority of these studies do not allow any conclusions about possible effects of glyphosate or GBFs because the exposure incidence was low or because there were reported exposures to a large number of pesticides. One report found an increase in alkaline SCGE effects in humans living in or near areas where a GBF was sprayed but that study had a number of methodology reporting and conduct deficiencies and the reported effects could well have been due to toxicity reported in the study population. A second study found some increases in cytokinesis-block micronucleus frequency in humans possibly exposed to GBFs but the effects were not concordant with application rates or self- reported exposures and thus do not constitute reliable indications of effects for this endpoint in humans exposed to GBFs. Neither of the two environmental monitoring studies in meadow voles or fish provide any reliable evidence of exposures to glyphosate or GBFs or adverse effects resulting from potential exposures to glyphosate or GBFs.

After submission of the first draft of this RAR for public comment the following additional studies have been included.

Koureas *et al.* (2014, ASB2014-9724) performed a study aimed at estimating the oxidative damage to DNA in different subpopulations in Thessaly region (Greece) and investing its correlation with exposure to pesticides and other potential risk factors. The study produced findings that support the hypothesis that

pesticide exposure is involved in the induction of oxidative damage to DNA. A correlation was found in this study between exposure to formulations containing neonicotinoids or glufosinate ammonium and oxidative damage to DNA. However, no significant correlation was reported for glyphosate.
Gentile *et al.* (2012, ASB2014-9482) submitted results of the micronucleus assay as a biomarker of genotoxicity in the occupational exposure to agrochemicals in rural workers in Argentina. The authors found significant differences in the frequency of micronuclei between occupationally exposed (20 individuals) and unexposed (10 individuals) workers. However, no conclusion on genotoxicity of glyphosate or other specific pesticides is possible on basis of this study.
Da Silva *et al.* (2014, ASB2014-9358) performed a genotoxic assessment in tobacco farmers at different crop times. The study sought to determine genotoxic effects in farmers occupationally exposed to agrochemicals and nicotine. A significant increase of micronucleated cells in the off-season group was observed. However, no conclusion on genotoxicity of glyphosate or other specific pesticides is possible on basis of this study.
Benedetti *et al.* (2013, ASB2014-9279) studied genetic damage in soybeans workers exposed to pesticides. The evaluation was performed with the comet and buccal micronucleus assays. The results of both tests revealed DNA damage in soybean workers. No special pesticide can be identified as cause of the observed effects.

B.6.4.8.4 DNA-Reactivity and carcinogenesis

As noted in the earlier review, ^{32}P-postlabelling DNA adduct studies in mice did not indicate formation of adducts from glyphosate and questionable evidence of adducts from Roundup GBF administered as a high 600 mg/kg i.p. dose in an unusual dimethylsulfoxide/olive oil vehicle (Peluso *et al.*, 1998, TOX1999-318; Williams *et al.*, 2000, ASB2012-12053). Another earlier reviewed study reported DNA strand breakage in liver and kidneys of mice injected i.p with glyphosate and Roundup GBF. This study also reported an increase in 8- hydroxydeoxyguanosine (8-OHdG) residues in liver DNA from mice injected with glyphosate but not GBF. Increased 8-OHdG was found in kidney DNA from mice injected with GBF but not glyphosate (Bolognesi *et al.*, 1997, Z59299; Williams *et al.*, 2000, ASB2012-12053). No new direct studies of DNA reactivity of glyphosate or GBFs were encountered in publications since 2000. One publication did report on studies in mice to further investigate toxic effects and 8-OHdG levels associated with the routes, vehicles and dose levels employed in earlier ^{32}P-postlabelling and DNA strand breakage and 8-OHdG studies (Heydens *et al.*, 2008, ASB2012-11845). This publication reported that high i.p. dose levels of GBF induced significant liver and kidney toxicity that were not observed with oral administration. Statistically significant increases in 8-OHdG were not observed in this study under the same conditions as employed by the earlier study. The dimethylsulfoxide/olive oil vehicle dramatically enhanced toxicity of GBF administered by the i.p. route and the toxicity was also observed for formulation components without glyphosate. These results indicated that the effects reported in the earlier studies were associated with high liver and kidney toxicity that was primarily due to the non-glyphosate components of the formulation and which were produced by the i.p. route of exposure to very high dose levels. The enhancement of toxicity by the unusual dimethylsulfoxide/olive oil dosing vehicle further calls into question whether the ^{32}P-postlabelling finding represented effects associated with unusual toxicity rather than being indicative of adducts formed from glyphosate or glyphosate formulation components.

Carcinogenicity is not a direct endpoint for genotoxicity but it is one of the possible consequences of genotoxicity and, conversely, lack of carcinogenicity in well-conducted experimental studies provides some evidence that a significant genotoxic mode of action is not operating *in vivo*. The earlier review of glyphosate concluded that it was not carcinogenic in mouse or rat chronic studies and notes that glyphosate was not considered carcinogenic by numerous regulatory agencies and scientific organisations (Williams *et al.*, 2000, ASB2012- 12053).

B.6.4.8.4 AMPA and POEA

B.6.4.8.5 Genotoxicity of glyphosate mixtures and photoactivation

B.6.4.8.6 Genotoxicity Weight of Evidence

The earlier review applied a weight of evidence analysis to the available genotoxicity data. Various weighted components included assay system validation, test system species, relevance of the endpoint to heritable mutation, reproducibility and consistency of effects and dose- response and relationship of effects to toxicity (Williams *et al.*, 2000, ASB2012-12053). The conclusion of this analysis was that glyphosate and Roundup GBFs were not mutagenic or genotoxic as a consequence of direct chemical reaction with DNA. This was supported by a strong preponderance of results indicating no effects in *in vivo* mammalian assays for chromosome effects and consistently negative results in gene mutation assays. Although some DNA damage responses were noted, these were judged likely to be secondary to toxicity rather than DNA reactivity.

Since this earlier review, a large number of genotoxicity studies have been conducted with glyphosate and GBFs. For gene mutation, one of the two primary endpoint categories with direct relevance to heritable mutation, one subsequent publication contains a summary of results from a bacterial gene mutation endpoint assay (Ames/*Salmonella* bacterial reversion assay). Although there were very significant limitations to the information published, the negative result is consistent with the majority of negative results reported for glyphosate and GBFs in Ames/*Salmonella* bacterial reversion assays. Another publication reported results for a *Drosophila* wing spot assay of glyphosate. Results were negative or inconclusive in this assay for crosses that would have detected gene mutation as loss of heterozygosity. The new results provide some support to reinforce the earlier conclusion that glyphosate and GBFs are not active for the gene mutation endpoint category.

The second primary endpoint category with direct relevance to heritable mutation is chromosome effects. The earlier review noted mixed results for two *in vitro* chromosome effects assays in mammalian cells but concluded that the most reliable result was the negative assay. A number of *in vitro* mammalian cell chromosome aberration or micronucleus assay results have been subsequently published using bovine or human lymphocytes. These assays suffer from some technical limitations in conduct or reporting of methodology that frequently included failure to indicate control of medium for pH and failure to indicate coding of slides for visual scoring. Both positive and negative results are reported in these assays. A large preponderance of results in the absence of an exogenous mammalian metabolic activation system were negative up to high (mM) dose levels that were toxic or close to toxic levels observed in parallel experiments. The exceptions were a weak and inconsistent response reported in two publications from the same laboratory and a positive response for the uncharacterized formulation, herbazed. In addition to these findings in mammalian cells negative results were also reported for Roundup GBF in an onion root tip assay conducted without exogenous mammalian metabolic activation. Thus, the preponderance of evidence from assays not employing an exogenous mammalian metabolic activation system indicates that glyphosate and GBFs are not structural chromosome breakage inducers (clastogenic) in *in vitro* mammalian chromosome aberration or micronucleus assays.

Two publications from one laboratory reported an increase in micronucleus frequencies for glyphosate in *in vitro* cultured mammalian cells in the presence of an exogenous S9 metabolic activation system (Mladinic *et al.*, 2009, ASB2012-11906; Mladinic *et al.*, 2009, ASB2012- 11907). An enrichment for centomeric-containing micronuclei suggested that the increased micronuclei observed in these studies were derived from aneugenic processes, probably mediated through toxicity, rather than chromosome breakage. Thus, these two reports of weak micronucleus responses in the presence of exogenous mammalian metabolic activation appear to result from toxicity-associated aneugenic rather than clastogenic mechanisms. A number of other gene mutation and *in vitro* chromosome effect genotoxicity studies are negative with exogenous metabolic activation which supports the conclusion that the weight of evidence does not indicate a DNA-reactive clastogenic activity in *in vitro* assays using mammalian cells.

All except one of a number of *in vivo* mouse bone marrow chromosome aberration or micronucleus assays of glyphosate and GBFs were reported as negative in the earlier review. In the updated review both positive and negative results were reported for glyphosate and GBFs in these types of assays. Many of these studies had limitations or deficiencies compared to international guidelines with the most common and significant being no indication of slide coding for visual scoring. Four publications from three laboratories reported negative results in mouse bone marrow erythrocyte micronucleus assays of glyphosate and GBFs which are consistent with the earlier reviewed studies. These studies used high, peri-lethal dose levels administered by the i.p. or oral routes.

Two publications from two laboratories reported positive results for glyphosate and GBFs in the mouse bone marrow erythrocyte micronucleus assay. One positive result for glyphosate was encountered using dose levels and routes that were similar to those employed in the negative glyphosate studies in the same assay system. The publication reporting this result indicates that erythrocytes rather than polychromatic erythrocytes were scored which would be inappropriate for the treatment protocol but it is possible that this is a misreporting of what types of cells were actually scored. Although there is no definitive explanation for the discordance, the preponderance of mouse bone marrow erythrocyte micronucleus studies of glyphosate are clearly negative. The reported positive result for Roundup GBF is discordant with a number of negative results for Roundup or other GBFs conducted at higher dose levels. The most unique feature of this study was the use of dimethylsulfoxide as a vehicle. The preponderance of mouse bone marrow erythrocyte micronucleus studies for Roundup and other GBF studies is negative.

Positive results were reported in an unusual test system (rabbit) and route (drinking water), but water intake was not reported and effects may therefore be attributable to dehydration. Furthermore, most of the effects were on endpoints not usually considered as indicators of clastogenicity and structural chromosome aberration. One laboratory reported positive results for chromosome aberration effects in bone marrow and spermatocytes after extended dosing. However, the herbazed formulation test material was not characterised. While more discordant results in the important *in vivo* mammalian chromosome effect assay category have been reported in publications subsequent to the earlier 2000 review the preponderance of evidence continues to indicate that glyphosate and GBFs are not active in this category of end point.

Several *in vivo* erythrocyte micronucleus assay results for GBFs in non-mammalian systems (fish and caiman eggs) have been published since the earlier review. These test systems have relatively little experience and are largely unvalidated in comparison to the mouse bone marrow erythrocyte micronucleus assay. Two publications report negative results and two publications report positive results in different fish species and there is no definitive explanation for the discordance. Both the positive and negative studies employed maximum dose levels that were toxic or close to toxic dose levels. One possible explanation for the discordance is that the positive effects were associated with toxicity that only occurred beyond an exposure threshold and over a fairly narrow dose range. Positive results in hatchlings derived from caiman eggs exposed to Roundup formulation are given relatively little weight because of extremely limited experience with this assay system and because of significant questions about how DNA damage effects induced in embryos can persist and be evident in cells of hatchlings after several weeks and numerous cell divisions. The reported weak and inconsistent response in one of four crosses for somatic recombination in the *Drosophila* wing spot assay is also accorded relatively low weight. These non-mammalian test systems are generally considered of lower weight for predicting mammalian effects than mammalian test systems. Also, the environmental significance of effects for GBFs should consider the relationship between concentrations or exposures producing effects and likely environmental concentrations or exposures. This is particularly important if the effects are produced by threshold mediated toxic processes.

There have been a significant number of publications since the earlier review of results for assays in the DNA damage category with some SCE and a large number of alkaline SCGE endpoint publications. In general, the DNA damage end point category is considered supplementary to the gene mutation and chromosome effect categories because this endpoint category does not directly measure heritable events or effects closely associated with heritable events. Regulatory genotoxicity testing recommendations and requirements focus on gene mutation and chromosome effect end points for initial core testing, particularly for *in vitro* testing. This consideration is underscored by the observation of some cases of compounds where positive effects are observed in these assays that are not observed for gene mutation or chromosome effect assays. Also, there are numerous examples of responses in these endpoints that do not appear to result from mechanisms of direct or metabolite DNA-reactivity. The unique response consideration is reinforced in this data set by observations of responses in DNA damage endpoints but not in chromosome effect end points.

Many DNA damage endpoint assays of glyphosate or GBFs have produced positive results at high, toxic or peri-toxic dose levels for the SCE and alkaline SCGE endpoints in a variety of test systems including cultured mammalian cells, several aquatic species and caiman eggs. The only new report of positive *in vivo* mammalian DNA damage effects are for an uncharacterised formulation, herbazed. There are several examples of negative results for a chromosome aberration or micronucleus endpoint and positive results for the alkaline SCGE or SCE endpoint in the same publication (Cavalcante *et al.*, 2008, ASB2012-11586;

Manas *et al.*, 2009, ASB2012-11892; Mladinic *et al.*, 2009, ASB2012-11906; Sivikova and Dianovsky, 2006, ASB2012-12029). These examples confirm the impression that the DNA damage endpoints are not necessarily predictive of heritable mutation effects and are also consistent with the DNA damage endpoints reflecting toxic effect mechanisms. While the number of reported positive responses in these endpoints does suggest that effects in these endpoints can be induced by glyphosate or GBFs, comparison with results for gene mutation and chromosome effects endpoints, examination of the dose response and association of the effects with toxic endpoints indicates that these effects are likely secondary to toxicity and are threshold mediated. Surfactants in GBFs increase toxicity compared to the active ingredient of glyphosate salts and are shown to induce effects such as membrane damage and oxidant stress which are likely capable of inducing DNA damage effects at cytotoxic doses. These factors as well as other considerations presented in Section 6.3 indicate that these DNA damage effects have negligible significance to prediction of hazard or risk at lower and more relevant exposure levels.

Most of the human studies do not provide interpretable or relevant information regarding whether there are *in vivo* human genotoxic effects of GBFs because the reported incidence of glyphosate formulation exposure in the population was low or because there were reported exposures to a relatively large number of pesticides. Two studies with focus on glyphosate exposure through presence in or near areas of glyphosate formulation spraying found increases in the DNA damage alkaline SCGE end point. In one study clinical signs of toxicity were reported in the population and spraying concentrations were reported to be many times the recommended application rate. Given the nature of the end point a reasonable interpretation is that effects might well be due to the overt toxicity that was reported in the publication. This would be a threshold mediated, non-DNA reactive mechanism and is consistent with experimental system results showing alkaline SCGE effects in animals exposed to high levels of formulation components. The low weight of evidence for significant genotoxic hazard indicated by this particular endpoint in human monitoring is reinforced by findings that exercise induces alkaline SCGE effects in humans. The other study found increases in binucleated micronucleated cell frequency in population in spraying areas but the increases were not consistent with spraying levels or self-reported exposure. These latter observations are not consistent with the study presenting clear evidence of GBF effects on this endpoint. In sum, the available human data do not provide any clear indications that exposed humans are substantially different in response than mammalian animal models or that exposure to GBFs produces DNA-reactive genotoxicity.

Carcinogenicity is an adverse effect that is a possible consequence of genotoxic and mutagenic activity. Conversely, lack of carcinogenicity in properly conducted animal models is supportive for lack of significant *in vitro* mammalian genotoxicity. The updated review provides one new study of glyphosate formulation which is negative for either initiator or complete carcinogenesis activity which provides additional evidence to reinforce the conclusion from earlier mammalian carcinogenicity assays that glyphosate and GBFs are non- carcinogenic. These findings support the conclusion that glyphosate and GBFs do not have *in vivo* mammalian genotoxicity or mutagenicity.

In addition to considering the results relevant to genotoxicity hazard assessment, an important additional perspective on risk can be provided by comparing levels used in experimental studies with expected human and environmental exposure levels. A study of farmers indicated a maximum estimated systemic glyphosate dose of 0.004 mg/kg for application without protective equipment and a geometric mean of 0.0001 mg/kg (Acquavella *et al.*, 2004, ASB2012-11528). When compared with *in vivo* mammalian test systems that utilize glyphosate exposures on the order of 50-300 mg/kg, the margins of exposure between the test systems and farmers is 12,500-75,000 for the maximum farmer systemic exposure and 0.5-3 million for the geometric mean farmer systemic exposure. These margins are quite substantial, especially considering that many of the *in vivo* genotoxicity studies are negative. Assuming reasonable proportionality between exposure to glyphosate and GBF ingredients, similar large margins of exposure would exist for GBF components. The margins of exposure compared to *in vitro* mammalian cell exposures are estimated to be even larger. Assuming uniform distribution, the systemic concentration of glyphosate from the Aquavella *et al.* (2004, ASB2012-11528) farmer biomonitoring study would be on the order of 24nM for the maximum and 0.59 nM for the geometric mean exposure. A typical maximum *in vitro* mammalian exposure of 1-5 mM represents a margin of exposure of 42,000-211,000 for the maximum farmer exposure and 1.7-8.4 million for the geometric mean farmer systemic exposures, respectively.

Overall, the weight of evidence of the studies considered in the earlier review as well as the studies considered in this review indicates that glyphosate and GBFs are not genotoxic in the two general endpoint categories most directly relevant to heritable mutagenesis, gene mutation and chromosome effects. This conclusion results from a preponderance of evidence; however, there are reports of positive discordant results in both end point categories. The new studies considered in this review provide some evidence for DNA damage effects induced by high, toxic exposures, particularly for the alkaline SCGE end point and for GBFs containing surfactant. Several considerations, including the lack of response in other endpoint categories, suggest that these effects result from toxic and not DNA-reactive mechanisms and that they do not indicate *in vivo* genotoxic potential under normal exposure levels.
Regulatory and authoritative reviews of glyphosate supporting registrations and registrations in all regions of the world over the last 40 years have consistently determined that glyphosate is nongenotoxic (Commission, 2002, ASB2009-4191; WHO/FAO, 2004, ASB2008-6266). Scientific publications contrary to these regulatory reviews should be evaluated using a weight of evidence approach with consideration for reliability of the assay used and data quality presented.

Alvarez-Moya, C., Silva, M.R., Arambula, A.R.V., Sandoval, A.I., Vasquez, H.C., Gonzales Montes, R.M.	2011	Evaluation of genetic damage induced by glyphosate isopropylamine salt using *Tradescantia* bioassays Genetics and Molecular Biology Volume: 34 Number: 1 Pages: 127-130 ASB2012-11538

Abstract*
Glyphosate is noted for being non-toxic in fishes, birds and mammals (including humans). Nevertheless, the degree of genotoxicity is seriously controversial. In this work, various concentrations of a glyphosate isopropylamine salt were tested using two methods of genotoxicity assaying, *viz*., the pink mutation assay with *Tradescantia* (4430) and the comet assay with nuclei from staminal cells of the same plant. Staminal nuclei were studied in two different forms, namely nuclei from exposed plants, and nuclei exposed directly. Using the pink mutation assay, isopropylamine induced a total or partial loss of color in staminal cells, a fundamental criterion utilised in this test. Consequently, its use is not recommended when studying genotoxicity with agents that produce pallid staminal cells. The comet assay system detected statistically significant ($p < 0.01$) genotoxic activity by isopropylamine, when compared to the negative control in both the nuclei of treated plants and directly treated nuclei, but only the treated nuclei showed a dose-dependent increase. Average migration in the nuclei of treated plants increased, when compared to that in treated nuclei. This was probably due, either to the permanence of isopropylamine in inflorescences, or to the presence of secondary metabolites. In conclusion, isopropylamine possesses strong genotoxic activity, but its detection can vary depending on the test systems used.

Klimisch evaluation

Not reliable
Exposure conditions of plants (immersion) not representative for glyphosate. Inappropriate test model as herbicides are toxic to plants. Presentation of results not sufficient for assessment. Reporting deficiencies (e.g. positive controls).
Not relevant (Due to reliability, and exposure conditions of plants and inappropriate test model).

Bolognesi, C. Bonatti, S. Degan, P. Gallerani, E. Peluso, M. Rabboni, R. Roggieri, P. Abbondandolo,A.	1997	Genotoxic activity of glyphosate and its technical formulation roundup Journal of Agricultural and Food Chemistry Volume: 45 Pages: 1957-1962 Z59299

Abstract*
Glyphosate (N-phosphonomethylglycine) is an effective herbicide acting on the synthesis of aromatic amino acids in plants. The genotoxic potential of this herbicide has been studied: the results available in the open literature reveal a weak activity of the technical formulation. In this study, the formulated commercial product, Roundup, and its active agent, glyphosate, were tested in the same battery of assays for the induction of DNA damage and chromosomal effects in vivo and in vitro. Swiss CD1 mice were treated intraperitoneally with test substances, and the DNA damage was evaluated by alkaline elution technique and 8- hydroxydeoxyguanosine (8-OHdG) quantification in liver and kidney. The chromosomal damage of the two pesticide preparations was also evaluated in vivo in bone marrow of mice as micronuclei frequency and in vitro in human lymphocyte culture as SCE frequency. A DNA-damaging activity as DNA single-strand breaks and 8-OHdG and a significant increase in chromosomal alterations were observed with both substances *in vivo* and *in vitro*. A weak increment of the genotoxic activity was evident using the technical formulation.

Klimisch evaluation

Reliability of study: Not reliable
Basic data given, however, the study is performed with methodological and reporting deficiencies (only data without metabolic activation generated in *in vitro* tests, no positive controls included in *in vitro* SCE and *in vivo* experiments, in some experiments only two test substance concentrations tested).
Not relevant (Due to methodological and reporting deficiencies data considered to be supplemental information; i.p. exposure route is not relevant for human exposure)

Bolognesi, C., Perrone, E., Landini, E.	2002	Micronucleus monitoring of a floriculturist population from western Liguria, Italy Mutagnesis Volume: 17 Number: 5 Pages: 391-397 ASB2012-11573

Abstract*
A biomonitoring study was carried out to investigate whether exposure to complex pesticide mixtures in ornamental crop production represents a potential genotoxic risk. Exposed and control subjects were selected in western Liguria (Italy). The area was chosen for its intensive use of pesticides. The main crops produced were roses, mimosas, carnations and chrysanthemums, as ornamental non-edible plants, and tomato, lettuce and basil, as edible ones. The levels of micronuclei (MN) were analysed in peripheral blood lymphocytes of 107 floriculturists (92 men and 15 women) and 61 control subjects (42 men and 19 women). A statistically significant increase in binucleated cells with micronuclei (BNMN) was detected in floriculturists with respect to the control population (4.41 +/- 2.14 MN/1000 cells versus 3.04 +/- 2.14, $P < 0.001$). The mean number of BNMN varied as a function of sex and age. Smoking habit had no effect on MN frequency. A positive correlation between years of farming and MN frequency in peripheral blood lymphocytes was observed ($r = 0.30$, $P = 0.02$). The conditions of exposure were also associated with an increase in cytogenetic damage, with a 28 % higher MN frequency in greenhouse workers compared with subjects working only outdoors in fields. Workers not using protective measures during high exposure activities showed an increase in MN frequency. Our findings suggest a potential genotoxic risk due to pesticide exposure.

Bolognesi, C., Landini, E., Perrone, E., Roggieri, P.	2004	Cytogenetic biomonitoring of a floriculturist population in Italy: micronucleus analysis by fluorescence in situ hybridization (FISH) with an all-chromosome centrometric probe Mutation Research Volume: 557 Number: 2 Pages: 109-117 ASB2012-11572

Abstract*
Flower production in greenhouses associated with a heavy use of pesticides is very wide- spread in the western part of the Ligurian region (Italy). The formation of micronuclei in peripheral blood lymphocytes is a valuable cytogenetic biomarker in human populations occupationally exposed to genotoxic compounds. In the present study we investigated the micronucleus frequency in peripheral blood lymphocytes of 52 floriculturists and 24 control subjects by use of the cytokinesis-block methodology associated with fluorescence in situ hybridization with a pan-centromeric probe that allowed to distinguish centromere-positive (C+) and centromere-negative (C−) micronuclei. The comparison between floriculturists and controls did not reveal any statistically significant difference in micronucleus frequency, although an increase was observed with increasing pesticide use, number of genotoxic pesticides used and duration of exposure. An increase in C+ as well as in C− micronuclei and in the percentage of C+ micronuclei with respect to the total number of micronuclei was detected in floriculturists, suggesting a higher contribution

of C+ micronuclei in the total number scored. The percentage C+ micronuclei was not related to the duration of exposure or to the number of genotoxic pesticides used, but a higher percentage (66.52% versus 63.78%) was observed in a subgroup of subjects using benzimidazolic compounds, compared with the floriculturist population exposed to a complex pesticide mixture not including benzimidazolics. These results suggest a potential human hazard associated with the exposure to this class of aneuploidy-inducing carcinogens.

Klimisch evaluation

Reliability of study: Not reliable for glyphosate
Comment: Well-documented study. MN-test comparable to OECD guidelines, but not equal. No information on exposure concentrations to individual pesticides.
Relevance of study: Not relevant (Due to the exposure of multiple pesticides, only general conclusions about pesticide exposure and cytogenic non-statistically significant differences possible. No statistically relevant findings reported for glyphosate alone).

Cavas, T., Könen S.	2007	Detection of cytogenetic and DNA damage in peripheral erythrocytes of goldfish (*Carassius auratus*) exposed to a glyphosate formulation using the micronucleus test and the comet assay Mutagenesis 22 263-268 ASB2012-11587

Abstract*
Glyphosate is a widely used broad-spectrum weed control agent. In the present study, an in vivo study on the genotoxic effects of a technical herbicide (Roundup®) containing isopropylamine salt of glyphosate was carried out on freshwater goldfish *Carassius auratus*. The fish were exposed to three doses of glyphosate formulation (5, 10 and 15 ppm). Cyclophosphamide at a single dose of 5 mg/L was used as positive control. Analysis of micronuclei, nuclear abnormalities and DNA damage were performed on peripheral erythrocytes sampled at intervals of 48, 96 and 144 h post treatment. Our results revealed significant dose-dependent increases in the frequencies of micronuclei, nuclear abnormalities as well as DNA strand breaks. Our findings also confirmed that the alkaline comet assay and nuclear deformations in addition to micronucleus test on fish erythrocytes in vivo are useful tools in determining the potential genotoxicity of commercial herbicides.

Guilherme, S. Gaivao, I. Santos, M.A. Pacheco, M.	2010	European eel (*Anguilla Anguilla*) genotoxic and pro-oxidant responses following short-term exposure to Roundup® - a glyphosate-based herbicide. Mutagenesis Volume: 25 Number: 5 Pages: 523-530 ASB2012-11836

Abstract*
The glyphosate-based herbicide, Roundup®, is among the most used pesticides worldwide. Due to its extensive use, it has been widely detected in aquatic ecosystems representing a potential threat to non-target organisms, including fish. Despite the negative impact of this commercial formulation in fish, as described in literature, the scarcity of studies assessing its genotoxicity and underlying mechanisms is evident. Therefore, as a novel approach, this study evaluated the genotoxic potential of Roundup® to blood cells of the European eel (*Anguilla anguilla*) following short-term (1 and 3 days) exposure to environmentally realistic concentrations (58 and 116 mg/L), addressing also the possible association with oxidative stress. Thus, comet and erythrocytic nuclear abnormalities (ENAs) assays were adopted, as genotoxic end points, reflecting different types of genetic damage. The prooxidant state was assessed through enzymatic (catalase, glutathione-S-transferase, glutathione peroxidase and glutathione reductase) and non-enzymatic (total glutathione content) antioxidants, as well as by lipid peroxidation (LPO) measurements. The Roundup® potential to induce DNA strand breaks for both concentrations was demonstrated by the comet assay. The induction of chromosome breakage and/or segregational abnormalities was also demonstrated through the ENA assay, though only after 3-day exposure to both tested concentrations. In addition, the two genotoxic indicators were positively correlated. Antioxidant defences were unresponsive to Roundup®. LPO levels increased only for the high concentration after the first day of exposure, indicating that oxidative stress caused by this agrochemical in blood was not severe. Overall results suggested that both DNA damaging effects induced by Roundup® are not directly related with an increased pro-oxidant state. Moreover, it was demonstrated that environmentally relevant concentrations of Roundup® can pose a health risk for fish populations.

Kale, P.G. Petty, B.T. Jr. Walker, S. Ford, J.B. Dehkordi, N. Tarasia, S. Tasie, B.O. Kale, R. Sohni, Y.R.	1995	Mutagenicity Testing of Nine Herbicides and Pesticides Currently Used in Agriculture. Environmental and Molecular Mutagenesis Volume: 25 Pages: 148-153 Z73986, ASB2012-11860

Abstract*
Nine herbicides and pesticides were tested for their mutagenicity using the *Drosophila* sex- linked recessive lethal mutation assay. These are Ambush, Treflan, Blazer, Roundup, 2,4-D Amine, Crossbow, Galecron, Pramitol, and Pondmaster. All of these are in wide use at present. Unlike adult feeding and injection assays, the larvae were allowed to grow in medium with the test chemical, thereby providing long and chronic exposure to the sensitive and dividing diploid cells, i.e., mitotically active spermatogonia and sensitive spermatocytes. All chemicals induced significant numbers of mutations in at least one of the cell types tested. Some of these compounds were found to be negative in earlier studies. An explanation for the difference in results is provided. It is probable that different germ cell stages and treatment regimens are suitable for different types of chemicals. Larval treatment may still be valuable and can complement adult treatment in environmental mutagen testing.

Manas, F. Peralta, L. Raviolo, J. Garcia Ovando, H. Weyers, A. Ugnia, L. Gonzalez Cid, M. Larripa, I. Gorla, N.	2009	Genotoxicity of AMPA, the environmental metabolite of glyphosate, assessed by the Comet assay and cytogenetic tests. Ecotoxicology and Environmental Safety Volume: 72 Pages: 834-837 ASB2012-11891

Abstract*
Formulations containing glyphosate are the most widely used herbicides in the world. AMPA is the major environmental breakdown product of glyphosate. The purpose of this study is to evaluate the in vitro genotoxicity of AMPA using the Comet assay in Hep-2 cells after 4h of incubation and the chromosome aberration (CA) test in human lymphocytes after 48 h of exposition. Potential in vivo genotoxicity was evaluated through the micronucleus test in mice. In the Comet assay, the level of DNA damage in exposed cells at 2.5-7.5 mM showed a significant increase compared with the control group. In human lymphocytes we found statistically significant clastogenic effect AMPA at 1.8 mM compared with the control group. In vivo, the micronucleus test rendered significant statistical increases at 200-400 mg/kg. AMPA was

genotoxic in the three performed tests. Very scarce data are available about AMPA potential genotoxicity.

Abstract*
It was evaluated the genotoxicity of glyphosate which up to now has heterogeneous results. The comet assay was performed in Hep-2 cells. The level of DNA damage in the control group (5.42±1.83 arbitrary units) for tail moment (TM) measurements has shown a significant increase ($p < 0.01$) with glyphosate at a range concentration from 3.00 to 7.50mM. In the chromosome aberrations (CA) test in human lymphocytes the herbicide (0.20–6.00 mM) showed no significant effects in comparison with the control group. In vivo, the micronucleus test (MNT) was evaluated in mice at three doses rendering statistical significant increases at 400 mg/kg (13.0±3.08 micronucleated erythrocytes/1000 cells, $p < 0.01$). In the present study glyphosate was genotoxic in the comet assay in Hep-2 cells and in the MNT test at 400 mg/kg in mice. Thiobarbituric acid reactive substances (TBARs) levels, superoxide dismutase (SOD) and catalase (CAT) activities were quantified in their organs. The results showed an increase in these enzyme activities.

Mladinic, M. Berend, S. Vrdoljak, A.L. Kopjar, N. Radic, B. Zeljezic, D.	2009	Evaluation of Genome Damage and Its Relation to Oxidative Stress Induced by Glyphosate in Human Lymphocytes *in Vitro* Environmental and Molecular Mutagenesis Volume: 50 Number: 9 Pages: 800-807 ASB2012-11906

Abstract*
In the present study we evaluated the genotoxic and oxidative potential of glyphosate on human lymphocytes at concentrations likely to be encountered in residential and occupational exposure. Testing was done with and without metabolic activation (S9). Ferric-reducing ability of plasma (FRAP), thiobarbituric acid reactive substances (TBARS) and the hOGG1 modified comet assay were used to measure glyphosate's oxidative potential and its impact on DNA. Genotoxicity was evaluated by alkaline comet and analysis of micronuclei and other nuclear instabilities applying centromere probes. The alkaline comet assay showed significantly increased tail length (20.39 µm) and intensity (2.19%) for 580 µg/mL, and increased tail intensity (1.88%) at 92.8 µg/mL, compared to control values of 18.15 µm for tail length and 1.14% for tail intensity. With S9, tail length was significantly increased for all concentrations tested: 3.5, 92.8, and 580 µg/mL. Using the hOGG1 comet assay, a significant increase in tail intensity was observed at 2.91 µg/mL with S9 and 580 µg/mL without S9. Without S9, the frequency of micronuclei, nuclear buds and nucleoplasmic bridges slightly increased at concentrations 3.5 µg/mL and higher. The presence of S9 significantly elevated the frequency of nuclear instabilities only for 580 µg/mL. FRAP values slightly increased only at 580 µg/mL regardless of metabolic activation, while TBARS values increased significantly. Since for any of the assays applied, no clear dose-dependent effect was observed, it indicates that glyphosate in concentrations relevant to human exposure do not pose significant health risk.

Mladinic, M., Perkovic, P., Zeljezic, D.	2009b	Characterization of chromatin instabilities induced by glyphosate, terbuthylazine and carbofuran using cytome FISH assay Toxicology Letters Volume: 189 Number: 2 Pages: 130-137 ASB2012-11907

Abstract*
Possible clastogenic and aneugenic effects of pesticides on human lymphocytes at concentrations likely to be encountered in residential and occupational exposure were evaluated with and without the use of

metabolic activation (S9). To get a better insight into the content of micronuclei (MN) and other chromatin instabilities, lymphocyte preparations were hybridized using pancentromeric DNA probes. Frequency of the MN, nuclear buds (NB) and nucleoplasmic bridges (NPB) in cultures treated with glyphosate slightly increased from 3.5 µg/mL onward. Presence of S9 significantly elevated cytome assay parameters only at 580 µg/mL. No concentration-related increase of centromere (C+) and DAPI signals (DAPI+) was observed for glyphosate treatment. Terbuthylazine treatment showed a dose dependent increase in the number of MN without S9 significant at 0.0008 µg/mL and higher. At concentration lower than 1/16 LD_{50} occurrence of C + MN was significantly elevated regardless of S9, but not dose related, and in the presence of S9 only NBs containing centromere signals were observed. Carbofuran treatment showed concentration dependent increase in the number of MN. The frequency of C + MN was significant from 0.008 µg/mL onward regardless of S9. Results suggest that lower concentrations of glyphosate have no hazardous effects on DNA, while terbuthylazine and carbofuran revealed a predominant aneugenic potential.

Abstract*
We analyzed the consequences of aerial spraying with glyphosate added to a surfactant solution in the northern part of Ecuador. A total of 24 exposed and 21 unexposed control individuals were investigated using the comet assay. The results showed a higher degree of DNA damage in the exposed group (comet length = 35.5 mu m) compared to the control group (comet length = 25.94 mu m). These results suggest that in the formulation used during aerial spraying glyphosate had a genotoxic effect on the exposed individuals.

Peluso, M. Munnia, A. Bolognesi, C. Parodi, S.	1998	32P-postlabeling detection of DNA adducts in mice treated with the herbicide Roundup. Environmental and Molecular Mutagenesis Volume: 31 Number: 4 Pages: 55-59 TOX1999-318

Abstract*
Roundup is a postemergence herbicide acting on the synthesis of amino acids and other important endogenous chemicals in plants. Roundup is commonly used in agriculture, forestry, and nurseries for the control or destruction of most herbaceous plants. The present study shows that Roundup is able to induce a dose-dependent formation of DNA adducts in the kidneys and liver of mice. The levels of Roundup-related DNA adducts observed in mouse kidneys and liver at the highest dose of herbicide tested (600 mg/kg) were 3.0 +/- 0.1 (SE) and 1.7 +/- 0.1 (SE) adducts/10(8) nucleotides, respectively. The Roundup DNA adducts were not related to the active ingredient, the isopropylammonium salt of glyphosate, but to another, unknown component of the herbicide mixture. Additional experiments are needed to identify the chemical specie(s) of Roundup mixture involved in DNA adduct formation. Findings of this study may help to protect agricultural workers from health hazards and provide a basis for risk assessment.

Poletta, G.L. Larriera, A. Kleinsorge, E. Mudry, M.D.	2009	Genotoxicity of the herbicide formulation Roundup® (glyphosate) in broad-snouted caiman (*Caiman latirostris*) evidenced by the Comet assay and Micronucleus test Mutation Research Volume: 672 Number: 2 Pages: 95-102 ASB2012-12002

Abstract*
The genotoxicity of pesticides is an issue of worldwide concern. The present study was undertaken to evaluate the genotoxic potential of a widely used herbicide formulation, Roundup® (glyphosate), in erythrocytes of broad-snouted caiman (*Caiman latirostris*) after in ovo exposure. Caiman embryos were exposed at early embryonic stage to different sub-lethal concentrations of Roundup® (50, 100, 200, 300, 400, 500, 750, 1000, 1250 and 1750 µg/egg). At time of hatching, blood samples were obtained from each animal and two short-term tests, the Comet assay and the Micronucleus (MN) test, were performed on erythrocytes to assess DNA damage. A significant increase in DNA damage was observed at a concentration of 500 µg/egg or higher, compared to untreated control animals ($p<0.05$). Results from both the Comet assay and the MN test revealed a concentration-dependent effect. This study demonstrated adverse effects of Roundup® on DNA of *C. latirostris* and confirmed that the Comet assay and the MN test applied on caiman erythrocytes are useful tools in determining potential genotoxicity of pesticides. The identification of sentinel species as well as sensitive biomarkers among the natural biota is imperative to thoroughly evaluate genetic damage, which has significant consequences for short- and long-term survival of the natural species.

* Quoted from article

Klimisch evaluation

Reliability of study: Not reliable

Comment: Non-GLP studies in a unique test model. Micronucleus assay followed guideline, Comet assay similar to guideline. Test methods have been modified to be applied caiman species. Methodological deficiencies: housing and feeding conditions of parents not specified; sex not distinguished, stability and homogeneity assessment of test substance preparations not reported. Results not reported separately for replicate individual animals.

Relevance of study: Not relevant. Highly artificial *in ovo* exposure scenario not relevant to real world environmental exposures. Caiman eggs are covered and not exposed to the surface. Any glyphosate in a potential herbicide overspray would sorb to sediment and organic matter and not transport to the egg surface.

Rodrigues, H.G. Penha-Silva, N. Ferreira Pereira de Araujo, M. Nishijo, H. Aversi-Ferreira, T.A.	2011	Effects of Roundup® Pesticide on the Stability of Human Erythrocyte Membranes and Micronuclei Frequency in Bone Marrow Cells of Swiss Mice The Open Biology Journal, Volume: 4 Pages: 54-59 ASB2012-12010

Abstract*
Pesticides can affect the health of living organisms through different mechanisms such as membrane denaturation. The evaluation of the deleterious effects of chemical agents on biological membranes can be performed through the analysis of the stability of erythrocytes against a concentration gradient of certain chemical agent in physiologic saline solution. This work analyzed the effect of the herbicide Roundup® on the membrane of human erythrocytes in blood samples collected with EDTA or heparin as anticoagulant agent. The results were analyzed through spectrophotometry at 540 nm and light microscopy. There was an agreement between spectrophometric and morphologic analyses. At the concentration limit recommended for agricultural purposes, Roundup® promoted 100% of hemolysis. The D50Roundup® values obtained for human blood samples collected with EDTA were not significantly different from those obtained for samples collected with heparin. However, the lysis curves presented lower absorbance values at 540 nm in the presence of blood collected with EDTA in relation to that collected with heparin, probably due to haemoglobin precipitation with EDTA. This work also analyzed the effects of three different Roundup® doses (0.148, 0.754 and 1.28 mg/kg) on the micronuclei frequency in bone marrow cells of Swiss mice in relation to a positive control of cyclophosphamide (250 mg/kg). The two highest Roundup® doses showed the same genotoxicity level as the positive control.

Vigfusson, N.V. Vyse, E.R.	1980	The effect of the pesticides Dexon, Captan and Roundup on sister chromatid exchanges in human lymphocytes in vitro. Mutation Research Volume: 79 Pages: 53-57 TOX9700576, ASB2012-12044

Abstract*
Three pesticides at varying concentration were tested for the induction of SCE [sister chromatid exchanges] in human lymphocytes in vitro. The fungicide, Dexon, sodium (4- (dimethylamino)phenyl)diazene sulfonate, caused the greatest increase in SCE frequency and the response was dose related. The herbicide,

Roundup, isopropylamide salt of N- (phosphonomethyl)glycine, had the least effect on SCE requiring the use of much higher concentrations to produce an effect. Limited results were obtained with the fungicide Captan, cis-N-((trichloromethyl)thio)-4-cyclo-hexene-1, 2-dicarboximide, because of toxic levels of the fungicide or solvent used.

Epidemiology studies

A number of epidemiology studies over the last decade have focused on pesticide exposure and associated health outcomes. Publications vary in the specificity of their conclusions regarding pesticides in general, classes of pesticides and in some cases individual insecticides, herbicides or fungicides. While some of these publications specifically mention glyphosate, few draw tenable associations with any specific cancer outcome. Publications suggesting glyphosate is associated with any cancer outcome are discussed below.

An essential consideration in both, risk assessment and interpreting the relevance of toxicology data is exposure assessment. An inherent low level of confidence exists for epidemiological studies where tenuous links to exposure exist. Suggested associations between health outcomes and any possible causative agent are merely speculation if exposures are not identifiable. Pivotal to the understanding of glyphosate exposure are data published by Acquavella *et al.* (2004, ASB2012-11528; 2005, ASB2012-11530), which quantified human systemic glyphosate exposure levels in farmer applicators and their families. The geometric mean systemic dose for farmers applying glyphosate, some of whom applied glyphosate to areas up to 400 acres, was 0.0001 mg/kg/day, approximately 0.03% of the EU glyphosate acceptable operator exosure Level (AOEL) according to EU Review Report 6511/VI/99-final (21 January 2008, ASB2009-4191). The highest systemic dose, skewed well above the geometric mean, was 0.004 mg/kg/day, which is 1.95% EU glyphosate AOEL according to EU Review Report 6511/VI/99-final (21 January 2008, ASB2009-4191) and 1.3% of the current EU glyphosate attapcable daily intake (ADI) according to EU Review Report 6511/VI/99-final (21 January 2008, ASB2009-4191). Even lower systemic doses were determined for spouses and children, 0.00004 mg/kg and 0.0008 mg/kg, respectively. Multiple carcinogenicity studies have since been conducted by numerous glyphosate registrants demonstrating NOAELs of at least ten-fold higher than the highest dose tested in the study driving the current EU ADI calculation.

The largest epidemiological study of pesticide exposure and health outcomes in the United States is the Agricultural Health Study (AHS), which included glyphosate. Dozens of publications have resulted from data generated in this study of approximately 57,000 enrolled farmer applicators. Blair *et al.* (2009, ASB2012-11566) provided an overview of cancer endpoints associated with different agricultural chemicals reported in earlier AHS publications. Glyphosate was not reported to be associated with leukemia, melanoma, or cancers of the prostate, lung, breast, colon or rectum. De Roos *et al.* (2005, ASB2012-11605) reported AHS data evaluating glyphosate use and multiple cancer endpoints; no association was noted for glyphosate with all cancers, including cancer of the lung, oral cavity, colon, rectum, pancreas, kidney, bladder, prostate, melanoma, all lymphohematopoietic cancers, non- Hodgkin's lymphoma (NHL) and leukemia. In an earlier publication based on another data set, however, De Roos *et al.*, (2003, ASB2012-11606) reported an association between NHL and glyphosate use. McDuffie *et al.* (2001, ASB2011-364) reported a non-significant positive association between self-reported glyphosate exposure and NHL in a Canadian study. Blair *et al.* (2009, ASB2012-11566) did not report an association between glyphosate use and NHL in the AHS data, but a "possible association" between glyphosate use and multiple myeloma was mentioned. The AHS publication reporting this refers to a "suggested association" between glyphosate use and multiple myeloma (De Roos *et al.*, 2005, ASB2012-11605), yet it did not demonstrate significant increase in relative risk for multiple myeloma. Both De Roos papers will be discussed in more detail below. Interestingly, a subsequent AHS review paper for the President's Cancer Panel (Freeman, 2009, ASB2012-11623) specifically references De Roos (2005 ASB2012-11605) as providing no observed incidents of cancers of any type being associated with glyphosate.

Lee *et al.* (2005, ASB2012-11882) reported a glyphosate association with gliomas, with the odds ratio differing between self-respondents (OR = 0.4) and proxy respondents (OR = 3.1). The authors expressed concern that higher positive associations observed for proxy respondents with glyphosate and several other pesticides, and suggested perhaps more accurate reporting of proxies for cases, and underreporting by proxies for controls; proxy respondents were spouses in 62 % of cases versus 45% of controls, lending to lower reported incidents in the control group.

Monge et al (2007, ASB2012-11909) investigated associations between parental pesticide exposures and childhood Leukaemia in Costa Rica. Results are not interpretable for glyphosate as exposure was estimated with "other pesticides", including paraquat, chlorothalanil and "others". No association was noted for paternal exposures, but elevated leukaemias were associated with maternal exposures to "other pesticides" during pregnancy. Similarly, glyphosate is captured under "other pesticides" being associated with NHL by Fritschi *et al.* (2005, ASB2012-11624) and therefore should not be interpreted as an association with glyphosate.

Some further epidemiologic studies are focused on an association between pesticide exposure and Non-Hodgkin`s Lymphoma (NHL). Hardell and Eriksson (1999, ASB2012-11838) investigated in a case-control study the incidence of NHL in relation to pesticide exposure in Sweden. 404 cases and 741 controls have been included. The authors discussed an increased risk for NHL especially for phenoxyacetic acids. Glyphosate was included in the uni-variate and multi-variate analyses. However, only 7 of 1145 subjects in the study gave exposure histories to this agent. The authors reported a moderately elevated odds ratio (OR) of 2.3 for Glyphosate. This OR was not statistically significant oand was based on only 4 "exposed" cases and 3 "exposed" controls. The major limitations of this study were: the reliance on reported pesticide use (not documented exposure) information, the small number of subjects who reported use of specific pesticides, the possibility of recall bias, the reliance on secondary sources (next-of-kin interviews) for approximately 43% of the pesticide use information, and the dificulty in the controlling for potential confounding factors given the small number of exposed subjects.

A further study was submitted by Hardell *et al.* (2002, ASB2012-11839). This study pools data from the above mentioned publication by Hardell and Eriksson (1999, ASB2012-11838) with data from a previously submitted publication from Nordström, Hardell at al. (1998, TOX1999-687).

The authors found increased risks in an uni-variate analysis for subjects exposed to herbicides, insecticides, fungicides and impregnating agents. Among herbicides, significant associations were found for glyphosate and MCPA. However, in multi-variate analyses the only significantly increased risk was for a heterogenous category of other herbicides than above, not for glyphosate. No information is given about exposure

duration, exposure concentration, as well as medical history, lifestyle factors (e.g. smoker, use of prescribed drugs etc.). In all, the above mentioned limitations of the publication from Hardell and Eriksson (1999, ASB2012-11838) are also the limitions of the publication from Hardell *et al.* (2002, ASB2012-11839).
Fritschi *et al.* (2005, ASB2012-11624) submitted a case-control study with 694 cases of NHL and 694 controls in Australia. Substantial exposure to any pesticide was associated with an increase of NHL. However, no association between NHL and glyphosate can be made on basis of this study. No information was given about exposure duration, used glyphosate products, exposure duration and application rates. Therefore, the documentation is considered to be insufficient for assessment.
Eriksson *et al.* (2008, ASB2012-11614) reported a case-control study which included 910 cases of NHL and 1016 controls living in Sweden. The highest risk was calculated for MCPA. Glyphosate exposure was reported by 29 cases and 18 controls, and the corresponding odds ratio (OR) was 2.02. Results and reliability of the study are discussed below.
Alavanja *et al.* (2013, ASB2014-9174) reviewed studies on cancer burden among pesticide applicators and others due to pesticide exposure. In this article the epidemiological, molecular biology, and toxicological evidence emerging from recent literature assessing the link between specific pesticides and several cancers including prostate cancer, non-Hodgkin lymphoma, leukemia, multiple myeloma, a breast cancer were integrated. Glyphosate was reported to be the most commonly used in conventional pesticide active ingedient worldwide. The only association between the use of glyphosate and cancer burden described in this review was the result of Eriksson *et al.* (2008, ASB2012-11614) which was described above.

The following epidemiology publications report a lack of association between glyphosate and specific cancer types.

- Alavanja *et al.* (2003, ASB2012-11535) reported on prostate cancer associations with specific pesticide exposures in the AHS; glyphosate did not demonstrate a significant exposure-response association with prostate cancer.
- Multigner et al, (2008, ASB2012-11917) also reported a lack of association between glyphosate use and prostate cancer. This data appears to have also been reported by Ndong *et al.* (2009, ASB2012-11922).
- The lack of association between glyphosate use and prostate cancer was also supported recently in an epidemiology study of Farmers in British Columbia, Canada by Band *et al.* (2011, ASB2012-11555).
- Lee *et al.* (2004, ASB2012-11883) reported a lack of association between glyphosate use and stomach and esophageal adenocarcinomas.
- Carreon *et al.* (2005, ASB2012-11585) reported epidemiological data on gliomas and farm pesticide exposure in women; glyphosate had no association with gliomas.
- Engel *et al.* (2005, ASB2012-11613) reported AHS data on breast cancer incidence among farmers' wives, with no association between breast cancer and glyphosate.
- Flower et al (2004, ASB2012-11620) reported AHS data on parental use of specific pesticides*a* and subsequent childhood cancer risk among 17,280 children, with no association between childhood cancer and glyphosate.
- Andreotti *et al.* (2009, ASB2012-11544) reported AHS data where glyphosate was not associated with pancreatic cancer.
- Landgren *et al.* (2009, ASB2012-11875) reported AHS data on monoclonal gammopathy of undetermined significance (MGUS), showing no association with glyphosate use.
- Karunanayake *et al.* (2011, ASB2012-11865) reported a lack of association between glyphosate and Hodgkin's lymphoma.
- Pahwa *et al.* (2011, ASB2012-11987) reported a lack of association between glyphosate and multiple myeloma.
- Schinasi and Leon (2014, ASB2014-4819) published the results of epidemiologic research on the relationship between non-Hodgkin lymphoma (NHL) and occupational exposure to pesticides. Phenoxy herbicides, carbamate insecticides, organophosphorus insecticides and lindane were positively associated with NHL. However, no association between NHL an glyphosate was reported.
- Kachuri *et al.* (2013, ASB2014-8030) investigated the association between lifetime use of multiple

pesticides and multiple myeloma in Canadian men. Excess risks of multiple myeloma were observed among men reported using at least one carbamate pesticide, one phenoxy herbicide and ≥ organochlorines. However, no excess risk was observed for glyphosate.

- Cocco *et al.* (2014, ASB2014-7523) investigated the role of occupational exposure to agrochemicals in the aetiology of lymphoma overall, B cell lymphoma and its most prevalent subtypes. No increased CLL risk in relation to glyphosate was evidenced.
- Alavanja and Bonner (2012, ASB2014-9173) reviewed studies on occupational pesticide exposure and cancer risk. Twenty one pesticides identified subsequent to the last IARC review showed significant exposure-response associations in studies of specific cancers. No significant association was observed for glyphosate
- El-Zaemy and Heyworth (2012, ASB2014-9473) reported a case control study on the association between pesticide spray drift from agricultural pesticide application areas and breast cancer in Western Australia. The findings support the hypothesis that woman who ever noticed spray drift or who first noticed spray drift at a younger age had increased risk of breast cancer. However, it was not possible to examine whether the observed associations are the result of a particular class of pesticides.
- Pahwa *et al.* (2011, ASB2014-9625) investigated the putative association of specific pesticides with soft-tissue sarcoma (STS). A Canadian population-based case-control study conducted in six provinces was used on this analysis. The incidence of STS was associated with insecticides aldrin and diazinon after adjustment for other independent predictors. However, no statistically significant association between STS and exposure to glyphosate or other herbicides was observed.
- Koutros *et al.* (2011, ASB2014-9594) studied associations between pesticide and prostate cancer. No statistically significant positive association between pesticides and prostate cancer were observed. There was suggestive evidence on an increased risk (OR>1.0) with an increasing number of days of use of petroleum oil/petroleum distillate used as herbicide, terbufos, fonofos, phorate and methyl bromide. However, no increased risk (OR>1.0) was observed for glyphosate.

In summarizing AHS publications, Weichenthal *et al.* (2010, ASB2012-12048) noted that increased rates in the following cancers were not associated with glyphosate use; overall cancer incidence, lung cancer, pancreatic cancer, colon or rectal cancer, lymphohematopoietic cancers, leukemia, NHL, multiple myeloma, bladder cancer, prostate cancer, melanoma, kidney cancer, childhood cancer, oral cavity cancers, stomach cancer, esophagus cancer and thyroid cancer.
Mink *et al.* (2012, ASB2014-9617) submitted a comprehensive review of epidemiologic studies of glyphosate and cancer. To examine potential cancer risks in humans they reviewed the epidemiologic literature to evaluate whether exposure to glyphosate is associated causally with cancer risk in humans. They also reviewed relevant methodological and biomonitoring studies of glyphosate. The review found non consistent pattern of positive assciations indicating a causal relationship between total cancer (in adults or in children) or any site- specific cancer and exposure to glyphosate.

Animal studies
Just recently (*i.e.*, after submission of the GTF dossier), a two-year study in rats was published (Séralini *et al.*, 2012, ASB2012-15514). Its main objective was to show a possible impact of long-term feeding of genetically modified (and glyphosate treated) maize to rats but three of the test groups were administered a commercially available formulation (Roundup GT Plus, apparently authorised at least in Belgium) containing 450 g glyphosate/L at different concentrations ranging from 0.1 ppb (50 ng glpyphosate/L) to 0.5% (2.25 g glyphosate/L) in drinking water. In these groups, the authors reported alterations in some clinical chemistry (blood and urine) parameters and hormone levels and histopathological lesions concerning the liver and the gastrointestinal tract but also a higher incidence of mammary tumours in females resulting in a shorter lifespan. This study was heavily discussed in the scientific community as well as in the general public where it gained remarkable attention due to massive promotion although it was clearly flawed by many serious deficiencies. A major point of concern was the small group size of only 10 males and 10 females per dose, *i.e.*, the test design was that one of a subchronic study. Such a small number of animals is not appropriate for a long-term study because age-related changes cannot be adequaetely

taken into account. Following the receipt of contributions from many MS authorities, a comprehensive critical assessment was published by EFSA (2012, ASB2012-15513, EFSA Journal, 2012, 10 (11), 2986). The conclusion was that "the currently available evidence does not impact on the ongoing re- evaluation of glyphosate…". This opinion on the Séralini study is agreed with and supported by the RMS.
In reaction to this publication a large number of letters was send to the editor: Barale-Thomas (2012, ASB2013-10998), Berry (2012, ASB2013-10988), Grunewald (2012, ASB2013-11001), Hammond *et al.* (2012, ASB2013-10995), Heinemann (2012, ASB2013-10987), Langridge (2012, ASB2013-10986), Ollivier (2012, ASB2013-11000), Panchin (2013, ASB2013-10937), Pilu (2012, ASB2013-10992), Schorsch (2013, ASB2013-10996), Tester (2012, ASB2013-10994), Tien & Huy (2012, ASB2013-10984), Trewavas (2012, ASB2013- 10989), Tribe (2012, ASB2013-10997), Wager (2012, ASB2013-10993), de Souza (2012, ASB2013-10999).

Chruszielska *et al.* (2000, ASB2013-9829) published a combined long term toxicity and carcinogenicity study in rats. The active substance glyphosate was used in the study and the study was performed on basis of OECD guideline 453. The number of animals per dose group and sex (85 animals) was even higher than required in guideline 453. Therefore, the study is considered to be relevant. No carcinogenic effects have been registered in the study.

George *et al.*, (2010, ASB2012-11829) used a 2-stage cancer model in mice to evaluate a glyphosate formulation for tumor promotion. A known tumor promoter, 12-o-tetradecanoyl- phorbol-13-acetate (TPA) was used as a positive control and for comparison with glyphosate effects after exposure to a tumor initiator, 7, 12-dimethylbenz[a]anthracene. Proteomics were later applied to extrapolate a basis for glyphosate formulation tumor promotion. The results are considered by the authors to indicate a tumor promoting potential of glyphosate. However, the formulation Roundup was used in the study and not the active substance glyphosate. Furthermore, the up- and down-regulation of protein expression is not sufficient to prove a carcinogenic effect.

Mechanistic studies
Andreotti *et al.* (2012, ASB2014-9198) investigated the interaction between pesticide use and genetic variants involved in lipid metabolism on prostate cancer risk. The authors examined the interactions between 39 pesticides and 220 single nucleotide polymorphisms (SNPs) in 59 genes. They found 17 interactions that displayed a significant monotonic increase in prostate cancer risk with pesticides exposure in one genotype and no significant association in the other genotype. The most noteworthy association was for ALOXE3 rs 3027208 and terbufos. A higher risk was also reported with this method for glyphosate and other pesticides. However, the authors emphasize that glyphosate was not associated with prostate cancer risk in the main effect studies (Agricultural Health Study AHS.

Barry *et al.* (2011, ASB2014-9247) evaluated interactions between 39 pesticides and 394 tag single-nucleotide polymorphisms (SNPs) for 31 BER genes among 776 prostate cancer cases and 1444 male controls in a nested case-control study of Agricultural Healt Study (AHS) pesticide applicators. The authors used likelihood ratio tests from logistic regression models to determine p-values for interactions between three-level pesticide variables and SNP (assuming a dominant model) and the false discovery rate multiple comparison adjustment approach. The authors observed notable interactions between several pesticides and BER gene variants with respect to prostate cancer. However, only fonofos x NEIL3 rs 1983132 showed an interaction fitting an expected biological pattern that remained significant after adjustment for multiple comparisons. No significant association was observed for glyphosate.

Hardell, L. Eriksson, M.	1999	A Case-Control Study of Non-Hodgkin Lymphoma and Exposure to Pesticides. Cancer, Volume: 85, Number: 6, Pages: 1353-1360 ASB2012-11838

The following studies are described more detailed:

Abstract*

Background. The incidence of non-Hodgkin lymphoma (NHL) has increased in most Western countries during the last few decades. Immunodefective conditions are established risk factors. In 1981, the authors reported an increased risk for NHL following exposure to certain pesticides. The current study was designed to further elucidate the importance of phenoxyacetic acids and other pesticides in the etiology of NHL.

Methods. A population-based case–control study in northern and middle Sweden encompassing 442 cases and twice as many controls was performed. Exposure data were ascertained by comprehensive questionnaires, and the questionnaires were supplemented by telephone interviews. In total, 404 cases and 741 controls answered the questionnaire. Uni- variate and multi-variate analyses were performed with the SAS statistical data program.

Results. Increased risk for NHL was found for subjects exposed to herbicides (odds ratio [OR], 1.6; 95% confidence interval [CI], 1.0 –2.5) and fungicides (OR, 3.7; 95% CI, 1.1–13.0). Among herbicides, the phenoxyacetic acids dominated (OR, 1.5; 95% CI, 0.9 –2.4); and, when subclassified, one of these, 4-chloro-2-methyl phenoxyacetic acid (MCPA), turned out to be significantly associated with NHL (OR, 2.7; 95% CI, 1.0–6.9). For several categories of herbicides, it was noted that only exposure during the most recent decades before diagnosis of NHL was associated with an increased risk of NHL. Exposure to impregnating agents and insecticides was, at most, only weakly related to NHL.

Conclusions. Exposure to herbicides in total, including phenoxyacetic acids, during the decades before NHL diagnosis resulted in increased risk for NHL. Thus, the risk following exposure was related to the latency period. Fungicides also increased the risk for NHL when combined, but this group consisted of several different agents, and few subjects were exposed to each type of fungicide.

Klimisch evaluation

Reliability of study: Not reliable

Comment: Study prone to selection and recall bias. No evidence of relevant glyphosate exposures. Medical history was assessed, but not reported.

Relevance of study: Not relevant (Exposure to multiple chemicals and though glyphosate exposure data were convincing (7/1145 subjects) and statistically non-significant positive associations reported.)

Klimisch code: 3

Additional comments:

Hardell and Eriksson (1999, ASB2012-11838) conducted a case control study to look for associations between reported pesticide use and non-Hodgkin's lymphoma (NHL). The study included 404 NHL cases and 741 controls. The measure of association in this study was the odds ratio (OR), a statistic that estimates of the ratio of disease rates (in this case NHL rates) for exposed and unexposed populations.

The authors reported statistically significant associations for NHL with: reported use of any herbicide (OR = 1.6), reported use of any fungicide (OR = 3.7), and reported use of 4-chloro- 2-methylphenoxyacetic acid (OR = 2.7). The major limitations of this study were: the reliance on reported pesticide use (not documented exposure) information, the small number of subjects who reported use of specific pesticides, the possibility of recall bias, the reliance on secondary sources (next-of-kin interviews) for approximately 43% of the

pesticide use information, and the difficulty in controlling for potential confounding factors, given the small number of exposed subjects.
The authors also reported a moderately elevated OR of 2.3 for glyphosate. This OR was not statistically significant and was based on only four "exposed" cases and three "exposed" controls.
This study has several important limitations: no exposure assessment, dependence on next-of- kin's recollections of study subjects' pesticide use for approximately 43% of study subjects, potential recall bias, and the very small number of subjects who reported using specific herbicides. The latter leads to findings that are statistically imprecise. Due to the potential for bias and the statistical imprecision, the results of this study are not convincing.

Hardell, L. Eriksson, M. Nordstrom, M.	2002	Exposure to pesticides as risk factor for non-Hodgkin's lymphoma and hairy cell leukemia: Pooled analysis of two Swedish case-control studies. Leukemia & Lymphoma Volume: 43 Number: 5 Pages: 1043-1049 ASB2012-11839

Abstract*
Increased risk for non-Hodgkin's lymphoma (NHL) following exposure to certain pesticides has previously been reported. To further elucidate the importance of phenoxyacetic acids and other pesticides in the etiology of NHL a pooled analysis was performed on two case-control studies, one on NHL and another on hairy cell leukemia (HCL), a rare subtype of NHL. The studies were population based with cases identified from cancer registry and controls from population registry. Data assessment was ascertained by questionnaires supplemented over the telephone by specially trained interviewers. The pooled analysis of NHL and HCL was based on 515 cases and 1141 controls. Increased risks in uni-variate analysis were found for subjects exposed to herbicides (OR 1.75, CI 95% 1.26-2.42), insecticides (OR 1.43, CI 95% 1.08-1.87), fungicides (OR 3.11, CI 95% 1.56-6.27) and impregnating agents (OR 1.48, CI 95% 1.11-1.96). Among herbicides, significant associations were found for glyphosate (OR 3.04, CI 95% 1.08-8.52) and 4-chloro-2-methyl phenoxyacetic acid (MCPA) (OR 2.62, CI 95% 1.40-4.88). For several categories of pesticides the highest risk was found for exposure during the latest decades before diagnosis. However, in multi-variate analyses the only significantly increased risk was for a heterogeneous category of other herbicides than above.

Abstract*
Pesticide exposure may be a risk factor for non-Hodgkin's lymphoma, but it is not certain which types of pesticides are involved. A population-based case-control study was undertaken in 2000-2001 using detailed methods of assessing occupational pesticide exposure. Cases with incident non-Hodgkin's lymphoma in two Australian states (n = 694) and controls (n = 694) were chosen from Australian electoral rolls. Logistic regression was used to estimate the risks of non-Hodgkin's lymphoma associated with exposure to subgroups of pesticides after adjustment for age, sex, ethnic origin, and residence. Approximately 10% of cases and controls had incurred pesticide exposure. Substantial exposure to any pesticide was associated with a trebling of the risk of non-Hodgkin's lymphoma (odds ratio = 3.09, 95 % confidence interval: 1.42, 6.70). Subjects with substantial exposure to organochlorines, organophosphates, and "other pesticides" (all other pesticides excluding herbicides) and herbicides other than phenoxy herbicides had similarly increased risks, although the increase was statistically significant only for "other pesticides." None of the exposure metrics (probability, level, frequency, duration, or years of exposure) were associated with non- Hodgkin's lymphoma. Analyses of the major World Health Organization subtypes of non- Hodgkin's lymphoma suggested a stronger effect for follicular lymphoma. These increases in risk of non-Hodgkin's lymphoma with substantial occupational pesticide exposure are consistent with previous work.

De Roos, A. J. Zahm, S. H. Cantor, K. P. Weisenburger, D. D. Holmes, F. F. Burmeister, L. F. Blair, A.	2003	Integrative assessment of multiple pesticides as risk factors for non-Hodgkin's lymphoma among men. Occupational and Environmental Medicine Volume: 60, Number: 9, Pages: -E11 ASB2012-11606

Abstract*
Background: An increased rate of non-Hodgkin's lymphoma (NHL) has been repeatedly observed among farmers, but identification of specific exposures that explain this observation has proven difficult.
Methods: During the 1980s, the National Cancer Institute conducted three case-control studies of NHL in the midwestern United States. These pooled data were used to examine pesticide exposures in farming as risk factors for NHL in men. The large sample size (n = 3417) allowed analysis of 47 pesticides simultaneously, controlling for potential confounding by other pesticides in the model, and adjusting the estimates based on a prespecified variance to make them more stable.
Results: Reported use of several individual pesticides was associated with increased NHL incidence,

including organophosphate insecticides coumaphos, diazinon, and fonofos, insecticides chlordane, dieldrin, and copper acetoarsenite, and herbicides atrazine, glyphosate, and sodium chlorate. A subanalysis of these "potentially carcinogenic" pesticides suggested a positive trend of risk with exposure to increasing numbers.
Conclusion: Consideration of multiple exposures is important in accurately estimating specific effects and in evaluating realistic exposure scenarios.

De Roos, A.J. Blair, A. Rusiecki, J.A. Hoppin, J.A. Svec, M. Dosemeci, M. Sandler, D.P. Alavanja, M.C.	2005	Cancer Incidence among Glyphosate-Exposed Pesticide Applicators in the Agricultural Health Study Environmental Health Perspectives Volume: 113, Number: 1, Pages: 49-54 ASB2012-11605

Abstract*
Glyphosate is a broad-spectrum herbicide that is one of the most frequently applied pesticides in the world. Although there has been little consistent evidence of genotoxicity or carcinogenicity from *in vitro* and animal studies, a few epidemiologic reports have indicated potential health effects of glyphosate. We evaluated associations between glyphosate exposure and cancer incidence in the Agricultural Health Study (AHS), a prospective cohort study of 57,311 licensed pesticide applicators in Iowa and North Carolina. Detailed information on pesticide use and other factors was obtained from a self-administered questionnaire completed at time of enrolment (1993–1997). Among private and commercial applicators, 75.5% reported having ever used glyphosate, of which > 97% were men. In this analysis, glyphosate exposure was defined as *a*) ever personally mixed or applied products containing glyphosate; *b*) cumulative lifetime days of use, or "cumulative exposure days" (years of use × days/year); and *c*) intensity-weighted cumulative exposure days (years of use × days/year × estimated intensity level). Poisson regression was used to estimate exposure–response relations between glyphosate and incidence of all cancers combined and 12 relatively

common cancer subtypes. Glyphosate exposure was not associated with cancer incidence overall or with most of the cancer subtypes we studied. There was a suggested association with multiple myeloma incidence that should be followed up as more cases occur in the AHS. Given the widespread use of glyphosate, future analyses of the AHS will allow further examination of long-term health effects, including less common cancers.

Klimisch evaluation

Reliability of study:	Reliable without restrictions
Comment:	Well documented publication. Study included glyphosate exposure, as well as demographic and lifestyle factors. However, adjusted relative risk calculations eliminated a significant proportion of the data set without justification.
Relevance of study:	Relevant (Evaluation focussed on glyphosate, although other pesticides were also considered in the data evaluation)
Klimisch code:	2

Additional comments:
Study included glyphosate exposure, as well as demographic and lifestyle factors. However, adjusted relative risk calculations eliminated a significant proportion of the data set without justification.

Response 1 – summary from Letter to the Editor by Farmer et al. (2005, ASB2012- 11616)
Authors provided an incomplete genotoxicity review which was inconsistent with opinions of regulatory agencies and experts around the world, that glyphosate is not genotoxic. An extensive toxicology review of glyphosate was cited by the authors, mentioning a lack of carcinogenicity with glyphosate exposures, yet neglected to cite the extensive genotoxicity review in the same publication by Williams *et al.* (2000, ASB2012-12053)
Biological plausibility of a cancer effect should be considered in the light of exposure. Acquavella et al (2004, ASB2012-11528) reported the maximum systemic dose to resulting from application of glyphosate to areas as large as 400 acres was 0.004 mg/kg, and the geometric mean systemic dose was 0.0001 mg/kg in farmers. If these glyphosate applications and exposures continued daily over the course of a lifetime, the systemic dose would be at least 250,000-fold lower than the cancer no-effect level in rodents.
The authors were requested to further evaluate their models for confounding and selection bias in the multiple myeloma analysis.

Response 2 – summary from Lash (2007, ASB2012-11877)
Table 2 of De Roos *et al.* (2005, ASB2012-11605) noted 32 cases of multiple myeloma associated with "ever-use" of glyphosate and when compared with "never-use" (adjusted for age only) yielded a rate ratio of 1.1 (95% CI 0.5-2.4). However, when the data set was adjusted for age, demographic and lifestyle factors and other pesticide use, the rate ratio increased to 2.6 (95% CI 0.7-9.4).
The adjusted estimate merits careful inspection and can only be undertaken with access to the primary data, not made available by the authors.
Bias analysis was conducted, accounting for confounding and exposure misclassification.
Adjustment for confounders in De Roos *et al.* (2005, ASB2012-11605), which resulted in limiting the data set by 25 % because of missing data on the adjustment variables, likely introduced selection bias and produced the a rate ratio of 2.6 that was substantially biased.

Eriksson, M. Hardell, L. Carlberg, M. Akerman, M.	2008	Pesticide exposure as risk factor for non-Hodgkin lymphoma including histopathological subgroup analysis International Journal of Cancer Volume: 123, Pages: 1657-1663 ASB2012-11614

Abstract*
We report a population based case-control study of exposure to pesticides as risk factor for non-Hodgkin lymphoma (NHL). Male and female subjects aged 18-74 years living in Sweden were included during December 1, 1999, to April 30, 2002. Controls were selected from the national population registry. Exposure to different agents was assessed by questionnaire. In total 910 (91%) cases and 1016 (92%) controls participated. Exposure to herbicides gave odds ratio (OR) 1.72, 95% confidence interval (CI) 1.18-2.51. Regarding phenoxyacetic acids highest risk was calculated for MCPA; OR 2.81, 95% CI 1.27-6.22, all these cases had a latency period >10 years. Exposure to glyphosate gave OR 2.02, 95% CI 1.10-3.71 and with
>10 years latency period OR 2.26, 95% CI 1.16-4.40. Insecticides overall gave OR 1.28, 95% CI 0.96-1.72 and impregnating agents OR 1.57, 95% CI 1.07-2.30. Results are also presented for different entities of NHL. In conclusion our study confirmed an association between exposure to phenoxyacetic acids and NHL and the association with glyphosate was considerably strengthened.

Reliability of study:	Not reliable
Comment:	Multiple avenues for bias were introduced in study design, execution and data processing. No information about exposure duration, used glyphosate products and application rates. Other factors (i.e. smoking habits, medication etc.) were assessed but not included in the evaluation.
Relevance of study:	Relevant with reservation
Klimisch code:	3

Additional comments:
The authors (Eriksson *et al*. 2008, ASB2012-11614) conducted a population-based case- control study of exposure to a variety of pesticides and non-Hodgkin lymphoma (NHL), including separate analyses of histopathological categories of NHL. Study subjects were males and females, ages 18-74, living in Sweden between December 1, 1999 and April 30, 2002. The final study group included 910 cases and 1016 controls. Exposure, ascertained via an interviewer-administered questionnaire, focused on pesticide and other chemical agents, and included a total work history (although a job-exposure matrix was not used). For pesticide exposure, information on number of years, number of days per year, and approximate length of exposure per day was also obtained. A minimum of one full day of exposure was required for categorization as "exposed."

The authors reported a statistically significant positive association between "herbicide exposure" and NHL (OR = 1.72; 95% CI: 1.18-2.51). Glyphosate exposure was reported by 29 cases and 18 controls, and the corresponding odds ratio (OR) was 2.02 (95% CI: 1.10-3.71). The ORs for glyphosate exposure of <10 days and >10 days were 1.69 (95% CI: 0.70-4.07) and 2.36 (1.04-5.37), respectively. The ORs for glyphosate were 1.11 (95% CI: 0.24-5.08) and 2.26 (95% CI: 1.16-4.40) for "latency" periods of 1-10 years and >10 years, respectively. In analyses of glyphosate and type of NHL, statistically significant positive associations were observed for small lymphocytic lymphoma/chronic lymphocytic leukemia (SLL/CLL) (OR = 3.35; 95% CI: 1.42-7.89) and for "unspecified NHL" (OR = 5.63; 95% CI: 1.44-22.0). Odds ratios for the other types (total B-cell lymphomas, grade I-III follicular lymphoma, diffuse large B-cell

lymphoma, other specified B-cell lymphoma, unspecified B- cell lymphoma, and T-cell lymphomas) were above 1.0, but were not statistically significant (i.e., the 95% confidence intervals were relatively wide and included the null value of 1.0).

The authors concluded, "Glyphosate was associated with a statistically significant increased OR for lymphoma in our study, and the result was strengthened by a tendency to dose- response effect…" (p. 1662). The authors suggested that their findings are consistent with results of a previous case-control study (Hardell and Eriksson 1999, ASB2012-11838) and pooled analysis (Hardell *et al.* 2002, ASB2012-11839) that they conducted. In the case-control study, an OR of 2.3 (95% CI: 0.4-13.0), based on 4 exposed cases and 3 exposed controls, was reported for glyphosate and NHL. In the pooled analysis of two case-control studies, which included data from Hardell and Eriksson (1999, ASB2012-11838), an OR of 3.04 (95% CI: 1.08- 8.52) was reported, based on 8 exposed cases and 8 exposed controls. The authors also cited three studies (De Roos *et al.* 2003, ASB2012-11606; McDuffie *et al.* 2001; ASB2011-364, De Roos *et al.* 2005, ASB2012-11605) by other groups as being consistent with their results in that they "also associate glyphosate with different B-cell malignancies such as lymphomas and myelomas." It should be noted, however, that the relative risk (RR) reported by De Roos *et al.* (2005, ASB2012-11605) for the highest versus lowest category of cumulative exposure days of glyphosate and NHL in the prospective Agricultural Health Study was 0.9.

Interpretation Issues

Identification of Cases and Potential Referral Bias. It is noteworthy that the cases in the current analysis were identified from some of the same hospitals as the authors' prior publication; thus, referral bias may have been an issue. In particular, the researchers approached the patients after diagnosis if the physicians deemed it appropriate. Therefore, if the physicians were concerned that their patient's NHL was associated with agricultural exposures, they may have suggested participation in the study.

Participation Rates and Potential Selection Bias. The authors report a participation rate of 91% and 92% for cases and controls, respectively; however, these figures are based on completed questionnaires out of those who had previously said they would participate in the study. The number of eligible patients (i.e., prior to physician approval to "approach") was not reported, so the computation of an exact participation rate is difficult. Based on information provided in the paper, participation among cases is estimated to be about 80%. Nonparticipation is a concern for several reasons. First, in a case-control study, an odds ratio will be an accurate representation of the exposure-disease association when the cases are representative of all cases and the controls are representative of the exposure experience of the population that gave rise to the cases. If the final study sample is not representative of this "target population" then measures of effect (e.g., the odds ratio) may not be valid. In addition, one must be concerned about selection bias. Selection bias occurs in a case-control study when the exposure distribution for cases and controls differ for those who participate in the study compared to those who are eligible but do not participate in the study. It is not possible to determine whether there is selection bias without information about nonparticipants.

Strengths and Limitations of Using Living Cases Only versus All Cases (Living + Dead).

The authors noted that 88 potential cases died before they could be interviewed and were therefore excluded from the study. It is also stated in the Discussion that restricting the study to living cases and controls was an "advantage" of the study, as interviewing cases and controls directly compared to interviewing next-of-kin was preferable. While it is generally true that this would be an advantage, the following statement by the authors, therefore, is not accurate, "The study covered all new cases of NHL during a specified time" (p. 1660). The study did not include all new cases; it included only those cases who survived until the time of the interview. Thus, while there may have been an advantage to restricting the study to living cases, there was a trade-off in that the study population did not represent all cases, specifically those cases with more aggressive disease. This disadvantage was not discussed by the authors, nor was the potential bias that could have resulted from excluding many eligible cases.

Exposure Measurement and Information Bias. Exposure was ascertained via a questionnaire oriented towards pesticide and other chemical agents. In addition, interviewers collected information by telephone

if "important" data were lacking, incomplete, or unclear. It is unknown what is meant by "important," and the proportion of cases and controls who received phone calls was not reported. Thus, information bias may be a concern. Even though interviewers were blinded to case and/or control status, they may have been able to determine this information during the course of the interview. Furthermore, recall bias may be an issue because exposure information was based on participant response and cases and controls may recall and/or report past pesticide exposures differently. No exposure validation techniques were implemented, nor did an industrial hygienist (or any other type of personnel trained in assessing occupational exposures) independently validate/estimate the frequency and/or intensity of exposure. The authors assumed that "some misclassification regarding quantity of exposure has probably occurred, but such misclassification would most probably be nondependent of case/control status, and therefore only weaken any true risks" (p. 1660). They do not provide any explanation as to why they believe that exposure misclassification would be "most probably" nondifferential. If NHL cases believe that pesticides may be related to their disease, then it is certainly possible that they may recall and/or report pesticide exposure differently than NHL-free controls, which could result in odds ratios that are inflated as a result of bias.

Interpretation of "dose-response" analyses. The referent group in the statistical analyses consisted of participants who were unexposed to all pesticides. The dose-response analyses were based on a dichotomy of the median number of days exposed to a particular agent. It is difficult to analyze "dose-response" when only two exposure categories are considered. Furthermore, the dose-response analyses were based on median values of exposure but heterogeneity of cut-points is evident across agents. For example, glyphosate was analyzed as < 10 days and > 10 days, whereas, "other" herbicides were analyzed as < 32 days and > 32 days. Although analytical cut-points were data driven, interpretation across the wide varietyof exposures is complicated by the variability in exposure cut-points. In addition, even though though the OR for the higher category of exposure days was greater than the OR for the lower category, the two 95% confidence intervals were wide and overlapped considerably (0.70-4.07 and 1.04-5.37).
Thus, it is not clear whether the two point estimates reported (1.69 and 2.36) are significantly different from each other. Finally, this result cited in the "dose-response" analyses may have been confounded by exposure to other herbicides. In Table II (Eriksson *et al.* 2008, ASB2012- 11614), the authors observed elevated associations for other herbicides, including MCPA, 2,4,5-T and/or 2,4-D. The correlation between exposure to glyphosate and other herbicides was not provided nor were analyses of glyphosate-exposed individuals after accounting for the collinear relation between this agent and other agents. The odds ratio for "ever" exposure to glyphosate was attenuated after additional adjustment for other pesticides (Table VII, Eriksson *et al.* 2008, ASB2012-11614), but multi-variate -adjusted estimates for the "dose-response" odds ratios were not reported.
Unusual Pattern of Positive Associations. The authors conducted multiple comparisons, and one would expect a certain proportion of their findings to be statistically significant (whether in the positive or inverse direction) simply as a result of chance. It is somewhat surprising, therefore, that the vast majority of the ORs presented in this manuscript are greater than 1.0, regardless of the statistical significance. The authors do note that for some of the analyses (e.g., latency), only chemicals for which ORs were greater than 1.5 and for which there were at least 10 exposed cases, or for which there was a statistically significant OR were evaluated. On the other hand, dose-response was evaluated based on the number of exposed subjects and not on the strength or significance of the findings. The authors do not address this directly, but do state in their Discussion, "…several pesticides are chemically related and may exert their effects on humans through a similar mechanism of action, which may explain the wide range of pesticides that have been related to NHL over time in different countries and with different exposure conditions" (p. 1661). On the other hand, this pattern of positive findings could be a result of bias, including recall bias (or other information bias), selection bias, uncontrolled confounding, or a combination of these and other factors.

Interpretation of Eriksson *et al.* (2008, ASB2012-11614) in Context of Other Studies. Despite the statement by the authors that, "Recent findings from other groups also associate glyphosate with different B-cell malignancies such as lymphomas and myeloma" (p. 1662), most multi-variate analyses of glyphosate and NHL do not report statistically significant associations (De Roos *et al.* 2005, ASB2012-11605; De Roos *et al.* 2003; ASB2012-11606, Hardell and Eriksson 1999, ASB2012-11838; Hardell *et al.* 2002; ASB2012-11839, Lee *et al.* 2004; ASB2012-11883, McDuffie *et al.* 2001; ASB2011-364, Nordström *et al.* 1998,

TOX1999-687) (Tables B.6.5-62 and B.6.5-63). It is notable that Hardell *et al.* (2002, ASB2012-11839) reported a significant positive association between glyphosate association and NHL, but the multi-variate -adjusted odds ratio was attenuated and not statistically significant. Similar findings were reported by Eriksson *et al.* (2008, ASB2012-11614). Specifically, the association reported by the authors in the abstract (OR = 2.02; 95% CI: 1.10- 3.71) was adjusted for age, sex and year of diagnosis or enrollment. When other pesticides were added to that model (i.e., agents with statistically significant increased odds ratios, or with an odds ratio greater than 1.5 and with at least 10 exposed subjects), the adjusted odds ratio was 1.51 (95% CI: 0.77-2.94). Thus, the authors' final statement, "Furthermore, our earlier indication of an association between glyphosate and NHL has been considerably strengthened" is questionable. Their previous findings showed a non-significant association after multi-variate adjustment (OR = 1.85; 95% CI: 0.55-6.20). The 2008 study similarly reported a statistically non-significant association between glyphosate and NHL after multi- variate adjustment (OR = 1.51; 95% CI: 0.77-2.94). The results reported for analyses of duration of exposure and latency of exposure did not adjust for other pesticides, and one would expect that those ORs would also be attenuated.

Summary of Findings: Cohort and Case-Control Studies of Exposure to Glyphosate and Non-Hodgkin Lymphoma

Table B.6.5-62: Cohort Studies

Author Year	Description	No. of Exposed Cases	Type of Relative Risk Estimate	Relative Risk Estimate	95% Confidence Limits	Variables Included in Statistical Model
De Roos *et al.* 2005 (ASB2012 -11605)	57-2,678 vs. 1-20 Cumulative Exposure Days[a]	17	RR	0.9	0.5-1.6	Age at enrollment, education, pack-years of cigarette smoking, alcohol consumption in the past year, family history of cancer in first-degree relatives, and state of residence
	337.2-18,241 vs. 0.1-79.5 Intensity-Weighted Exposure Days[b]	22	RR	0.8	0.5-1.4	Also adjusted for other pesticides

George, J. Prasad, S. Mahmood, Z. Shukla, Y.	2010	Studies on glyphosate-induced carcinogenicity in mouse skin: A proteomic approach Journal of Proteomics Volume: 73, Pages: 951-964 ASB2012-11829

Abstract*

Glyphosate is a widely used broad spectrum herbicide, reported to induce various toxic effects in non-target species, but its carcinogenic potential is still unknown. Here we showed the carcinogenic effects of glyphosate using 2-stage mouse skin carcinogenesis model and proteomic analysis. Carcinogenicity study revealed that glyphosate has tumor promoting activity. Proteomic analysis using 2-dimensional gel electrophoresis and mass spectrometry showed that 22 spots were differentially expressed (>2 fold) on glyphosate, 7, 12- dimethylbenz[a]anthracene (DMBA) and 12-O-tetradecanoyl-phorbol-13-acetate (TPA) application over untreated control. Among them, 9 proteins (translation elongation factor eEF- 1 alpha chain, carbonic anhydrase III, annexin II, calcyclin, fab fragment anti-VEGF antibody, peroxiredoxin-2, superoxide dismutase [Cu–Zn], stefin A3, and calgranulin-B) were common and showed similar expression pattern in glyphosate and TPA-treated mouse skin. These proteins are known to be involved in several key processes like apoptosis and growth- inhibition, anti-oxidant responses, etc. The up-regulation of calcyclin, calgranulin-B and down-regulation of superoxide dismutase [Cu–Zn] was further confirmed by immunoblotting, indicating that these proteins can be good candidate biomarkers for skin carcinogenesis induced by glyphosate. Altogether, these results suggested that glyphosate has tumor promoting potential

in skin carcinogenesis and its mechanism seems to be similar to TPA.

Klimisch evaluation

Reliability of study:	Reliable with restrictions
Comment:	Non-guideline mechanistic study. Scientifically acceptable study with deficiencies (controls with glyphosate alone, and co-formulants were not included)
Relevance of study:	Relevant with restrictions (Glyphosate formulation not glyphosate alone was tested.)
Klimisch code:	2

Additional comments:

The authors use glyphosate as a synonym for what is really a glyphosate based formulated product. Doses in this study are not representative of human exposures to glyphosate or glyphosate based formulations. Mice in the tumor promoting group VIII received topical applications of concentrated glyphosate formulated product three times per week for over thirty weeks without washing after an initial treatment with the potent tumor initiator DMBA. Glyphosate had been shown to have very low dermal absorption, even in formulated products, and since is non-volatile, would likely accumulate on mouse skin. Surfactants are typically irritating and non-volatile. Given the irritation potential of the unwashed exposed mouse skin over the course of thirty or more weeks, tumor promotion may be a physical response to substantial localized dermal irritation. Epidemiological studies reported above note no association with glyphosate and either skin or lip cancers.

Label directions outline appropriate personal protective equipment such as gloves and long sleeves. Furthermore, any dermal exposure of concentrated product to human skin would prove irritating and prompt handlers to wash off soon after dermal exposure.

Human *in vitro* dermal absorption studies reported for a range of glyphosate based formulations containing different surfactant systems all demonstrate extremely low dermal absorption of glyphosate active ingredient for concentrated products, of less than 0.2%. Test material recovery in each of the four reported dermal absorption studies was very good, close to 100%. Most of the glyphosate was removed during skin surface washing at either eight or twenty four hours of in vitro human skin exposure. This also suggests significant potential for accumulation of glyphosate on the surface of the mice skin in George *et al.* (2010, ASB2012- 11829).

The up-regulation / down-regulation of protein expression reported after a single dermal dose of a glyphosate formulated product (proteomics experiment, group II), while interesting, does not demonstrate any toxicological endpoint. Rather, perturbations may well represent normal homeostatic fluctuations and be a natural response to insult.

Author(s)	Year	Study title
Seralini, G.-E. Clair, E. Mesnage, R. Gress, S. Defarge, N. Malatesta, M. Hennequin, D. Spiroux de Vendomois, J.	2012	Long term toxicity of a Roundup herbicide and a Roundup-tolerant genetically modified maize. Food and Chemical Toxicology 50, 4221-4231 ASB2012-15514

Abstract*

The health effects of a Roundup-tolerant genetically modified maize (from 11% in the diet), cultivated with or without Roundup, and Roundup alone (from 0.1 ppb in water), were studied 2 years in rats. In females, all treated groups died 2–3 times more than controls, and more rapidly. This difference was visible in 3 male groups fed GMOs. All results were hormone and sex dependent, and the pathological profiles were comparable. Females developed large mammary tumors almost always more often than and before controls, the pituitary was the second most disabled organ; the sex hormonal balance was modified by GMO and Roundup treatments. In treated males, liver congestions and necrosis were 2.5–5.5 times higher. This pathology was confirmed by optic and transmission electron microscopy. Marked and severe kidney nephropathies were also generally 1.3–2.3 greater. Males presented 4 times more large palpable tumors than controls which occurred up to 600 days earlier. Biochemistry data confirmed very significant kidney chronic deficiencies; for all treatments and both sexes, 76% of the altered parameters were kidney related. These results can be explained by the non linear endocrine-disrupting effects of Roundup, but also by the overexpression of the transgene in the GMO and its metabolic consequences.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	The study was performed to investigate the long term toxicity and carcinogenicity. However the study design does not agree with the OECD guidelines on long term toxicity and carcinogenicity.
Relevance of study:	Relevant with restrictions (Glyphosate formulation not glyphosate alone was tested.)
Klimisch code:	3

Comments:

Seralini *et al.* (2012, ASB2012-15514) submitted a report of long term toxicity of a Roundup herbicide and a Roundup-tolerant genetically modified maize. The health effects have been studied 2 years in rats. Six groups of rats were fed with 11, 22 and 22% of genetically modified NK603 maize either treated or not with Roundup. Three further groups of rats were fed with control diet and had access to water supplemented with 50 ng/L, 400 mg/L and 2.25 g/L of the commercial product Roundup (GT Plus, 450 g/L of glyphosate). The pure active substance glyphosate was not tested in this study.

The study is not considered reliable because of several important limitations. According to the authors the studies have been performed to investigate the long term toxicity and carcinogenicity. However, the number of animals per dose and sex was only 10 and also the further study design does not agree with the OECD guidelines on long term toxicity and carcinogenicity. The spontaneous incidence of mammary tumors in the used Sprague Dawley rats is much higher than in most other rat strains. Therefore, a higher number of animals would be necessary for the differentiation between treatment related carcinogenicity and accidental aberrations. Also for the assessment of mortality and further described toxic effects a higher number of animals would be needed.

The presented results in the publication are incomplete and therefore, an evaluation of the presented results was complicated.

The study was extensively discussed and criticized in the public. In an additional paper Seralini *et al.* (2013, ASB2013-10985) gave some answers to the critics. The authors admit that the study "should not be considered as a final point in knowing the toxicological effects of NK603 and Roundup)" and that the study has limits.

Jany (2012, ASB2014-9580) submitted a critical review of the study by Seralini *et al.* (2012). The authors conclude that the scientific value of this publication would be limited and non conclusions are possible concerning maize NK603 with and without Roundup treatment.

Ollivier (2012, ASB2013-11000) proposes to use the Chi-square test to compare mortality rates in the study of Seralini *et al.* (2012). In result of this test there would be no statistical significance.

In a further paper Seralini *et al.* (2014, ASB2014-9632) discuss criticisms which have been published in

reaction on the study by Seralini *et al.* (2012, ASB2012-15514).
John (2014, ASB2014-9584) reacts in a letter on the decision of the publisher to retract the article of Seralini *et al.* (2012). John concludes that there would be no grounds for retraction
Wallace-Hayes (2014, ASB2014-9559), the editor-in-chief of Food and Chemical Toxicology, gives answers on questions on the retraction of the paper of Seralini *et al.* (2012). He concludes once more that "a careful and time-consuming analysis found that the data were inconclusive, and therefore the conclusion described in the article were unreliable. Accordingly, the article was retracted."
Folta (2014, ASB2014-9478) writes in a letter to the editor that he would see this work of Seralini (2012) as a manipulation of the scientific process to achieve activist gains. He stands behind the journal`s decision to retract the work.
Rosanoff (2014, ASB2014-9397) proposes in a letter concerning the Seralini (2012) study that the raw data should be published.
Roberfroid (2014, ASB2014-9393) writes in a letter concerning the Seralini (2012) study that he is ashamed about the decision to retract this paper.
In a further letter Roberfroid (2014, ASB2014-9392) writes that in his understanding the study of Seralini (2012) remains an important scientific (not a regularory) observation that can not be ignored.
Pilu (2012, ASB2014-9387) writes in a letter to the editor on the Seralini (2012) study that mycotoxins in maize could have influenced the results of the study. Therefore, he asks for further information on the mycotoxin content in the maize used in the Seralini study.

Author(s)	Year	Study title
Chruscielska, K. Brzezinski, J. Kita, K. Kalhorn, D. Kita, I. Graffstein, B. Korzeniowski, P.	2000	Glyphosate Evaluation of chronic activity and possible far-reaching effects. Part 1. Studies on chronic toxicity Pestycydy 2000, (3-4), 11-20 ASB2013-9829

Abstract*:
The combined test of chronic toxicity and carcinogenicity of glyphosate was performed on Wistar-RIZ rats. The herbicide was administered in water at concentrations: 0, 300, 900, 2700 m/L. The examination of the peripheral blood parameters and the smears of bone marrow did not reveal harmful effect of the herbicide on haematopoietic system of rats. The biochemical parameters determined on blood and urine only in some cases showed significant deviations in comparison with the control group, but in any examined indices dose-effect-time occurred what could manifest the toxic influence of glyphosate. In pathomorphological studies on the organs no correlation was stated between the number of observed tumours and the concentrations of the herbicide. It indicates lack of pathogenic influence of glyphosate on neoplastic pathogenesis.

Klimisch evaluation

Reliability of study:	Reliable with restrictions
Comment:	The published details of the study are limited. However, according to the authors the study was performed on basis of OECD guideline No. 453
Relevance of study:	Relevant

Klimisch code: 2

Comments:
The active substance glyphosate was used in the study and the study was performed on basis of OECD guideline 453. The number of animals per dose group and sex (85 animals) was even higher than required in guideline 453. Therefore, the study is considered to be relevant. No carcinogenic effects have been registered in the study.

B.6.5 Reproductive toxicity (Annex IIA 5.6)

B.6.5.1 Published data (released since 2000)

A large number of studies on developmental and reproductive toxicity (DART) was published since 2000. These studies are reported and discussed below. Furthermore, also studies on endocrine disruption (ED) have been included in this chapter because they are mainly related to developmental and reproductive toxicity.

Published studies on developmental toxicity, reproductive toxicity and an endocrine disrupting potential of glyphosate and glyphosate based formulations include *in vitro* studies, *in vivo* studies and epidemiological studies. Many studies since 2000 are specifically discussed in a comprehensive glyphosate DART review publication by Williams *et al.* (2012, ASB2012-12052). Further discussions of significant papers follow.

In addition, glyphosate was included on the US EPA Endocrine Disruptor Screening Program's (EDSP) first list of 67 compounds to Tier 1 Screening. The US EPA published the criteria for inclusion on List 1 was strictly based on exposure potential, not hazard, specifically stating in the Federal Register (2009, ASB2012-12041); "This list should not be construed as a list of known or likely endocrine disruptors".

A consortium of glyphosate registrants in North America, the Joint Glyphosate Task Force, LLC (JGTF), coordinated the conduct of the glyphosate battery of Tier 1 screening assays under the EDSP and submitted these assays to the US EPA. The US EPA will evaluate the full battery of Tier 1 screening assays together using a weight of evidence approach, for glyphosate's potential to interact with the estrogen, androgen and thyroid endocrine pathways. The following below were submitted by the JGTF to the US EPA in early 2012 and are reviewed. However, the Agency has announced they will not release their Data Evaluation Records (DERs) for individual EDSP studies until a weight of evidence review has been completed for List 1 compounds.

In Vitro EDSP Glyphosate Studies submitted to the US EPA

- Androgen Receptor Binding (Rat Prostate Cytosol); OCSPP 890.1150
- Aromatase (Human Recombinant); OCSPP 890.1200
- Estrogen Receptor Binding Assay Using Rat Uterine Cytosol (ER-RUC); OCSPP 890.1250
- Estrogen Receptor Transcriptional Activation (Human cell Line, HeLa-9903); OCSPP 890.1300; OECD 455
- Published OECD Validation of the Steroidogenesis Assay (Hecker *et al.*, 2010, ASB2012-11840)

- *In Vivo* Hershberger Assay (Rat); OCSPP 890.1600; OECD 441
- Female Pubertal Assay; OCSPP 890.1450; OECD None
- Male Pubertal Assay; OCSPP 890.1500
- Uterotrophic Assay (Rat); OCSPP 890.1600; OECD 440
- Fish Short-Term Reproduction Assay; OCSPP 890.1350; OECD 229

The glyphosate Tier 1 screening assay study reports are owned by the JGTF. The European Glyphosate

Task Force (GTF) is negotiating to procure access rights to the battery of glyphosate EDSP Tier 1 screening study reports. Results of the Hershberger and Uterotrophic *in vivo* rat studies, now in the public domain, as are the published results of the OECD validation of the Steroidogenesis assay, in which glyphosate clearly had no impact on steroidogenesis, are discussed below.
Recently, the first publicly data available from the glyphosate Tier 1 assays under the US EPA Endocrine Disruptor Screening Program, were reported at the 2012 Society of Toxicology meeting (Saltmiras & Tobia 2012, ASB2012-12016) for the Hershberger and Uterotrophic assays. No effects were noted for any potential for glyphosate to interact with androgenic or estrogenic pathways under these GLP studies following the US EPA 890 Series Test Guidelines.
Bailey *et al.* (2013, ASB2013-3464) summarized the first results of the male and female Pubertal assay of this programm. Based on these results, glyphosate does not exhibit endocrine disruption in Male and Female Pubertal assays.
Levine *et al.* (2012, ASB2014-9609) published a short summary of the results of tests with glyphosate in the EPA`s Endocrine Disruptor Screening Program (EDSP). They conclude that from the weight of evidence provided by the Tier 1 assays, performed at independent labs, under the EDSP along with the higher Tier regulatory safety studies, with a high level of confidence glyphosate would not be an endocrine disruptor.

In Vitro Glyphosate DART/ED Publications

Many *in vitro* research publications have characterised pesticide formulations, including glyphosate based formulations, as toxic and endocrine disrupting products. Researchers and editorial boards did in some cases not consider the fact that surfactants (which are often components of formulated pesticide products), by their physico-chemical nature, are not suitable test substances using *in vitro* cell models. Surfactants compromise the integrity of cellular membranes, including mitochondrial membranes, and thus confound endpoint measurements considered as representative of specific toxicological modes of action or pathways.

A laboratory at the University of Caen, France, has multiple recent publications of *in vitro* research with glyphosate and glyphosate based formulations (Richard *et al.*, 2005, ASB2009- 9024; Benachour *et al.*, 2007, ASB2009-9018; Benachour and Seralini, 2009, ASB2012- 11561; Gasnier *et al.*, 2009, ASB2012-11629; Gasnier *et al.*, 2010, ASB2012-11628; Gasnier *et al.*, 2011, ASB2012-11630; Clair *et al.*, 2012, ASB2012-11592; Mesnage *et al.*, 2012, ASB2012-11900), with proposed extrapolations to an array of *in vivo* effects including potent endocrine disruption, aromatase inhibition, estrogen synthesis, placental toxicity, foetotoxicity, embryotoxicity and bioaccumulation. These publications are in some cases replicates of earlier studies, using different cell lines or primary cell cultures and in some cases the same data are reported again in a subsequent publication. Firstly, the *in vitro* synergism claims are conjecture, because no control groups of surfactant without glyphosate were tested. Secondly, the extrapolations to *in vivo* effects are unjustifiable based on both the unsuitability of surfactants in such test systems and the supraphysiological cytotoxic concentrations at which *in vitro* effects are reported. Again often overlooked by *in vitro* researchers and editorial boards, Levine *et al.* (2007, ASB2009-9030) presented convincing data demonstrating a lack of *in vitro* synergism for glyphosate with other formulation ingredients. Regarding Seralini's repeated claims of glyphosate induced aromatase inhibition in mircosomes (Richard *et al.*, 2005; TOX2005-1743, Benachour *et al.*, 2007, ASB2009-9018; Gasnier *et al.*, 2009, ASB2012-11629), the data are confounded and thus uninterpretable where surfactants are introduced to such *in vitro* systems. This is noted in the US EPA Aromatase Inhibition Test Guideline, OECD 890.1200, in which notes, "Microsomes can be denatured by detergents [surfactants]. Therefore, it is important to ensure that all glassware and other equipment used for microsome preparations be free of detergent residue."

Another *in vitro* publication claiming a specific developmental toxicity pathway has gained significant public attention. Paganelli *et al.* (2010, ASB2012-11986) conducted three *in vitro* assays, (i) frog embryos exposed to glyphosate formulation; (ii) frog embryos directly injected without injection blank negative controls; and (iii) fertilised chicken embryos exposed directly to a glyphosate formulation through a hole cut in the egg shell. Key issues surrounding this research include irrelevant routes of exposure as well as excessively high and environmentally unrealistic doses.

Thongprakaisang *et al.*, (2013, ASB2013-11991) submitted a study on the effects of pure glyphosate on estrogen receptors mediated transcriptional activity and their expressions. The following cell lines have been used: a hormone-dependent breast cancer, T47D, a stably EREC-luc construct tranfected hormone-dependent breast cancer T47D-KBluc and a hormone-independent human breast cancer, MDA-MB231. Glyphosate (purity ≥ 98%) was tested in concentrations from 10^{-12} to 10^{-6} M. Glyphosate exerted proliferative effects on human hormone-dependent cell lines but not in hormone-independent cell lines. Furthermore, an additive estrogenic effect between glyphosate and genistein, a phytoestrogen, was reported. The authors conclude that these in vitro results need further investigation in an animal study. It must be emphasised that no increase in mammary tumours was reported in any of the numerous long-term studies in rats or mice (see Vol. 3, B.6.5 and Vol. 1, B.2.6).
Cavalli *et al.* (2013, ASB2014-7495) studied the effects of the formulation Roundup Original in rat testis and Sertoli cells in vitro. The authors propose that Roundup toxicity, implicated in Ca2+ overload, cell signalling misregulation, stress response of the endoplasmatic reticulum, and/or depleted antioxidant defenses, could contribute to Sertoli cell disruption in spermatogenesis that could have an impact on male fertility.

***In Vivo* Glyphosate DART/ED Publications**
Relatively few *in vivo* publications on glyphosate DART and ED exist in comparison with the list of *in vitro* publications. Some lack appropriate interpretation of basic toxicology; e.g. Daruich *et al.* (2001, ASB2012-11601). Beuret *et al.* (2005, ASB2012-11564) investigated the effects of 1% Glyphosate oral exposure (a trade product from Argentina described as "Herbicygon" was used which is a commercial herbicide formulation) on lipoperoxidation and antioxidant enzyme systems in pregnant rats and in fetuses. Lipoperoxidation was higher in both maternal and fetal livers in the glyphosate treated groups. Catalase and Superoxide dismutase activity were not altered. Both studies are reviewed in Williams *et al.* (2012, ASB2012-12052).

Dallegrave *et al.* (2003, ASB2012-11600; 2007, ASB2012-2721) published results of two non-guidelines rat developmental toxicity studies, in which a glyphosate based formulation containing POEA was evaluated. However, reporting deficiencies and inconsistencies pose difficulties in data interpretation. These studies are dicussed in detail in the Appendix on tallowamines (please refer to B.6.13).

Romano *et al.* (2010, ASB2012-12012) evaluated a glyphosate based formulation in a male pubertal-like assay in Wistar rats, reporting decreased preputial separation, reduced seminiferous epithelial height, increased luminal diameter of seminiferous tubules, and increased relative testicular and adrenal weights. Given the gravity of the reported findings in this publication, a review was undertaken by Kelce *et al.* (2010, ASB2012-11867). Most recently, Romano *et al.* (2012, ASB2012-12011) reported additional findings in male ratsafter supposed *in utero* and *post natal* exposures which include "behavioral changes and histological and endocrine problems in reproductive parameters and these changes are reflected by a hypersecretion of androgens and increased gonadal activity, sperm production and libido". As in their first publication, Romano *et al.* (2012, ASB2012-12011) base their hypothesis on selectively discussed literature implicating glyphosate as an endocrine disruptor, predominantly with citations to research from the Seralini laboratory.

Kimmel *et al.* (2013, ASB2013-3462) analyzed the information from 7 unpublished developmental studies in rabbits and 6 developmental toxicity studies in rats to determine if glyphosate poses a risk for cardiovascular malformations. In summary, assessment of the reviewed data fails to support a potential risk for increased cardiovascular defects as a result of glyphosate exposure during pregnancy.
Chruscielska *et al.* (2000, ASB2013-9831) submitted a teratogenicity study in Wistar outbred rats. The used test guideline was not indicated. Doses of 0-750-1500-3000 mg/kg bw/dayhave been administered from day 7-14 of pregnancy to 20 females per dose group. No embryotoxic and no teratogenic effects have been administered.
Omran and Salama (2013, ASB2014-7614) report that the exposition of snails to atrazine or glyphosate resultet in signs of endocrine disruption and cellular toxicity. However, in this study only the formulation "Herfosate" was used and no pure active substance glyphosate.

Razi *et al.* (2012, ASB2014-9390) consider that glyphosate (125 mg/kg bw/d oral administered for 10, 20, 30 & 40 days) effects testicular tissue and sperm parameters in male Wistar rats. Clear effects were already seen after 10 days administration and thereafter, however accompanied by significant clinical symptoms (decreased movement, staggering gait, occasional trembling, diarrhea) and reduced body weight gain of 20 %. These findings are in contrast to those in rat studies submitted for EU evaluation. For comparison, the current EU evaluation of glyphosate proposes an overall subchronic (90-d) NOAEL of 414 mg/kg bw/d (rats) and for reproductive toxicity of 351 mg/kg bw/d, albeit generated from feeding studies. Similarily, after oral administration in female rats an NOAEL of 300 mg/kg bw/d for maternal and developmental effects was established, toxic effects were observed at much higher dose levels, only. The high toxicity described in the present publication is hardly to explain, because the publication does not give any information whether technical material or a glyphosated based formulation was tested. To conclude, the results of the publication does not affect the current assessment of glyphosate.
Cassault-Meyer *et al.* (2014, ASB2014-5615) investigated the effects of a glyphosate-based herbicide (Roundup Grand Travaux Plus) after an 8-day exposure of adult rats. Endocrine (aromatase, estrogen and androgen receptors, Gperl in testicular and sperm mRNAs) and testicular functions (organ weight, sperm parameters and expression of the blood-testis barrier markers) were monitored at day 68, 87, and 122 after treatment, spermiogenesis and spermatogenesis. A significant and differential expression of aromatase in testis and a diminution of mRNA expression of nuclear markers in spermatozoa were observed. The authors conclude that results suggest changes in androgen/estrogen balance and in sperm nuclear quality.

POEA DART Studies

Polyethoxylated alkylamine (POEA) surfactants are a class of non-ionic surfactant, containing a tertiary amine, an aliphatic group of variable carbon chain length and two separate sets of ethoxy (EO) chains of variable length. A dietary exposure assessment of POEAs was submitted by Bleeke *et al.* (2010, ASB2010-6123). This exposure assessment report also refers to the US EPA Alky Amine Polyalkoxylates Human Health Risk Assessment, which includes POEAs (http://www regulations.gov/search/Regs/home.html#documentDetail?R=09000064809b983b). Williams *et al.* (2012, ASB2012-12052) recently evaluated and detailed the results of DART studies with two different POEA surfactants.
Furthermore, a detailed comparison of the toxicity of tallowamine and glyphosate was submitted in the appendix "Toxicological evaluation of the POE-tallowamine surfactant (CAS no. 61791-26-2)" which is attached to this report.

Epidemiology Glyphosate DART/ED Publications

Several epidemiology studies in which glyphosate exposure was considered have evaluated the following range of reproductive outcomes: miscarriage, fecundity, pre-term delivery, gestational diabetes mellitus, birth weights, congenital malformations, neural tube defects, attention-deficit disorder / attention-deficit hyperactive disorder (ADD/ADHD). In most instances, glyphosate and reproductive outcomes lack a statistically significant positive association, as described in a recent review of glyphosate non-cancer endpoint publications (Mink *et al.*, 2011, ASB2012-11904). In evaluating ADD/ADHD, a positive association with glyphosate use was reported by Garry *et al.* (2002, ASB2012-11626), but cases were reported by parents with no clinical confirmation and the reported incidence rate of approximately 1% for the study population was well below the general population incidence rate of approximately 7%. Regarding *in utero* exposures, McQueen *et al.* (2012, ASB2012-11898) report very low measured dietary exposures, from 0.005% to 2% of the current glyphosate ADI in Europe. Given the low perfusion rate of glyphosate across the placenta (Mose *et al.*, 2008, ASB2012-11914), human *in utero* exposures would be very limited. Campana *et al.* (2010, ASB2013-10559) estimated the frequency of 27 birth defects in 7 geographical regions of Argentina. A sample of 21,844 newborn with birth defects was selected, ascertained from 855,220 births, between 1994 and 2007, in 59 hospitals. The study results suggested that frequencies of 14 of the 27 examined birth defects were higher in one or more regions. This study was discussed in some publications in relation to the use of glyphosate pesticides. However, Campana *et al.* (2010, ASB2013-10559) commented on secular trends, altitude above sea level, folic acid fortification and ethnic factors and further variables. It was not indicated that any of these variables was associated with an increased occurrence of any type of birth defects.

Two studies of residential proximity to agriculture-related pesticide applications (California) by Carmichael *et al.* (2013, ASB2014-9307) and Yang *et al.* (2013, ASB2014-9644) examined whether early gestational exposure to pesticides were associated with an increased risk of hypospadia, neural tube defects or orofacial clefts in offspring. In both studies formulated glyphosate was mentioned only as one out of five chemicals to which controls were most frequently exposed. The authors of both studies concluded the few positive findings on chemicals, but other than glyphosate, should be interpreted with caution and need to be repeated in other populations.

Manfo *et al.* (2010, ASB2014-9611) examined the effect of pesticides use on male reproductive function in a study on farmers in Cameroon. The farmers of Djutitsa (West Cameroon) used 25 active substances (in 57 preparations) amongst others glyphosate in different formulations and were exposed to agro-pesticides due to inappropriate handling and improper protective tools. Furthermore, the authors concluded, that male farmers, who are exposed to pesticides might have impaired reproductive function through inhibition of testosterone synthesis. Serum biochemical parameter (total testosterone, estradiol/testosterone, androstenedione) were altered compared to the unexposed control group, but these alterations of chemical parameter cannot be related to single pesticides, e.g. glyphosate. Moreover, the fungicides were the most used active ingredients. However, considering the obvious alterations, the authors concluded, that there is urgent need for more training to enable improvement of equipment and efficiency of application to minimize exposure risks.

Further reviews on DART

Antoniou *et al.* (2012, ASB2012-15927) submitted a review article on "Teratogenic Effects of Glyphosate-Based Herbicides: Divergence of Regulatory Decisions from Scientific Evidence". According to the authors published studies "have raised concern regarding the potential for glyphosate and its commercial formulations to cause birth defects and other reproductive problems". The "draft assessment report revealed that industry tests contained clear evidence of glyphosate-mediated teratogenicity and reproductive toxicity". The EU adopted "an acceptable daily intake (ADI) for glyphosate that is unreliable and could potentially result in exposures that cause harm to humans." The authors suggest that a "new risk assessment should be conducted with full public transparency by scientists who are independent of industry."

Lopez *et al.* (2012, ASB2013-10534) submitted a review article on "Pesticides used in South American GMO-Based Agriculture: a review on their effects on humans and animal models". The authors discuss the results of genetic studies in agricultural regions in the province of Cordoba, Argentina, biomarkers in agricultural regions in the province of Santa Fe, Argentina and congenital malformations and genotoxicity in populations exposed to pesticides in Paraguay. According to the authors, human health in these areas was damaged by pesticides. However, a relation to glyphosate or another substance or pesticide was not evidenced. Nevertheless, based on the results of Paganelli *et al.* (2010, ASB2012-11986), it was concluded that glyphosate-based herbicides) would be linked to an increased activity of the retinoic acid signaling pathways and this might explain the higher incidence of embryonic malformations and spontaneous abortions observed in populations exposed to pesticides.

Basrur (2006, ASB2014-7492) submitted a review on disrupted sex differentiation and feminization of men. In this review the studies of Arbuckle and associates are cited which report a relation between pesticide exposure (including glyphosate) and reproductive risk.

Vandenberg *et al.* (2012, ASB2014-9635) submitted a review on low dose effects an nonmonotonic dose responses of hormones and endocrine disrupting chemicals. The authors reviewed two major concepts on EDC studies: low dose and nonmonotonicity. They conclude that nonmonotonic responses and low-dose effects would be remarkably common in studies of natural hormones and EDSs. Whether low doses of EDCs influence certain human disorders would be no longer conjecture, because epidemiologic studies would show that environmental exposures to ECDs would be associated with human diseases and disabilities. The authors demand that fundamental changes in chemical testing and safety determination woud be needed to protect human health.

In a direct response on the article of Vandenberg *et al.* (2012, ASB2014-9635) a discussion paper was

submitted by Rhomberg and Goodman (2012, ASB2014-9391). These authors conclude that Vandenberg *et al.* (2012, ASB2014-9635) presented examples as anecdotes without attempting to review all available pertinent data, selectively citing studies without evaluating most of them or examining whether their putative examples are consistent and coherent with other relevant information. Many of their examples have been questioned by many scientists. Overall, Vandenberg *et al.* (2012, ASB2014-9635) put forth many asserted illustrations of their two conclusions without providing sufficient evidence to make the case for either and while overlooking evidence that suggest the contrary.
Lamb *et al.* (2014, ASB2014-9605) submitted a review with critical comments on the WHO- UNEP state of the science of endocrine disrupting chemicals – 2012. The authors conclude that the 2012 report does not provide a balanced perspective, nor does it accurately reflect the state fo the science on endocrine disruption.

Borgert *et al.* (2013, ASB2014-9292) reviewed literature on thresholds of endocrine activity. The brief review highlights how the fundamental principles governing hormonal effects – affinity, potency, and mass action – dictate the existence of thresholds and why these principles also define the potential that exogenous chemicals might have to interfere with normal endocrine functioning.
The review by Sengupta and Banerjee, (2013, ASB2014-9730) is related to impacts of pesticides on male fertility. With respect to glyphosate the authors only cited in vitro data published by Richard *et al.* (2005, ASB2009-9025), and these have been already reported and evaluated in the present renewal assessment report (please refer to 'In vitro Glyphosate DART/ED Publications').
Kumar (2011, ASB2014-9725) submitted a review on occupational, environmental and lifestyle factors associated with spontaneous abortion. In this review Arbuckle *et al.* (2001, ASB2012-11545) was cited who reported a relation between pesticide exposure (including glyphosate) and reproductive risk. This publication was already reported and discussed under 'Epidemiology DART/ED Publication'.
The extensive review by Wigle *et al.* (2008, ASB2014-9637) summarised the level of epidemiologic evidence of relationships between reproductive and child health outcomes and environmental chemical contaminants. Several references related to glyphosate were cited by the authors [(Curtis *et al.*1999, cited in Arbuckle *et al.* (2001, ASB2012-11545), Arbuckle *et al.* (2001, ASB2012-11545), Savitz *et al.* (1997, ASB2012-12022), Garry (2002, ASB2012-
11626))], which were already reported and discussed under to 'Epidemiology DART/ED Publication'.
The mechanism based short review by Jamkhande *et al.* (2014, ASB2014-9573) summarised common human teratogenic agents. With respect to glyphosate (-based formulations) the authors cited merely data published by Antoniou *et al.* (2012, ASB2012-15927); Paganelli *et al.* (2010, ASB2012-11986). Both publications were already reported and evaluated in the present renewal assessment report (please refer to 'Further reviews on DART').
The English abstract of a Chinese publication by Zhang *et al.* (2013, ASB2014-9643) give notice of a summary on reproductive and developmental toxicity studies on glyphosate and the related mechanisms on humans and animals to provide suggestions for further research.

Comparison of the active substance glyphosate and glyphosate containing formulations concerning DART and ED
For the active substance glyphosate a very comprehensive data package of guideline conform studies on developmental and reproductive toxicity is available. This data package was prepared over the last decades and updated within the last years.
In these submitted studies it was demonstrated that glyphosate is not a teratogenic substance. NOEL values for developmental toxicity and reproductive toxicity can be derived from the results of these studies. There are no relevant indications of an endocrine disrupting activity of the active substance glyphosate. Additionally, also in the further guideline conform toxicological studies (e.g. the subchronic and chronic toxicity studies) no indications of an endocrine disrupting activity of glyphosate (e.g. organ weight and histology of sexual organs, behaviour etc.) have been observed. Therefore, on basis of this comprehensive and high quality data package the active substance glyphosate is not considered to be an endocrine disruptor or a teratogenic substance.
Additionally to the studies which have been performed according to validated EU- and OECD guidelines a large number of studies has been published on DART and ED. Most of these studies use glyphosate containing preparations instead of the pure active substance glyphosate. However, some studies directly

compare the toxicity of the active substance glyphosate and glyphosate conaining preparations. Furthermore, studies have been performed on the toxicity of surfactants which are used in preparations together with glyphosate, especially tallowamine. The results of these surfactant studies can be compared with the results of the above mentioned guideline conform studies on glyphosate.

In result of these comparisons it can clearly be concluded that the toxicity of preparations and the toxicity of surfactants like tallowamine / polyethoxylated alkylamine is significantly higher than the toxicity of the active substance glyphosate.

A detailed comparison of the toxicity of tallowamin and glyphosate was submitted in the appendix "Toxicological evaluation of the POE-tallowamine surfactant (CAS no. 61791-26-2)" which is attached to this report. In this evaluation is clearly demonstrated that there is a significantly higher toxicity of the surfactant tallowamin with regard to all of the following endpoints investigated:

- acute oral toxicity
- acute dermal toxicity
- skin irritation
- eye irritation
- skin sensitization
- short term toxicity, rat
- short term toxicity, dog
- reproduction toxicity study, parental toxicity
- reproduction toxicity study, reproductive toxicity
- reproduction toxicity study, offspring toxicity
- developmental toxicity, rat, fetal effects

Walsh *et al.* (2000, ASB2012-12046) published research claiming that a glyphosate based formulation, but not glyphosate alone, adversely affected the steroidogenesis pathway by inhibiting progesterone production resulting in downstream reduction in mitochondrial levels of StAR protein. Subsequent research by Levine *et al.* (2007, ASB2009-9030) demonstrated no synergism between glyphosate and the surfactant since the cytotoxic effects were completely independent of glyphosate. Identical dose-response curves were noted for formulated product with and without the glyphosate active ingredient.

Further research addressing the steroidogenesis pathway confirmed glyphosate lacked endocrine disruption potential specific to this pathway. Quassinti *et al.* (2009, ASB2012- 12007) evaluated effects on gonadal steroidogenesis in frog testis and ovaries on glyphosate and another active substance, noting that glyphosate unequivocally demonstrated no effect. Forgacs *et al.* (2012, ASB2012-11621) also tested glyphosate alone and demonstrated no effect on testosterone levels in BLTK1 murine leydig cells *in vitro*. Furthermore, the OECD multi-laboratory validation of the Steroidogenesis Assay used for Tier 1 screening of the US EPA EDSP, evaluated glyphosate and concluded no impact on steroidogenesis (Hecker *et al.*, 2011, ASB2012-11840). Consequently, the US EPA considered reference to the OECD validation report sufficient for meeting the glyphosate Steroidogenesis Assay Test Order in the EDSP Tier 1 screening of glyphosate.
Recently, the first publicly data available from the glyphosate Tier 1 assays under the US EPA Endocrine Disruptor Screening Program, were reported at the 2012 Society of Toxicology meeting (Saltmiras & Tobia, 2012, ASB2012-12016) for the Hershberger and Uterotrophic assays. No effects were noted for any potential for the active substance glyphosate to interact with androgenic or estrogenic pathways under these GLP studies following the US EPA 890 Series Test Guidelines.
Richard *et al.* (2005, TOX2005-1743) studied effects of glyphosate and roundup on human placental cells and aromatase. Summarising their results they stated that "roundup is always more toxic than its active ingredient."
In a further study from the same institute Benachour *et al.* (2007, ASB2009-9018) studied time- and dose-dependent effects of roundup on human embryonic and placental cells. They summarized that "in all instances, roundup is more efficient than its active ingredient, glyphosate…". And in a further publication by Benachour and Seralini (2009, ASB2012- 11561) it was stated "this work clearly confirms that the

adjuvants in roundup formulations are not inert." In a response to this publication by the French Agency for Food Safety (AFSSA, 2009, ASB2012-11532) it was answered that surfactant effects are known to increase membrane permeability, causing cytotoxicity and induction of apoptosis. In the most recent publication from the same institute, Mesnage *et al.* (in press, ASB2012-13917) the potential active principle for toxicity on human cells for 9 glyphosate-based formulations was studied. The authors summarized that "ethoxylated adjuvants of glyphosate-based herbicides are active principles of human cell toxicity."

In a comprehensive analysis of the available literature in developmenat and reproductive outcomes in humans and animals after glyphosate exposure, Williams *et al.* (2012, ASB2012- 12052) summarized: "An evaluation of this database found no consistent effects of glyphosate exposure on reproductive health or the developing offspring. Furthermore, no plausible mechanism of action for such effects were elucidated. Although toxicity was observed in studies that used glyphosate-based formulations, the data strongly suggest that such effects were due to surfactants present in the formulations and not the direct result of glyphosate exposure."

Author(s)	Year	Study title
Walsh, L.P. McCormick, C. Martin, C. Stocco, D.M.	2000	Roundup inhibits steroidogenesis by disrupting steroidogenic acute regulatory (StAR) protein expression. Environmental Health Perspectives Volume: 108 Number: 8 Pages: 769-776 ASB2012-12046

Abstract*
Recent reports demonstrate that many currently used pesticides have the capacity to disrupt reproductive function in animals. Although this reproductive dysfunction is typically characterized by alterations in serum steroid hormone levels, disruptions in spermatogenesis, and loss of fertility, the mechanisms involved in pesticide-induced infertility remain unclear. Because testicular Leydig cells play a crucial role in male reproductive function by producing testosterone, we used the mouse MA-10 Leydig tumor cell line to study the molecular events involved in pesticide-induced alterations in steroid hormone biosynthesis. We previously showed that the organochlorine insecticide lindane and the organophosphate insecticide Dimethoate directly inhibit steroidogenesis in Leydig cells by disrupting expression of the steroidogenic acute regulatory (StAR) protein. StAR protein mediates the rate-limiting and acutely regulated step in steroidogenesis, the transfer of cholesterol from the outer to the inner mitochondrial membrane where the cytochrome P450 side chain cleavage (P450scc) enzyme initiates the synthesis of all steroid hormones. In the present study, we screened eight currently used pesticide formulations for their ability to inhibit steroidogenesis, concentrating on their effects on StAR expression in MA-10 cells. In addition, we determined the effects of these compounds on the levels and activities of the P450scc enzyme (which converts cholesterol to pregnenolone) and the 3 β-hydroxysteroid dehydrogenase (3 β-HSD) enzyme (which converts pregnenolone to progesterone). Of the pesticides screened, only the pesticide Roundup inhibited dibutyryl [(Bu)2]cAMP-stimulated progesterone production in MA-10 cells without causing cellular toxicity. Roundup inhibited steroidogenesis by disrupting StAR protein expression, further demonstrating the susceptibility of StAR to environmental pollutants.

*Quoted from article

Klimisch evaluation

Reliability of study:	Reliable with restrictions
Comment:	Non-standard test systems, but publication meets basic

	scientific principles. However, surfactant blend in Roundup confounds results.
Relevance of study:	Relevant with restrictions: Different effects of glyphosate alone and glyphosate formulations were observed. No conclusion can be drawn that the observed effects are result of glyphosate exposure.
Klimisch code:	2

Additional comments:
Glyphosate did not affect steroidogenesis in the test system.
Roundup formulation data was confounded by mitochondrial membrane damage, attributable to the surfactant in the tested formulation.
Roundup results were comprehensively addressed in Levine *et al.* (2007, ASB2009-9030): Roundup formulation containing glyphosate and Roundup formulation blank without the active ingredient was shown to have "indistinguishable" dose response curves for reductions in progesterone production in hCG stimulated MA-10 Leydig cells. Therefore the effect on progesterone levels shown by Walsh (2000, ASB2012-12046) were independent of glyphosate and attributable to the surfactant component of the formulation.
Comparable rates of progesterone inhibition for several different surfactants suggest a common mode of action for surfactants.
Roundup formulation containing glyphosate and Roundup formulation blank without the active ingredient was shown to have almost identical concentration-dependent decreases in MTT activity in MA-10 cells, suggesting the surfactant alone was responsible for the observed cytotoxicity and effect on mitochondrial function.
The JC-1 assay demonstrated the decreased progesterone production in MA-10 Leydig cells was accompanied by loss of mitochondrial membrane potential. These results confirm StAR protein function and steroidogenesis require intact mitochondrial membrane potential.
StAR protein expression were not affected by treatments, indicating that perturbed mitochondrial membrane, not StAR protein inhibition, was responsible for the effects noted by Walsh *et al.* (2000, ASB2012-12046).

Paganelli, A. Gnazzo, V. Acosta H. Lopez, S.L. Carrasco, A.E.	2010	Glyphosate-Based Herbicides Produce Teratogenic Effects on Vertebrates by Impairing Retinoic Acid Signalling Chemical Research in Toxicology Volume: 23 Pages: 1586-1595 ASB2010-11410

Abstract*
The broad spectrum herbicide glyphosate is widely used in agriculture worldwide. There has been ongoing controversy regarding the possible adverse effects of glyphosate on the environment and on human health. Reports of neural defects and craniofacial malformations from regions where glyphosatebased herbicides (GBH) are used led us to undertake an embryological approach to explore the effects of low doses of glyphosate in development. *Xenopus laevis* embryos were incubated with 1/5000 dilutions of a commercial GBH. The treated embryos were highly abnormal with marked alterations in cephalic and neural crest development and shortening of the anterior-posterior (A-P) axis. Alterations on neural crest markers were later correlated with deformities in the cranial cartilages at tadpole stages. Embryos injected with pure glyphosate showed very similar phenotypes. Moreover, GBH produced similar effects in chicken embryos, showing a gradual loss of rhombomere domains, reduction of the optic vesicles, and microcephaly. This suggests that glyphosate itself was responsible for the phenotypes observed, rather than a surfactant or other

component of the commercial formulation. A reporter gene assay revealed that GBH treatment increased endogenous retinoic acid (RA) activity in *Xenopus* embryos and cotreatment with a RA antagonist rescued the teratogenic effects of the GBH. Therefore, we conclude that the phenotypes produced by GBH are mainly a consequence of the increase of endogenous retinoid activity. This is consistent with the decrease of Sonic hedgehog (Shh) signaling from the embryonic dorsal midline, with the inhibition of *otx2* expression and with the disruption of cephalic neural crest development. The direct effect of glyphosate on early mechanisms of morphogenesis in vertebrate embryos opens concerns about the clinical findings from human offspring in populations exposed to GBH in agricultural fields.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Non-guideline study that is not sufficiently described for assessment. Inadequate positive and negative control experiments.
Relevance of study:	Not relevant: Irrelevant routes of exposure and inappropriately high doses. Test system not adequate for human risk assessment.
Klimisch code:	3

Additional comments:

Response 1 – summarized from Williams *et al.* (2012, ASB2012-12052)

No pH adjustment for doses and thus effects may be in response to the acidic nature of glyphosate technical acid.

Inappropriate and irrelevant routes of exposure.

Data requires further substantiation before consideration in risk assessment.

Response 2 – Saltmiras et al. (2011, ASB2012-12015) letter to the Editor

Multiple high quality toxicological studies and expert review panels consistently agree glyphosate is not a teratogen or reproductive toxicant.

The authors' justification for this research is flawed, providing no valid basis, other than an opinion, of an increase in the rate of birth defects in Argentina.

Direct injection of frog embryos and through chicken shells do not reflect real world exposure scenarios to either environmental species or humans.

Doses were excessively high and irrelevant for risk assessment purposes. Frog embryos were also bathed in glyphosate formulation at doses 9-15 times greater than the acute LC50 same species of frog. Calculating equivalent oral doses based on pharmacokinetics studies, such doses are 150000000 times greater than worst case human exposure monitoring data.

"…. the results from this research cannot be used in isolation to reach the conclusions expressed in the publication. Instead, the type of data in this research paper must be interpreted relative to all other available data on the specific materials under study and with balanced consideration for higher tier apical studies."

Response 3 – Mulet (2011, ASB2012-11916) letter to the Editor

Notes the premise for this research is falsely based on an incorrectly cited local pediatric bulletin from Paraguay.

"…. this article refers to a study in a single hospital in Paraguay showing a correlation between pesticide use (not herbicides as mentioned by Paganelli *et al.*, ASB2010-11410) and birth malformations. In the cited study, (Benitez *et al.*, ASB2012-11563), the authors state that the results are preliminary and must be confirmed. Is important to remark that the Benitez *et al.* study does not include any mention to glyphosate, so does not account for what the authors are stating in the introduction…..This journal is also wrongly cited in the discussion referring to increased malformations due to herbicides, which is not the result of the study."

Response 4 – comments from BVL (2010, ASB2012-11579)
Highly artificial experimental conditions.
Inappropriate models to replace validated mammalian reproductive and developmental toxicity testing methods for use in human health risk assessment.
Inappropriate routes of exposure.
Lack of corroborative evidence in humans.
"In spite of long-lasting use of glyphosate-based herbicides worldwide, no evidence of teratogenicity in humans has been obtained so far."

Response 5 – comments from European Commission Standing Committee on the Food Chain and Animal Health (2011, ASB2012-11615)
The EU commission supports the German Authorities position, "that that there is a comprehensive and reliable toxicological database for glyphosate and the effects observed have not been revealed in mammalian studies, nor evidenced epidemiologically in humans." "…. the Commission does not consider there is currently a solid basis to ban or impose specific restrictions on the use of glyphosate in the EU."
Response 6 – Palma, G. (2010, ASB2012-11989) letter to the Editor
The author of the letter claims that the study by Paganelli *et al.*, 2010 (ASB2010-11410), described effects of glyphosate only at unrealistic high concentrations or via unrealistic routes of exposure. The data are thought to be inconsistent with the literature, and therefore not suitable or relevant for the risk assessment for humans and wildlife. Furthermore the author asserts that findings do not support the extrapolation to human health as stated in the publication.

Richard, S. Moslemi, S. Sipahutar, H. Benachour, N. Seralini, G.E.	2005	Differential effects of glyphosate and roundup on human placental cells and aromatase. Environmental Health Perspectives Volume: 113 Pages: 716-720 TOX2005-1743

Abstract*
Roundup is a glyphosate-based herbicide used worldwide, including on most genetically modified plants that have been designed to tolerate it. Its residues may thus enter the food chain, and glyphosate is found as a contaminant in rivers. Some agricultural workers using glyphosate have pregnancy problems, but its mechanism of action in mammals is questioned. Here we show that glyphosate is toxic to human placental JEG3 cells within 18 hr with concentrations lower than those found with agricultural use, and this effect increases with concentration and time or in the presence of Roundup adjuvants. Surprisingly, Roundup is always more toxic than its active ingredient. We tested the effects of glyphosate and Roundup at lower nontoxic concentrations on aromatase, the enzyme responsible for estrogen synthesis. The glyphosate-based herbicide disrupts aromatase activity and mRNA levels and interacts with the active site of the purified enzyme, but the effects of glyphosate are facilitated by the Roundup formulation in microsomes or in cell culture. We conclude that endocrine and toxic effects of Roundup, not just glyphosate, can be observed in mammals. We suggest that the presence of Roundup adjuvants enhances glyphosate bioavailability and/or bioaccumulation.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Study design is insufficient for risk assessment of real exposure concentrations. Methodological deficiencies (no controls were included). Exceedingly high doses above the limit dose for this study type. Inappropriate test system for

	formulations containing surfactant; cytoxic membrane disruption potential of surfactants are well known for in vitro test systems. EPA Test Guideline OCSPP 890.1200 specifically notes that microsomes are denatured by detergents (i.e. surfactants) and that all glassware should be thoroughly rinsed.
Relevance of study:	Not relevant: Excessive doses exceed typical *in vitro* limit doses. *In vitro* test system is inappropriate with surfactants.
Klimisch code:	3

Additional comments:

Response 1 – summarized from Williams *et al.* (2012, ASB2012-12052)
Glyphosate at non-cytotoxic concentrations in this test system was demonstrated to have no effects on aromatase activity.
Likewise, did not affect mRNA levels after 18 hours treatment at ≤ 0.1% glyphosate.
Roundup aromatase activity measurements are confounded by surfactant effects on microsomes.
The *in vitro* test system is non-validated Physiologically irrelevant concentrations tested.
Testing surfactant-like substances in such systems is now recognized to be not valid.

Response 2 – summarized from the French Ministry of Agriculture and Fish, Committee for Study of Toxicity (2005, ASB2009-9025)
Major methodological gaps.
JEG3 cells, a choriocarcinoma human cell line (average of 70 chromosomes vs 46 in normal human cells).
Concentrations of Roundup used in the various experiments considered to be extremely high. In consideration of limiting factors (oral absorption, 30%; skin absorption, 0.3%; rapid elimination kinetics), such levels would involve considerable human exposure, or several dozen liters of Roundup diluted at 2%. concentrations of Roundup that trigger an effect on aromatase (0.5% - 2%) are at least 1000 times more effective than those of known aromatase inhibitors, such as azole derivatives Study design does not make it possible to show the influence of the adjuvants, nor synergism of adjuvants and glyphosate.
Multiple non-specific effects of surfactant agents on a broad range of cellular targets not discussed.
No comparison with comparable surfactant agents intended for household use. Multiple instances of bias in its arguments and its interpretation of the data.
The authors over-interpret their results in the area of potential health consequences for humans (unsuitable references, non-sustained in vitro-in vivo extrapolation, etc.).

Author(s)	Year	Study title
Benachour, N. Sipahutar, H. Moslerni, S. Gasnier, C. Travert, C. Seralini, G. E.	2007	Time- and dose-dependent effects of roundup on human embryonic and placental cells. Archives of Environmental Contamination and Toxicology Volume: 53 Pages: 126-133 ASB2009-9018

Abstract*
Roundup® is the major herbicide used worldwide, in particular on genetically modified plants that have been designed to tolerate it. We have tested the toxicity and endocrine disruption potential of Roundup (Bioforce®) on human embryonic 293 and placental-derived JEG3 cells, but also on normal human placenta and equine testis. The cell lines have proven to be suitable to estimate hormonal activity and toxicity of pollutants. The median lethal dose (LD_{50}) of Roundup with embryonic cells is 0.3% within 1 h in serum-free medium, and it decreases to reach 0.06% (containing among other compounds 1.27 mM glyphosate) after 72 h in the presence of serum. In these conditions, the embryonic cells appear to be 2-4

times more sensitive than the placental ones. In all instances, Roundup (generally used in agriculture at 1 – 2%, i.e., with 21-42 mM glyphosate) is more efficient than its active ingredient, glyphosate, suggesting a synergistic effect provoked by the adjuvants present in Roundup. We demonstrated that serum-free cultures, even on a short-term basis (1 h), reveal the xenobiotic impacts that are visible 1-2 days later in serum. We also document at lower non-overtly toxic doses, from 0.01% (with 210 µM glyphosate) in 24 h, that Roundup is an aromatase disruptor. The direct inhibition is temperature-dependent and is confirmed in different tissues and species (cell lines from placenta or embryonic kidney, equine testicular, or human fresh placental extracts). Furthermore, glyphosate acts directly as a partial inactivator on microsomal aromatase, independently of its acidity, and in a dose-dependent manner. The cytotoxic, and potentially endocrine-disrupting effects of Roundup are thus amplified with time. Taken together, these data suggest that Roundup exposure may affect human reproduction and fetal development in case of contamination. Chemical mixtures in formulations appear to be underestimated regarding their toxic or hormonal impact.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Study report has several reporting deficiencies in the methods section (e.g. test conditions for the pH- and temperature dependent assay not reported). There is no information on the suitability of the used HEK 293 cell line for assessment of hormonal activity. Exceedingly high doses above the limit dose for this study type. Inappropriate test system for formulations containing surfactant; cytoxic membrane disruption potential of surfactants are well known for in vitro test systems.
Relevance of study:	Not relevant: Excessive doses exceed typical *in vitro* limit doses. *In vitro* test system is inappropriate with surfactants.
Klimisch code:	3

Additional comments:
Glyphosate at and above relevant concentrations for this test system was demonstrated to have no effects on aromatase activity.
Roundup aromatase activity measurements are confounded by surfactant effects on microsomes.
Comparable research to Richard et al (2005, TOX2005-1743), but with an additional cell line, HEK 293, derived from aborted human embryo kidneys, transformed by inserting adenovirus DNA.
Excessively high doses tested, not environmentally relevant for human health or environmental risk assessment.
Aromatase production within the steroidogenesis pathway. Therefore, aromatase inhibition would be detected in the steroidogenesis assay. The OECD multi-laboratory validation of the steroidogenesis assay evaluated glyphosate, demonstrating no impact on the steroidogenesis pathway (Hecker *et al.*, 2011, ASB2012-11840).

Response – summarized from Williams *et al.* (2012, ASB2012-12052)
pH of test system not adjusted to physiologically appropriate levels; Negative controls were not pH adjusted to appropriate levels.
Confounding surfactant effects due to cell membrane damage render data generated with formulated products in this test system null.

Benachour, N. Seralini, G. E.	2009	Glyphosate formulations induce apoptosis and necrosis in human umbilical, embryonic, and placental cells. Chemical Research in toxicology Volume: 22, Pages: 97-105 ASB2012-11561

Abstract*
We have evaluated the toxicity of four glyphosate (G)-based herbicides in Roundup formulations, from 10(5) times dilutions, on three different human cell types. This dilution level is far below agricultural recommendations and corresponds to low levels of residues in food or feed. The formulations have been compared to G alone and with its main metabolite AMPA or with one known adjuvant of R formulations, POEA. HUVEC primary neonate umbilical cord vein cells have been tested with 293 embryonic kidney and JEG3 placental cell lines. All R formulations cause total cell death within 24 h, through an inhibition of the mitochondrial succinate dehydrogenase activity, and necrosis, by release of cytosolic adenylate kinase measuring membrane damage. They also induce apoptosis via activation of enzymatic caspases 3/7 activity. This is confirmed by characteristic DNA fragmentation, nuclear shrinkage (pyknosis), and nuclear fragmentation (karyorrhexis), which is demonstrated by DAPI in apoptotic round cells. G provokes only apoptosis, and HUVEC are 100 times more sensitive overall at this level. The deleterious effects are not proportional to G concentrations but rather depend on the nature of the adjuvants. AMPA and POEA separately and synergistically damage cell membranes like R but at different concentrations. Their mixtures are generally even more harmful with G. In conclusion, the R adjuvants like POEA change human cell permeability and amplify toxicity induced already by G, through apoptosis and necrosis. The real threshold of G toxicity must take into account the presence of adjuvants but also G metabolism and time-amplified effects or bioaccumulation. This should be discussed when analyzing the in vivo toxic actions of R. This work clearly confirms that the adjuvants in Roundup formulations are not inert. Moreover, the proprietary mixtures available on the market could cause cell damage and even death around residual levels to be expected, especially in food and feed derived from formulation-treated crops.

Reliability of study:	Not reliable
Comment:	Exceedingly high doses above the limit dose for this study type. Inappropriate test system for formulations containing surfactant; cytoxic membrane disruption potential of surfactants are well known for in vitro test systems. No positive controls were included.
Relevance of study:	Not relevant (Excessive doses exceed typical *in vitro* limit doses. *In vitro* test system is inappropriate with surfactants)
Klimisch code:	3

Additional comments:

Response – summarized from the French Agency for Food Safety (AFSSA, 2009, ASB2012-11532)
Cell lines used present characteristics which may be at the source of a significant bias in the interpretation of the results.
Experiments were conducted with 24 hours exposure in a medium without serum, which could lead to disturbance of the physiological state of the cells.
The glyphosate used in the study is glyphosate acid, whereas in the preparations tested it is in the form of an isopropylamine salt. No precise information is given about the pH of test concentrations except the highest dose.
No mention of any positive evidence for the apoptosis test.

Cytoxicity and induction of apoptosis may due to pH and/or variations in osmotic pressure on cell survival at the high doses tested.
Surfactant (tensoactive) effects and increased osmolality are known to increase membrane permeability, causing cytotoxicity and induction of apoptosis.
Conclusions are based on unvalidated, non-representative cell models (in particular tumour or transformed cell lines) directly exposed to extremely high product concentrations in culture conditions which do not observe normal cell physiological conditions.
No new information is presented on mechanism of action of glyphosate and preparations containing glyphosate.
The authors over-interpret their results with regard to potential health consequences for humans, based in particular on an unsupported *in vitro–in vivo* extrapolation.
The cytotoxic effects of glyphosate, its metabolite AMPA, the tensioactive POAE and other glyphosate-based preparations proposed by Benachour and Seralini do not add any pertinent new facts which call into question the conclusions of the European assessment of glyphosate or those of the national assessment of the preparations.

Gasnier, C., Dumont, C., Benachour, N., Clair, E., Chagnon, M. C., Seralini, G. E	2009	Glyphosate-based herbicides are toxic and endocrine disruptors in human cell lines. Toxicology Volume: 262, Number: 3, Pages: 184-191 ASB2012-11629

Abstract*
Glyphosate-based herbicides are the most widely used across the world; they are commercialised in different formulations. Their residues are frequent pollutants in the environment. In addition, these herbicides are spread on most eaten transgenic plants, modified to tolerate high levels of these compounds in their cells. Up to 400 ppm of their residues are accepted in some feed. We exposed human liver HepG2 cells, a well-known model to study xenobiotic toxicity, to four different formulations and to glyphosate, which is usually tested alone in chronic in vivo regulatory studies. We measured cytotoxicity with three assays (Alamar Blue, MTT, ToxiLight), plus genotoxicity (comet assay), anti-estrogenic (on ERα, ERß) and anti-androgenic effects (on AR) using gene reporter tests. We also checked androgen to estrogen conversion by aromatase activity and mRNA. All parameters were disrupted at sub-agricultural doses with all formulations within 24h. These effects were more dependent on the formulation than on the glyphosate concentration. First, we observed a human cell endocrine disruption from 0.5 ppm on the androgen receptor in MDA-MB453-kb2 cells for the most active formulation (R400), then from 2 ppm the transcriptional activities on both estrogen receptors were also inhibited on HepG2. Aromatase transcription and activity were disrupted from 10 ppm. Cytotoxic effects started at 10 ppm with Alamar Blue assay (the most sensitive), and DNA damages at 5 ppm. A real cell impact of glyphosate-based herbicides residues in food, feed or in the environment has thus to be considered, and their classifications as carcinogens/mutagens/reprotoxics is discussed.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Due to reporting deficiencies (e.g. correlation between concentration used in toxicity tests and concentrations used in comet assay) assessment of results difficult. Exceedingly high doses above the limit dose for this study type. Inappropriate test system for formulations containing surfactant; cytoxic membrane disruption potential of surfactants are well known for in vitro test systems.

Relevance of study:	Not relevant: Excessive doses exceed typical *in vitro* limit doses. *In vitro* test system is inappropriate with surfactants.
Klimisch code:	3

Additional comments:

Response 1 – summarized from Williams *et al.* (2012, ASB2012-12052)
Glyphosate demonstrated no significant anti-estrogenic potential.
Glyphosate demonstrated some anti-androgenic potential at lower concentrations, but not as doses increased and therefore results are considered unrelated to treatment.
Four glyphosate based formulations demonstrated both estrogenic and androgenic activity. Results are confounded due to surfactants within the formulated products tested, which affect cell membrane integrity and produces false findings.

Response 2 – summarized from BfR Review (2009, ASB2012-11565)
Numerous methodological flaws are noted. Test substance(s) not characterized.
Source of materials for cell culture not provided. Dosing concentrations not well described.
Serum free media only appropriate for short term (3-4 hour) *in vitro* exposures. pH control of dilutions not clear.
Osmolality of test solutions not reported.
Electrophoresis parameters insufficiently or inaccurately reported. Numerous reporting deficiencies are noted.
Influence of serum-free cell culturing on endpoints can not be determined
Incomplete data reporting, in cluding β-galactosirase activity, cototoxicity for select assays. Positive control data not reported.
Confusion between maximum residue levels verses systemic concentrations in humans.

Clair, E., Mesnage, R., Travert, C., Seralini, G.E.	2012	A glyphosate-based herbicide induces necrosis and apoptosis in mature rat testicular cells *in vitro*, and testosterone decrease at lower levels. Toxicology in Vitro Volume: 26, Number: 2, Pages: 269-279 ASB2012-1628

Abstract*
The major herbicide used worldwide, Roundup, is a glyphosate-based pesticide with adjuvants. Glyphosate, its active ingredient in plants and its main metabolite (AMPA) are among the first contaminants of surface waters. Roundup is being used increasingly in particular on genetically modified plants grown for food and feed that contain its residues. Here we tested glyphosate and its formulation on mature rat fresh testicular cells from 1 to 10000 ppm, thus from the range in some human urine and in environment to agricultural levels. We show that from 1 to 48 h of Roundup exposure Leydig cells are damaged. Within 24–48 h this formulation is also toxic on the other cells, mainly by necrosis, by contrast to glyphosate alone which is essentially toxic on Sertoli cells. Later, it also induces apoptosis at higher doses in germ cells and in Sertoli/germ cells co-cultures. At lower non toxic concentrations of Roundup and glyphosate (1 ppm), the main endocrine disruption is a testosterone decrease by 35%. The pesticide has thus an endocrine impact at very low environmental doses, but only a high contamination appears to provoke an acute rat testicular toxicity. This does not anticipate the chronic toxicity which is insufficiently tested and only with glyphosate in regulatory tests.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Non-guideline *in vitro* test with methodological (i.e. no positive controls included) and reporting deficiencies (e.g. dose levels not always specified).
Relevance of study:	Not relevant (Due to reliability. In addition, *in vitro* data do not reflect real *in vivo* exposure situations, and therefore not relevant for human risk assessment purposes.)
Klimisch code:	3

Additional comments:
In vitro test with methodological (i.e. no positive controls included) and reporting deficiencies (e.g. dose levels not always specified). The concentrations used in these experiments are not relevant to human exposures to glyphosate and the experimental system used is not relevant to whole animal outcomes. Importantly, the alleged impacts on endocrine function have not been observed in animal studies of glyphosate or other components of glyphosate formulations at relevant concentrations. Authors state that the lowest concentration of glyphosate tested was 50 ppm, several orders of magnitude higher than an anticipated human intake (based on pharmacokinetics described in Anadon *et al.*, 2009, ASB2012-11542) following worst case dietary exposure at the ADI.

Hokanson, R. Fudge, R. Chowdhary, R. Busbee, D.	2007	Alteration of estrogen-regulated gene expression in human cells induced by the agricultural and horticultural herbicide glyphosate. Human & Experimental Toxicology Volume: 26, Pages: 747-752, ASB2012-11846

Abstract*
Gene expression is altered in mammalian cells (MCF-7 cells), by exposure to a variety of chemicals that mimic steroid hormones or interact with endocrine receptors or their co-factors. Among those populations chronically exposed to these endocrine disruptive chemicals are persons, and their families, who are employed in agriculture or horticulture, or who use agricultural/horticultural chemicals. Among the chemicals most commonly used, both commercially and in the home, is the herbicide glyphosate. Although glyphosate is commonly considered to be relatively non-toxic, we utilized *in vitro* DNA microarray analysis of this chemical to evaluate its capacity to alter the expression of a variety of genes in human cells. We selected a group of genes, determined by DNA microarray analysis to be dysregulated, and used quantitative real-time PCR to corroborate their altered states of expression. We discussed the reported function of those genes, with emphasis on altered physiological states that are capable of initiating adverse health effects that might be anticipated if gene expression were significantly altered in either adults or embryos exposed *in utero*.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Not acceptable *in vitro* methods for test mixtures containing surfactant. Well documented study publication, but surfactants are inappropriate test substance in cell lines.
Relevance of study:	Not relevant Temporal altered gene expression is not a biomarker for toxicity, but rather, may be within the range of normal biological responses of homeostasis. *In vitro* cytotoxicity of surfactants, however, is a significant confounder in data interpretation. Data do not reflect real *in*

	vivo exposure situations, and therefore not relevant for human risk assessment purposes.
Klimisch code:	3

Additional comments:
In vitro cytotoxicity of surfactants is a significant confounder in data interpretation. Relevance of altered gene expression in a cell line derived from a breast cancer should not be extrapolated to reflect human health endpoints. Altered gene expression should not be confused with adverse health outcomes. Rather altered gene expression may equally be considered a biological response within the range of normal homeostasis.

Yousef, M.I., Salem, M.H., Ibrahim, H.Z., Helmi, S., Seehy, M.A., Bertheussen, K.	1995	Toxic Effects of Carbofuran and Glyphosate on Semen Characteristics in Rabbits, Journal of Environmental Science and Health. Part B. Volume: 30, Number: 4, Pages: 513-534 ASB2012-12058

Abstract*
The present study was undertaken to investigate the effect of chronic treatment with two sublethal doses of Carbofuran (carbamate insecticide) and Glyphosate (organophosphorus herbicide) on body weight and semen characteristics in mature male New Zealand white rabbits. Pesticide treatment resulted in a decline in body weight, libido, ejaculate volume, sperm concentration, semen initial fructose and semen osmolality. This was accompanied with increases in the abnormal and dead sperm and semen methylene blue reduction time. The hazardous effect of these pesticides on semen quality continued during the recovery period, and was dose-dependent. These effects on sperm quality may be due to the direct cytotoxic effects of these pesticides on spermatogenesis and/or indirectly via hypothalami-pituitary- testis axis which control the reproductive efficiency.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Non-GLP, non-guideline study with major reporting deficiencies. Dose-levels poorly defined as 1/10 and 1/100 LD50. Purity of the test substances, source of animals, environmental conditions, mortality and clinical signs not reported. No testis and epididymis weights were determined or reported and no histopathological examination conducted. In addition, stability and homogeneity assessment of test substance preparations were not done or not reported. Rabbits have low body weights at study start, suggesting impaired health status.
Relevance of study:	Not relevant (Due to low confidence in study conduct and the inadequacy of reporting).
Klimisch code:	3

Additional comments:

Response – summarized from Williams *et al.* (2000, ASB2012-12053)
Numerous serious deficiencies in the design, conduct, and reporting of this study which make the results uninterpretable.
Only four rabbits per treatment group were used, and therefore statistics are questionable. Rabbits appeared to be small for their age; at study start (32 weeks) tested animals had 16 - 25% lower body weight than historical weights for commercially bred animals of the same age and strain.
Low body weights as study start suggest compromised health status of the animals at initiation.
Dose levels were not quantified.
Purity of glyphosate and composition of the glyphosate formulation were not reported. Inadequate description of test material administration.
Improper semen collection technique reported.
Report is unclear whether control animal sham handling was undertaken, a critical factor in stress related outcomes in this species.
Food consumption of test and control groups not adequately reported.
Variability not adequately reported for endpoint measurements in test and control groups, preventing statistical analysis to support the author's conclusions.
Dose-responses not observed, despite the wide dose spread.
Sperm concentrations of all groups within normal ranges for this strain of rabbit. No meaningful conclusions can be drawn from this publication.

Author(s)	Year	Study title
Daruich, J. Zirulnik, F. Gimenez, M. S.	2001	Effect of the herbicide glyphosate on enzymatic activity in pregnant rats and their fetuses Environmental Research Volume: 85 Pages: 226-231 ASB2012-11601

Abstract*
To prevent health risk from environmental chemicals, particularly for progeny, we have studied the effects of the herbicide glyphosate on several enzymes of pregnant rats. Glyphosate is an organo-phosphorated nonselective agrochemical widely used in many countries including Argentina and acts after the sprout in a systemic way. We have studied three cytosolic enzymes: isocitrate dehydrogenase-NADP dependent, glucose-6-phosphate dehydrogenase, and malic dehydrogenase in liver, heart, and brain of pregnant Wistar rats. The treatment was administered during the 21 days of pregnancy, with 1 week as an acclimation period. The results suggest that maternal exposure to agrochemicals during pregnancy induces a variety of functional abnormalities in the specific activity of the enzymes in the studied organs of the pregnant rats and their fetuses.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Basic data given, however, the study is performed with methodological and reporting deficiencies (unknown exposure levels, only cytosolic enzymes measured, inappropriate controls, lack of consistent dose-response data).
Relevance of study:	Not relevant (Due to reliability. In addition, study was performed with a glyphosate formulation (commercialised in Argentina) and not with glyphosate).
Klimisch code:	3

Additional comments:

The study was performed with a glyphosate formulation (commercialised in Argentina) and not with glyphosate. Test substance administration is poorly described, but rough calculations on approximate surfactant intake show excessively high and unrealistic exposures when compared to DART systemic parental and reproductive/developmental NOAEL values for POEA formulation surfactants.

Response summarized from Williams *et al.* (2012, ASB2012-12052)
Test substance and doses not adequately described. Inappropriate control groups.
Results suggest that the effect of treatment on body and organ weights may be due to reduced food and water intakes.
A consistent effect of treatment was not observed and dose-response relationships were generally lacking
The information gathered may be misleading because the enzymes monitored are found in both the cytosol and mitochondria.
Food restriction affects the activity of many enzymes, including those examined in this study.

Romano, R.M. Romano, M.A. Bernardi, M.M. Furtado, P.V. Oliveira, C.A.	2010	Prepubertal exposure to commercial formulation of the herbicide glyphosate alters testosterone levels and testicular morphology. Archives of Toxicology Volume: 84, Pages: 309-317 ASB2012-12012

Abstract*
Glyphosate is a herbicide widely used to kill weeds both in agricultural and non-agricultural landscapes. Its reproductive toxicity is related to the inhibition of a StAR protein and an aromatase enzyme, which causes an in vitro reduction in testosterone and estradiol synthesis. Studies in vivo about this herbicide effects in prepubertal Wistar rats reproductive development were not performed at this moment. Evaluations included the progression of puberty, body development, the hormonal production of testosterone, estradiol and corticosterone, and the morphology of the testis. Results showed that the herbicide (1) significantly changed the progression of puberty in a dose-dependent manner; (2) reduced the testosterone production, in semineferous tubules' morphology, decreased significantly the epithelium height (P < 0.001; control = 85.8 ± 2.8 µm; 5 mg/kg = 71.9 ± 5.3 µm; 50 mg/kg = 69.1 ± 1.7 µm; 250 mg/kg = 65.2 ± 1.3 µm) and increased the luminal diameter (P < 0.01; control = 94.0 ± 5.7 µm; 5 mg/kg = 116.6 ± 6.6 µm; 50 mg/kg = 114.3 ± 3.1 µm; 250 mg kg = 130.3 ± 4.8 µm); (4) no difference in tubular diameter was observed; and (5) relative to the controls, no differences in serum corticosterone or estradiol levels were detected, but the concentrations of testosterone serum were lower in all treated groups (P < 0.001; control = 154.5 ± 12.9 ng/dL; 5 mg/kg = 108.6 ± 19.6 ng/dL; 50 mg/dL = 84.5 ± 12.2 ng/dL; 250 mg/kg = 76.9 ± 14.2 ng/dL). These results suggest that commercial formulation of glyphosate is a potent endocrine disruptor in vivo, causing disturbances in the reproductive development of rats when the exposure was performed during the puberty period.

Romano, M.A. Romano, R.M. Santos, L.D. Wisniewski, P. Campos, D.A. de Souza, P.B. Viau, P. Bernardi, M.M. Nunes, M.T. de Oliviera, C.A.	2012	Glyphosate impairs male offspring reproductive development by disrupting gonadotropin expression Archives of Toxicology Volume: 86, Number: 4, Pages: 663-673 ASB2012-12011

Abstract*
Sexual differentiation in the brain takes place from late gestation to the early postnatal days. This is dependent on the conversion of circulating testosterone into estradiol by the enzyme aromatase. The glyphosate was shown to alter aromatase activity and decrease serum testosterone concentrations. Thus, the aim of this study was to investigate the effect of gestational maternal glyphosate exposure (50 mg/kg, NOAEL for reproductive toxicity) on the reproductive development of male offspring. Sixty-day-old male rat offspring were evaluated for sexual behavior and partner preference; serum testosterone concentrations, estradiol, FSH and LH; the mRNA and protein content of LH and FSH; sperm production and the morphology of the seminiferous epithelium; and the weight of the testes, epididymis and seminal vesicles. The growth, the weight and age at puberty of the animals were also recorded to evaluate the effect of the treatment. The most important findings were increases in sexual partner preference scores and the latency time to the first mount; testosterone and estradiol serum concentrations; the mRNA expression and protein content in the pituitary gland and the serum concentration of LH; sperm production and reserves; and the height of the germinal epithelium of seminiferous tubules. We also observed an early onset of puberty but no effect on the body growth in these animals. These results suggest that maternal exposure to glyphosate disturbed the masculinization process and promoted behavioral changes and histological and endocrine problems in reproductive parameters. These changes associated with the hypersecretion of androgens increased gonadal activity and sperm production.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Non-guideline, non-GLP study meeting scientific principles. Unusual and short dosing regiment commencing towards the end of pregnancy (GD18, rather than GD6 as per OECD Test Guidelines 414) through post natal day 5. *In vivo* study with reporting deficiencies (detailed strain description, source of animals, housing conditions, no information if clinical signs were assessed, stability and homogeneity assessment of test substance preparations, no of male offspring evaluated in individual tests evaluated). A number of atypical endpoints evaluated.
Relevance of study:	Not relevant (due to questionable dosing regimen and atypical

array of endpoints measured).

Klimisch code: 3

Additional comments:
Study with some reporting deficiencies (detailed strain description, source of animals, housing conditions, no information if clinical signs were assessed, stability and homogeneity assessment of test substance preparations, no of male offspring evaluated in individual tests evaluated). Dosing was limited to dams, starting on gestation day 18, well after organogenisis, through post natal day 5. No controls for litter effects appear to be reported, confounding interpretation of results. With the very short window of maternal exposure, biological plausibility of any test substance related effects in the mature offspring is questionable. However, the normal variability of some unusual or atypical endpoint measurements, such as "sexual partner preference" along with mRNA and protein expression, is not known. Of particular concern, however, are differences in critical endpoints for control animals reported in Romano *et al.* (2010, ASB2012-12012) compared to Romano *et al.* (2012, ASB2012- 12011); these include increased day of preputional sepratarion (PPS) of control male rate (37 days in 2010; 47 days in 2012), body weight at day of PPS (146 grams in 2010; 245 grams in 2012), serum testosterone concentrations (155 ng/dL in 2010; 63 ng/dL in 2012), estradiol concentrations (32 pg/mL in 2010; 1.4 pg/mL in 2012), subular diameter (266 μm in 2010; 479 μm in 2012), epithelial height (86 μm in 2010; 92 μmin 2012) and luminal height (94 μm in 2010; 257μm in 2012). Therefore, results are difficult to interpret, particularly for relevance to human health risk assessment.

A letter to the editor by DeSesso and Williams, (2012, ASB2014-9369) concluded as follows: "Taken together, the shortcomings in this paper erode any confidence that these experiments are able to demonstrate disruption in the development or function of the male reproductive system in offspring whose dame were treated with glyphosate". Romano and Romano (2012, ASB2014-9396) rebutted these comments and conclusions.

Arbuckle, T. E. Lin, Z. Mery, L. S.	2001	An exploratory analysis of the effect of pesticide exposure on the risk of spontaneous abortion in an Ontario farm population Environmental Health Perspectives Volume: 109 Pages: 851-857 ASB2012-11545

Abstract*
The toxicity of pesticides on human reproduction is largely unknown—particularly how mixtures of pesticide products might affect fetal toxicity. The Ontario Farm Family Health Study collected data by questionnaire on the identity and timing of pesticide use on the farm, lifestyle factors, and a complete reproductive history from the farm operator and eligible couples living on the farm. A total of 2,110 women provided information on 3,936 pregnancies, including 395 spontaneous abortions. To explore critical windows of exposure and target sites for toxicity, we examined exposures separately for preconception (3 months before and up to month of conception) and postconception (first trimester) windows and for early (< 12 weeks) and late (12–19 weeks) spontaneous abortions. We observed moderate increases in risk of early abortions for preconception exposures to phenoxy acetic acid herbicides [odds ratio (OR) = 1.5; 95% confidence interval (CI), 1.1–2.1], triazines (OR = 1.4; 95% CI, 1.0–2.0), and any herbicide (OR = 1.4; 95% CI, 1.1–1.9). For late abortions, preconception exposure to glyphosate (OR = 1.7; 95% CI, 1.0–2.9), thiocarbamates (OR = 1.8; 95% CI, 1.1–3.0), and the miscellaneous class of pesticides (OR = 1.5; 95% CI, 1.0–2.4) was associated with elevated risks. Postconception exposures were generally associated with late spontaneous abortions. Older maternal age (> 34 years of age) was the strongest risk factor for spontaneous abortions, and we observed several interactions between pesticides in the older age group using Classification and Regression Tree analysis. This study shows that timing of exposure and restricting

analyses to more homogeneous endpoints are important in characterizing the reproductive toxicity of pesticides.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	No information about exposure duration, used glyphosate products and application rates. No information if the subjects used more than one pesticide.
Relevance of study:	Not relevant (Study design is not suitable for assessment of glyphosate exposure).
Klimisch code:	3

Additional comments:
Pre-conception glyphosate exposure odds ratio for spontaneous abortion is considered of borderline significance (OR = 1.4). Post-conception glyphosate exposure was not associated with spontantous abortin (OR = 1.1). Authors note multiple limitations of the study relating to exposure, likely misclassification of pesticides and correct assignment of exposure window to pre- of/and post-conception OFFHS information gathering methodology has high potential recall bias. Blair and Zahm (1993, ASB2012-11567) report 60% accuracy when comparing self reported pesticide usage with purchasing records.
OFFHS relied exclusively on maternal self-reports of adverse pregnancy outcomes, not all of which were confirmed via medical or other records.
Three highly relevant confounding factors were not considered in the OFFHS questionnaire: history of previous spontaneous abortion(s), maternal age and smoking.

Response summarized from Williams *et al.* (2012, ASB2012-12052)
395 spontaneous abortions were reported out of 3936 pregnancies; rate of spontaneous aborting in Arbuckle *et al.* (2001, ASB2012-11545) was 10%.
The baseline rate of spontaneous abortions in the general populations is much higher, ranging from 12% to 25%.
Recall bias is reflected in the recall of spontaneous abortion over the previous 5 years (64% of all spontaneous abortions reported) being much higher than the recall of those greater than 10 years prior to the survey (34% of all spontaneous abortions reported).
Substantial exposure misclassification may have occurred (pre- versus post-conception) due to likely author extrapolation of exposure data.
Strong confounding variables are not apparent in previous data analyses published by the authors of the OFFHS, and therefore odds ratios are crude.
Published results fail to demonstrate a significant association of glyphosate exposure spontaneous abortion risk and therefore must be considered cautiously.

Savitz, D.A. Arbuckle, T. Kaczor, D. Curtis, K.M.	1997	Male pesticide exposure and pregnancy outcome. American Journal of Epidemiology Volume: 146, Number: 12, Pages: 1025-1036 ASB2012-12022

Abstract*
Potential health effects of agricultural pesticide use include reproductive outcomes. For the Ontario Farm Family Health Study, the authors sampled Ontario farms from the 1986 Canadian Census of Agriculture, identified farm couples, and obtained questionnaire data concerning farm activities, reproductive health experience, and chemical applications. Male farm activities in the period from 3 months before conception through the month of conception were evaluated in relation to miscarriage, preterm delivery, and small-

for- gestational-age births. Among the 1,898 couples with complete data (64% response), 3,984 eligible pregnancies were identified. Miscarriage was not associated with chemical activities overall but was increased in combination with reported use of thiocarbamates, carbaryl, and unclassified pesticides on the farm. Preterm delivery was also not strongly associated with farm chemical activities overall, except for mixing or applying yard herbicides (odds ratio = 2.1, 95% confidence interval 1.0-4.4), Combinations of activities with a variety of chemicals (atrazine, glyphosate, organophosphates, 4-[2,4-dichlorophenoxy] butyric acid, and insecticides) generated odds ratios of two or greater. No associations were found between farm chemicals and small-for-gestational-age births or altered sex ratio. Based on these data, despite limitations in exposure assessment, the authors encourage continued evaluation of male exposures, particularly in relation to miscarriage and preterm delivery.

Additional comments:
Glyphosate is one of many pesticides mentioned in three epidemiological reports that examine possible links between on-farm pesticide use and reproductive outcomes. All three reports - Savitz *et al.* (1997, ASB2012-12022), Curtis *et al.* (1999, cited in ASB2012-11545) and Arbuckle *et al.* (2001, ASB2012-11545) - use data from the Ontario Farm Family Health Study (OFFHS) (Arbuckle 1994, cited in ASB2012-11545). Savitz *et al.* (1997, ASB2012- 12022) investigated associations between reported pesticide use by males and pregnancy outcomes, specifically: miscarriage, pre-term delivery and small-for-gestational-age birth. Curtis *et al.* (1999, cited in ASB2012-11545) studied whether reported pesticide use by males or females was associated with delayed pregnancy, while Arbuckle *et al.* (2001, ASB2012- 11545) looked for associations between reported pesticide use and spontaneous abortion.

In the study by Savitz *et al.* (1997, ASB2012-12022), a number of specific pesticides had weak statistical associations with miscarriages and pre-term deliveries, but pesticides tended not to be associated with small for gestational age births. There were no statistically significant findings for glyphosate. In the study by Curtis *et al.* (1999, cited in ASB2012- 11545), for farms on which glyphosate was used, there was no significant association for women being engaged in pesticide activities. For men, glyphosate use was associated with a slight, but statistically significant, decrease in time to pregnancy. The authors dismissed this finding, which was contrary to their hypothesis that pesticide exposure delayed pregnancy, as probably due to uncontrolled factors or chance. Arbuckle *et al.* (2001, ASB2012-11545) found that reported preconception use of phenoxyacetic acids, triazines, glyphosate, and thiocarbamates were weakly, but statistically significantly, associated with spontaneous abortions. Post conception reported use was not associated with increased risk. The authors characterized the associations between pesticides and spontaneous abortions as "hypothesis generating" pending confirmation from other epidemiologic studies. These studies are not convincing evidence of a relationship between glyphosate exposure and adverse pregnancy outcomes for a number of reasons:

There was no actual exposure data per se in these three epidemiologic studies. Exposures were assumed based on questionnaire responses by study subjects about farm activities and pesticide use. This type of information can be inaccurate. For example, according to a study by the National Cancer Institute, self-reports of pesticide usage were found to be only 60 percent accurate when compared with purchasing

records (Blair & Zahm 1993, ASB2012- 11567). Further increasing the potential for inaccuracy is the fact that study subjects were only asked about pesticide use for the 5 years before the OFFS survey. These responses were assumed to be applicable to the entire farming careers of study subjects, an assumption inconsistent with changes in agricultural practice. Lastly, basing exposure estimation on questionnaire responses has the potential to be influenced by what epidemiologists call "recall bias." This refers to the likelihood that families that experienced an adverse reproductive outcome are more likely to remember use of certain pesticides than families that had only normal births.
The most widely used pesticides, like atrazine, glyphosate, and 2,4-D, are most easily recalled and most likely to be over-reported.
The OFFHS study relied exclusively on maternal self-reports of adverse pregnancy outcomes with no medical or other validation. Generally, scientists place less confidence in reports of health outcomes that are not validated with medical records.
A confounding factor is a cause of a disease that is correlated with another exposure being studied. Failure to control confounding factors, especially those that are strong causes of a disease, can create spurious associations between benign exposures and diseases. In the Arbuckle study, there were at least three important potential confounding factors that were not controlled: history of previous spontaneous abortion, maternal age, and smoking. Even a weak correlation between these factors and use (or recall of use) of pesticides would produce spurious associations. In addition, in all three studies, the authors did not control the putative effect of one pesticide for the putative effects of other pesticides. So, for example, since farmers tend to use 4 or more pesticides each year, a disease that is associated with one pesticide will likely be associated with all, since their use patterns are correlated. In the absence of an analysis that controls for multiple pesticides, the best that can be said is that the findings for any individual pesticide might be due to its correlation with another pesticide.

In summary, three publications based on data collected in the OFFHS found associations between several pesticides and various adverse reproductive outcomes. There was no actual exposure data per se in these three epidemiologic studies. Exposures were assumed based on questionnaire responses by study subjects about farm activities and pesticide use. This type of information can be inaccurate. Glyphosate was not significantly associated with adverse reproductive outcomes in two of these studies (Savitz *et al.* 1997, ASB2012-12022, Curtis *et al.* 1999, cited in ASB2012-11545). Glyphosate and other pesticides were weakly associated with spontaneous abortion in the study by Arbuckle (2001, ASB2012-11545). However, the author did not control for important personal confounding factors or for multiple exposures and no actual exposure data was used, casting doubt on the validity of the findings in this study.
Biomonitoring data for glyphosate collected as part of the Farm Family Exposure Study (FFES), provide assurance that human health effects related to glyphosate exposure are very unlikely. In the FFES, researchers from the University of Minnesota collected 5 days of urine samples from 48 farm families before, during, and after a glyphosate application (Mandel *et al.,* 2005, ASB2012-11893, accepted for publication). Only 60% of farmers showed detectable exposure to glyphosate, with a 1 part per billion limit of detection, and the maximum estimated absorbed dose was 0.004 *mg/kg* (Acquavella *et al.,* 2004, ASB2012-11528). For farmers who apply glyphosate 10 times per year for 40 years, this maximum dose is more than 30,000-fold less than the EPA reference dose1 of 2 mg/kg/day. For spouses, only 4% showed detectable exposures and the maximum systemic dose was 0.00004 mg/kg/day. Since glyphosate is not a reproductive toxic in high dose animal studies and since actual exposures on farms are so low, it is very unlikely that glyphosate would cause adverse reproductive outcomes for farmers or their spouses.

Garry, V. F. Harkins, M. E. Erickson, L. L. Long-Simpson, L. K. Holland, S. E. Burroughs, B. L.	2002	Birth defects, season of conception, and sex of children born to pesticide applicators living in the Red River Valley of Minnesota, USA. Environmental Health Perspectives Volume: 110 Pages: 441-449 ASB2012-11626

Abstract*
We previously demonstrated that the frequency of birth defects among children of residents of the Red River Valley (RRV), Minnesota, USA, was significantly higher than in other major agricultural regions of the state during the years 1989-1991, with children born to male pesticide applicators having the highest risk. The present, smaller cross-sectional study of 695 families and 1,532 children, conducted during 1997-1998, provides a more detailed examination of reproductive health outcomes in farm families ascertained from parent- reported birth defects. In the present study, in the first year of life, the birth defect rate was 31.3 births per 1,000, with 83% of the total reported birth defects confirmed by medical records. Inclusion of children identified with birth or developmental disorders within the first 3 years of life and later led to a rate of 47.0 per 1,000 (72 children from 1,532 live births). Conceptions in spring resulted in significantly more children with birth defects than found in any other season (7.6 vs. 3.7%). Twelve families had more than one child with a birth defect (n = 28 children). Forty-two percent of the children from families with recurrent birth defects were conceived in spring, a significantly higher rate than that for any other season. Three families in the kinships defined contributed a first-degree relative other than a sibling with the same or similar birth defect, consistent with a Mendelian inheritance pattern. The remaining nine families did not follow a Mendelian inheritance pattern. The sex ratio of children with birth defects born to applicator families shows a male predominance (1.75 to 1) across specific pesticide class use and exposure categories exclusive of fungicides. In the fungicide exposure category, normal female births significantly exceed male births (1.25 to 1). Similarly, the proportion of male to female children with birth defects is significantly lower (0.57 to 1; p = 0.02). Adverse neurologic and neurobehavioral developmental effects clustered among the children born to applicators of the fumigant phosphine (odds ratio [OR] = 2.48; confidence interval [CI], 1.2-5. 1). Use of the herbicide glyphosate yielded an OR of 3.6 (CI, 1.3-9.6) in the neurobehavioral category. Finally, these studies point out that a) herbicides applied in the spring may be a factor in the birth defects observed and b) fungicides can be a significant factor in the determination of sex of the children of the families of the RRV. Thus, two distinct classes of pesticides seem to have adverse effects on different reproductive outcomes. Biologically based confirmatory studies are needed.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Epidemiological study with some methodological / reporting deficiencies (selection of study subjects, no information about exposure duration, exposure concentration, pesticide use frequency).
Relevance of study:	Not relevant because of methodological deficiencies.
Klimisch code:	3

Additional comments:

Response 1 – summary from Mink *et al.* (2011) (ASB2012-11904)
Publication reports on different classes of pesticides and several birth defects and developmental outcomes. Paternal use of glyphosate was associated with parent-reported ADD/ADHD in children (OR = 3.6). Six out of 14 children with parent reported ADD/ADHD also reported exposure to glyphosate.
Diagnoses of ADD/AHDH were not all confirmed. However, overall rate for the sample population (14/1532) was well below ADD/ADHD rates for the general population (7%). Variables in statistical model analyses were not reported.

Response 2 – summary from Williams *et al.* (2012, ASB2012-12052)
Health data obtained via parent reporting for 695 families via written questionnaire and confirmed where possible.
Pesticide use information obtained initially via telephone then followed up by written questionnaire.
Reproductive health outcomes for births occurring between 1968 and 1998 were obtained for 1532 live

births. Over half the births occurred prior to 1978, approximately 20 years after study initiation.
All pesticide use classes (herbicide only; herbicide and insecticide; herbicide, insecticide and fungicide; herbicide, insecticide and fumigant) were associated with birth defects.
Authors state neurobehavioral disorder would not be considered based lack consistent diagnoses. However, a detailed analysis was conducted for ADD/ADHD.
43% (6/14) parent reported children with ADD/ADHD were associated with glyphosate formulation use.
14 cases of ADD/ADHD reported out of 1532 live births, which is substantially lower that the diagnosed incidence of 7% for the general population.
No conclusions regarding glyphosate exposure and ADD/ADHD outcome can be drawn. No other glyphosate specific data were reported.

Author(s)	Year	Study title
Garry, V.F., Holland, S.E., Erickson, L.L., Burroughs, B.L.	2003	Male Reproductive Hormones and Thyroid Function in Pesticide Applicators in the Red River Valley of Minnesota Journal of Toxicology and Environmental Health, Part A Volume: 66, Number: 11, Pages: 965-986 ASB2012-11627

Abstract*
In the present effort, 144 pesticide applicators and 49 urban control subjects who reported no chronic disease were studied. Applicators provided records of the season's pesticides used by product, volumes, dates, and methods of application. Blood specimens for examination of hormone levels were obtained in summer and fall. In the herbicide-only applicator group, significant increases in testosterone levels in fall compared to summer and also elevated levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in the fall were noted. With respect to fungicide use, in an earlier cross-sectional epidemiologic study, data demonstrated that historic fungicide use was associated with a significant alteration of the sex ratio of children borne to applicators. As before, among current study subjects it was noted that historic fungicide use was associated with increased numbers of girls being born. Lower mean total testosterone concentrations by quartile were also correlated with increased numbers of live-born female infants. A downward summer to fall seasonal shift in thyroid-stimulating hormone (TSH) concentrations occurred among applicators but not among controls. Farmers who had aerial application of fungicides to their land in the current season showed a significant shift in TSH values (from 1.75 to 1.11 mU/L). Subclinical hypothyroidism was noted in 5/144 applicators (TSH values >4.5 mU/L), but not in urban control subjects. Based on current and past studies, it was concluded that, in addition to pesticide exposure, individual susceptibility and perhaps economic factors may play a supporting role in the reported results.

* Quoted from article

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Epidemiological study with some methodological / reporting deficiencies (e.g. selection of control subjects/samples, no details of exposure). Documentation is insufficient for assessment.
Relevance of study:	Not relevant for glyphosate (due to reliability; in addition, no direct assessment of glyphosate exposure was made).
Klimisch code:	3

Additional comments:
The publication brings little information on endpoints attributable to glyphosate.
Given the subjects were pesticide applicators, little can be drawn from the findings other than perhaps

certain endpoints which may be associated with this specific occupation exposed to multiple chemical substances. Of the 136 participants volunteering blood samples, only one individual (subject D) was noted with one abnormally high thyroid hormone levels associated with glyphosate use; thyroid stimulating hormone (FSH) was about double the normal range in the fall and thyroid stimulating hormone (TSH) higher than normal in the summer.
Another individual (subject E) had abnormally high TSH levels associated with multiple pesticide usage of 12 different active ingredients.

Bell, E.M. Hertz-Picciotto, I. Beaumont, J.J.	2001	A Case-Control Study of Pesticides and Fetal Death Due to Congenital Anomalies Epidemiology Volume: 12, Number: 2, Pages: 148-156 ASB2012-11559

Abstract*
We examined the association between late fetal death due to congenital anomalies (73 cases, 611 controls) and maternal residential proximity to pesticide applications in ten California counties. A statewide database of all applications of restricted pesticides was linked to maternal address to determine daily exposure status. We examined five pesticide chemical classes. The odds ratios from logistic regression models, adjusted for maternal age and county, showed a consistent pattern with respect to timing of exposure; the largest risks for fetal death due to congenital anomalies were from pesticide exposure during the 3rd – 8th weeks of pregnancy. For exposure either in the square mile of the maternal residence or in one of the adjacent 8 square miles, odds ratios ranged from 1.4 (95% confidence interval = 0.8 – 2.4) for phosphates, carbamates, and endocrine disruptors to 2.2 (95% confidence interval = 1.3 – 3.9) for halogenated hydrocarbons. Similar odds ratios were observed when a more restrictive definition of nonexposure (not exposed to any of the five pesticide classes during the 3rd– 8th weeks of pregnancy) was used. The odds ratios for all pesticide classes increased when exposure occurred within the same square mile of maternal residence.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Epidemoliogical study with methodological deficiencies (e.g. glyphosate was included in the pesticide class of phosphates, thiophosphates, phosphonates; no differentiation between single and multiple exposures).
Relevance of study:	Not relevant (No glyphosate-specific results.)
Klimisch code:	3

Additional comments:

Response – summary from Williams *et al.* (2012, ASB2012-12052)
Classes of pesticides were evaluated in this study, with glyphosate included as one of 47 active ingredients in the broad category of "phosphates/thiophosphates/phosphonates".
Of the 47 active ingredients, many were organophosphate insecticide with known mammalian modes of action. The glyphosate mode of action is on the EPSPS enzyme in plants, which is not present in the animal kingdom.
Given the very low volatility of glyphosate and the low potential for inhalation exposures to aerosol sprays up to two miles away from the subjects, systemic doses to glyphosate would be considered negligible.
Mose *et al.*, (2008, ASB2012-11914) demonstrated a low perfusion rate of glyphosate across the placenta. Coupled with the known low dermal and gastrointestinal absorption of glyphosate and the rapid elimination of systemic doses of glyphosate in the urine, human *in utero* exposures would be extremely limited.

The reported congenital anomalies associated with fetal death in Bell *et al.* (2001, ASB2012- 11559) can in no way be linked to glyphosate exposure.

Aris, A. Leblanc, S.	2011	Maternal and fetal exposure to pesticides associated to genetically modified foods in Eastern Townships of Quebec, Canada. Reproductive toxicology Volume: 31, Pages: 528-533 ASB2012-11547

Abstract*
Pesticides associated to genetically modified foods (PAGMF), are engineered to tolerate herbicides such as glyphosate (GLYP) and gluphosinate (GLUF) or insecticides such as the bacterial toxin bacillus thuringiensis (Bt). The aim of this study was to evaluate the correlation between maternal and fetal exposure, and to determine exposure levels of GLYP and its metabolite aminomethyl phosphoric acid (AMPA), GLUF and its metabolite 3- methylphosphinicopropionic acid (3-MPPA) and Cry1Ab protein (a Bt toxin) in Eastern Townships of Quebec, Canada. Blood of thirty pregnant women (PW) and thirty-nine nonpregnant women (NPW) were studied. Serum GLYP and GLUF were detected in NPW and not detected in PW. Serum 3-MPPA and CryAb1 toxin were detected in PW, their fetuses and NPW. This is the first study to reveal the presence of circulating PAGMF in women with and without pregnancy, paving the way for a new field in reproductive toxicology including nutrition and utero-placental toxicities.

Author(s)	Year	Study title
Benítez-Leite, S. Macchi, ML and Acosta, M.	2009	Malformaciones congénitas asociadas a agrotóxicos. Arch Pediatr Urug Volume: 80, Number: 3, Pages: 237-247 ASB2012-11563

Abstract*
Introduction: exposure to pesticides is a known risk for human health. This paper describes the relationship between parental exposure and congenital malformations in the newborn. Objective: to study the association between exposure to pesticides and congenital malformations in neonates born in the Regional Hospital of Encarnación, in the Department of Itapúa, Paraguay. Materials and methods: a prospective case-controlled study carried out from March 2006 to February 2007. Cases included all newborns with congenital malformations, and controls were all healthy children of the same sex born immediately thereafter. Births outside the hospital were not counted. Exposure was considered to be any contact with agricultural chemicals, in addition to other known risk factors for congenital defects. Results: a total of 52 cases and 87 controls were analyzed. The average number of births each month was 216. The significantly associated risk factors were: living near treated fields (OR 2,46, CI95% 1,09-5,57, p<0,02), dwelling

located less than 1 km (OR 2,66, CI95% 1,19-5,97, p<0,008), storage of pesticides in the home (OR 15,35, CI95% 1,96-701,63), p<0,003), direct or accidental contact with pesticides (OR 3,19, CI95% 0,97-11,4, p<0,04), and family history of malformation (OR 6,81, CI95% 1,94-30,56, p<0,001). Other known risk factors for malformations did not show statistical significance. Conclusion: the results show an association between exposure to pesticides and congenital malformations. Further studies are required to confirm these findings.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Study design of epidemiological study for developmental toxicity insufficient for assessment, as well as methological and reporting deficiencies (no assessment to which pesticides / active substances the mothers were exposed, use frequency not specified, selection of control group after study period is questionable, no information on exposure situation of mother for this control group assessed, etc.).
Relevance of study:	Not relevant (The exposure to several pesticides was assessed in general, but no pesticide or active substance, including glyphosate, was specified or assessed).
Klimisch code:	3

B.6.5 Delayed neurotoxicity (Annex IIA 5.7.2)

B.6.5.1 Published data on neurotoxicity

Several publications over the last decade have evaluated glyphosate with respect to neurotoxicity endpoints. Three papers report a total of two human cases of Parkinson's disease. The first case followed acute exposure to a glyphosate formulation while spraying a garden (Barbosa *et al.*, 2001, ASB2012-11557; da Costa et al, 2003, ASB2012-11598). The second case reported chronic exposures to a factory worker in China, where a variety of pesticides including glyphosate were produced (Wang et al, 2011, ASB2012-12047). Several questions arise in attempting to link glyphosate exposures with each case of Parkinson's disease. Firstly, significant systemic exposures to glyphosate in each instance are questionable, given the poor dermal absorption and low volatility of the compound. Secondly, if glyphosate was a causative agent of this fairly common disease, a significant number of cases associated with either acute and/or chronic exposures would be evident. Glyphosate formulations are sometimes readily accessible for suicide attempts, which are usually unsuccessful, as less than 10% of glyphosate self administered ingestions result in death. No reports of Parkinson's disease in survivors following very acute ingestions of glyphosate products have been documented. Glyphosate has been manufactured and widely used in agriculture and consumer markets for approximately 40 years, so a single case of a pesticide factory worker developing Parkinson's disease, while unfortunate, does not constitute cause and effect; there is no evidence of a higher frequency of Parkinson's disease in glyphosate production workers.

Multiple long term animal studies with glyphosate have failed to demonstrate any evidence of neurotoxicity, and certainly have not shown evidence of Parkinson's-like abnormalities. While some studies have suggested statistical associations with general pesticide exposure or general insecticide or herbicide exposure (Engel *et al.*, 2001, ASB2012-11612), there is no evidence suggesting a specific association between glyphosate and Parkinson's disease. In the largest study to date of US Farmers (Agricultural Health Study), no increased risk of Parkinson's disease was found in association with reported glyphosate use (Kamel *et al.*, 2007, ASB2012-11862). Human non-cancer epidemiologic outcomes related to glyphosate have recently been reviewed (Mink *et al.* 2011, ASB2012-11904), and there is no convincing evidence for an increased incidence of Parkinson's disease or other neurological disorders in individuals reporting glyphosate exposure.

Several publications open with the premise that pesticide exposures are linked with Parkinson's disease, and then proceed to report *a priori* research linking glyphosate with a measurable endpoint. This endpoint is then extrapolated to link with Parkinson's disease in humans. Despite the lack of compelling human associations between glyphosate exposure and Parkinson's disease, such research continues to be published. Astiz *et al.*, (2009, ASB2012-11549), Negga *et al.* (2011, ASB2012-11923) and Gui *et al.* (2012, ASB2012-11835) all conducted glyphosate research in the above mentioned manner, all in very different test systems. Negga *et al.* (2011, ASB2012-11923) notes neurodegeneration in *Caenorhabditis elegans* worms following exposure to glyphosate (trimesium form, which has a different toxicology profile than glyphosate) uses concentrations equal to the LD25, LD50 and LD75, or actual concentrations of glyphosate of 3 to 10 percent, i.e.- the high concentration is approximately 10-fold higher than concentrations applied directly in the field. The relevance of such high-dose exposures to the trimesium salt in this experimental model to human Parkinson's disease is highly questionable and irrelevant to the Annex 1 renewal of glyphosate technical acid. Astiz *et al.* (2009, ASB2012-11549) and Gui *et al.* (2012, ASB2012-11835) both affirm their test models (in rats and in PC-12 cells respectively) for evaluating neurodegenerative disorders, then directly link their research results to Parkinson's disease in humans; these two studies are addressed below.

Cole *et al.* (2004, ASB2012-11594) evaluated 15 different pesticides for neurotoxic endpoints in *C. elegans* with analytical grade active ingredients, noting reduced cholinesterase for pesticides with this mode of action, but not glyphosate. Interestingly, the authors report a low pH effect resulting in reduced cholinesterase activity in the high dose of glyphosate and a plant growth promoter. Glyphosate formulations contain salt forms of glyphosate, not the technical acid and thus do not have a low pH. Additionally, human incidents of self induced glyphosate poisonings do not report the common symptoms of acute acetylcholinesterase inhibition; salivation, lacrimation, urination and defecation (SLUD).

After preparation of the original DAR in 2013, the following publications became available:

Cattani *et al.* (2014, ASB2014-3919) studied neurotoxic effects of the formulation Roundup in the hippocampus on immature rats following acute (30 min) and chronic (pregnancy and lactation) exposure. Results showed that acute exposure to Roundup increased CA2+ influx leading to oxidative stress and neural cell death. Taken together, the results demonstrate that Roundup might lead to excessive extracellular glutamate levels and to glutamate excitotoxicity and oxidative stress in rat hippocampus.

Chorfa *et al.* (2013, ASB2014-9328) studied the effects of four pesticides (paraquat, rotenone, maneb and glyphosate) on different molecular events in cell lines which are considered to be related to Parkinson`s disease. Three of the four pesticides triggered molecular events involved in Parkinson`s disease. However, glyphosate was not active in this study.

Seneff *et al.* (2013, ASB2014-9729) reviewed literature on autism. In conclusion they submit a theory on the biochemical mechanisms which could lead to autism. According to this theory, several environmental factors including pesticide exposure (glyphosate and other pesticides

are mentioned, together with, e.g., aluminium, mercury, intake of 'processed food', vaccinations) would promote the 'encephalopathy of autism'. The contribution of glyphosate is ascribed to a disturbance of gut microflora rather than to a direct effect on the neuronal system. Thus, there assumptions are based on certain in vitro results (e.g., Shehata *et al.*, 2013, ASB2012-16301) that are discussed in depth in section B.6.8.3.3. The authors propose dietary and lifestyle changes to prevent autism.

Narayan *et al.* (2013, ASB2014-9620) reviewed literature on Parkinson`s disease. The authors conclude that houshold use of organophosphorus pesticides is associated with increased risk of developing Parkinson`s disease. Glyphosate is considered by these authors to be an organophosphorus pesticide.

McConnell *et al.* (2012, ASB2014-9615) tested multi-well microelectrode arrays for neurotoxicity screening. In result of these tests glyphosate was considered negative concerning neurotoxic effects.

LeFew *et al.* (2013, ASB2014-9608) evaluated microelectrode array data using Bayesian modeling as an approach to screening and prioritization for neurotoxicity testing. Glyphosate was identified to be negative in these neurotoxicity tests.

Kim *et al.* (2013, ASB2014-9592) studied the relation between depressive symptoms and severity of acute occupational pesticide poisoning among male farmers in South Korea. Among the pesticides causing the poisonings, paraquat dichloride was found to be a significant predictor of depressive symptoms. Glyphosate did not cause significant effects.

Kamel *et al.* (2012, ASB2014-9586) summarized the literature on the association of amyotrophic lateral sclerosis (ALS) with pesticides. The meta-analysis suggest that ALS risk is associated with use of pesticides. ALS was associated with aldrin, dieldrin, DDT and toxaphene. However, no relevant association was evidenced for glyphosate.

Freire and Koifmann (2012, ASB2014-9479) conducted a review of the epidemologic literature over the past decade. A significantly increased Parkinson`s disease risk was observed in 13 out of 23 case-control studies. An increased risk has been associated with different pesticides. However, no relevant increase of the risk was evidenced for glyphosate.

Faria *et al.* (2014, ASB2014-9477) analysed the association between occupational exposures to pesticides, nicotine and minor psychiatric disorders (MPD) among tobacco farmers in southern Brazil. The study reinforces the evidence of the association between pesticide poisoning and mental health disorders. In this study organophosphates were the only chemical group positively asscíated with MPD. Glyphosate was not associated with MPD.

The study by Harrill *et al.* (2011, ASB2014-9558) compared the performance of two culture models, a rat primary cortical culture and a human embryonic stem cell-derived neural culture to be used as tools for screening potential developmental neurotoxicants. The authors concluded that based upon the small training set evaluated in their study, neither of the culture models performed better than the other across the determined criteria: the data demonstrated that the culture models performed differently in terms of reproducibility, dynamic range and sensitivity to neurite outgrowth inhibitors. In this study glyphosate was used as one out of six 'negative' chemicals and none of them inhibited neurite outgrowth in either model.

The study by Culbret *et al.* (2012, ASB2014-9355) compared the sensitivity of human (ReN CX) and mouse (mCNS) neuroprogenitor cell lines to chemicals using a multiplex assay for proliferation and apoptosis, endpoints critical for neural development. According to the authors, eleven chemicals reported to affect proliferation and/or apoptosis, and 5 chemicals, amongst others glyphosate, with no reports of effects on either endpoint were examined in concentrations of 0.001 up to 100 µM. High-content screening of markers for proliferation (BrdU incorporation) and apoptosis (activated caspase 3 and p53) was used to assess the effect of chemicals in both cell lines. Under the conditions described, the hypothesis that human cells are significantly more sensitive than rodent cells to chemical insult on proliferation and apoptosis was not supported by these results. Interestingly, the 'negative' chemical, glyphosate (technical material, purity > 99 %), reached the threshold for p53 activation in mCNS at 30 µM, but not in the human cell line.

The review by Grandjean and Landrigan (2014, ASB2014-9494) on neurobehavioural effects of developmental toxicity emphasise that the total number of neurotoxic substances now recognised almost certainly represents an underestimate of the true number of developmental neurotoxicants that have been released into the global environment. In this context, the authors considered glyphosate as a human toxicant based on a case report of a 71-year old male who attempted suicide with a glyphosate formulation published by Malhotra *et al.* (2010, ASB2012-11890, please refer to B.6.9.2. Reports on clinical cases and poisoning

incidents). This interpretation was disagreed by Goldstein and Saltmiras (2014, ASB2014-9493) and Malhotra *et al.* were cited, that this case raises "a suspicion of direct cerebral toxicity", but no conclusion was drawn on glyphosate to be a recognised neurotoxicant, but inquiry into other components of the ingested product was considered to be indicated.

Further studies are reported more detailed:

Abstract*
This 54-year-old man accidentally sprayed himself with the chemical agent glyphosate, an herbicide derived from the amino acid glycine. He developed disseminated skin lesions 6 hours after the accident. One month later, he developed a symmetrical parkinsonian syndrome. Two years after the initial exposure to glyphosate, magnetic resonance imaging revealed hyperintense signal in the globus pallidus and substantia nigra, bilaterally, on T2-weighted images. Levodopa/benserazide 500/125 mg daily provided satisfactory clinical outcome.

Wang, G., Xiao-Ning, F., Yu-Yan, T., Qi, Ch., Shen-Di, CH.	2011	Parkinsonism after chronic occupational exposure to glyphosate. Parkinsonism and related disorders ASB2012-12047

Abstract*
Here we report a patient with Parkinsonism following chronic occupational exposure to glyphosate. A previously healthy 44-year-old woman presented with rigidity, slowness and resting tremor in all four limbs with no impairment of short-term memory, after sustaining long term chemical exposure to glyphosate for 3 years as a worker in a chemical factory. The chemical plant produced a range of herbicides including: glyphosate, gibberilins, and dimethyl hydrogen phosphite; however, the patient worked exclusively in the glyphosate production division. She only wore basic protection such as gloves or a face mask for 50 h each week in the plant where glyphosate vapor was generated. She frequently felt weak.
Physical examination revealed a parkinsonian syndrome.
We cannot exclude the coincidence of idiopathic PD with exposure to glyphosate on our patient.

Astiz, M. de Alaniz, M.J. Marra, C.A.	2009	Effect of pesticides on cell survival in liver and brain rat tissues Ecotoxicology and Environmental Safety Volume: 72, Pages: 2025-2032, ASB2012-11549

Abstract*
Pesticides are the main environmental factor associated with the etiology of human neurodegenerative disorders such as Parkinson's disease. Our laboratory has previously demonstrated that the treatment of rats with low doses of dimethoate, zineb or glyphosate alone or in combination induces oxidative stress (OS) in liver and brain. The aim of the present work was to investigate if the pesticide-induced OS was able to affect brain and liver cell survival. The treatment of Wistar rats with the pesticides (i.p. 1/250 LD50, three times a week for 5 weeks) caused loss of mitochondrial transmembrane potential and cardiolipin content, especially in substantia nigra (SN), with a concomitant increase of fatty acid peroxidation. The activation of calpain apoptotic cascade (instead of the caspase-dependent pathway) would be responsible for the DNA fragmentation pattern observed.
Thus, these results may contribute to understand the effect(s) of chronic and simultaneous exposure to pesticides on cell survival.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Unsuitable test system (i.p exposure route is not relevant for human exposure). No information on purities of test substances used. Small group size (4 males/dose group), reporting deficiencies
Relevance of study:	Not relevant (intraperitoneal injection is a non-relevant route of exposure for humans)
Klimisch code:	3

Additional comments
This non-guideline study utilized very small group numbers (4 rats/group) and therefore is not sufficiently robust to appropriately identify changes attributable to the test material administration.
The test materials are not well described, without indication of whether a glyphosate salt form or acid was used and purity was not reported.
The publication focuses on the post necropsy data analysis and reporting. Data on animal husbandry, clinical observations, feed and water intake, weekly body weight were not reported, but the authors note there were no adverse observations.
No statistically significant effects were noted for liver endpoints, yet the liver is in close proximity to test material administration via intraperitoneal injection.
Statistically significant effects were noted for brain tissue endpoints in the substantia nigra and cerebral cortex. However, there is a lack of biological plausibility for brain exposures to glyphosate, given the necessity to pass the blood-brain barrier and the known rapid elimination kinetics of this polar molecule

via urine.

Abstract*
Herbicides have been recognized as the main environmental factor associated with human neurodegenerative disorders such as Parkinson's disease (PD). Previous studies indicated that the exposure to glyphosate, a widely used herbicide, is possibly linked to Parkinsonism, however the underlying mechanism remains unclear. We investigated the neurotoxic effects of glyphosate in differentiated PC12 cells and discovered that it inhibited viability of differentiated PC12 cells in dose-and time-dependent manners. Furthermore, the results showed that glyphosate induced cell death via autophagy pathways in addition to activating apoptotic pathways. Interestingly, deactivation of Beclin-1 gene attenuated both apoptosis and autophagy in glyphosate treated differentiated PC12 cells, suggesting that Beclin-1 gene is involved in the crosstalk between the two mechanisms.

Comment:	Documentation insufficient for assessment (not clearly stated dose levels and duration of exposure, as well as treatment conditions for all tests. In addition, tested doses were much higher than real in vivo concentrations).
Relevance of study:	Not relevant (Due to reliability)
Klimisch code:	3

Additional comments:
In this paper, the authors apply glyphosate to adrenal cancer cells in culture at concentrations sufficient to cause cell death. Two major interacting pathways leading to cell death (autolysis and apoptosis) are evaluated, and the results are hardly surprising - the cells do indeed die via known mechanisms leading to cell death. The authors use these observations, and the fact that Parkinson's disease involves the death of certain nerve cells in the brain, to try and create a link between glyphosate and Parkinson's disease. There are, however, many problems with this extrapolation.
The cells used are not the neurons involved in Parkinson's, but rather a cell line derived from an adrenal gland cancer (pheochromocytoma), and the doses used are very high- the high dose killed nearly 50 % of cells in 72 hours, and the low dose was ¼ this level. The high dose equates to approximately 1/10 the concentration applied directly in the field, and is far higher than any internal glyphosate concentration that could ever occur following glyphosate use. A sufficiently high dose of every substance will kill cells - but this does not mean that every substance causes Parkinson's disease.
Unprotected cells in culture are highly susceptible to changes in pH and other non-specific effects, and it is not clear that the researchers assessed or accounted for these possible effects.
This being said, the concentrations of glyphosate used (40 mM) are known to kill other cell types in culture (Heu *et al.*, 2012, ASB2012-11844) via induction of apoptosis. Thus, no particular specificity or neuronally-specific susceptibility exists for the cell line tested. While 40 mM glyphosate is toxic to cells in culture, the LD50 in rodents is over 5000 mg/kg and *C. elegans* will have a 25 % survival following

exposure to a 10 % solution of glyphosate. *In- vitro* results do not appear to reflect *in vivo* events.
Anadon *et al.* (2009, ASB2012-11542) dosed rates with 400 mg/kg of glyphosate, a massive dose relative to any environmental exposure, and achieved glyphosate peak modeled plasma concentrations of approximately 5 µg/mL (5 ppm). Assuming linear kinetics, the current maximum allowable EU daily intake (0.3 mg/kg/day) would give an approximated blood concentration of 0.17 ppm (170 ppb). This is conservative, as McQueen et al (2012, ASB2012-11898) recently evaluated glyphosate exposure to pregnant women and concluded that estimated exposures based on actual measurements in food were only 0.4 % of the current European acceptable daily intake.
The lowest glyphosate concentration used in this experiment is 5mM (830 ppm), or 5000 times higher than the estimated blood concentration following the current EU maximum allowable daily exposure. It is also 166 times higher than the concentrations Anadon *et al.* (2009, ASB2012-11542) achieved using doses of 400 mg/kg glyphosate. In short, the concentrations used in this work are massively higher than any concentration is blood (let alone brain tissue) that can be achieved following normal human exposures.

Urinary concentrations of glyphosate in cattle and other species
Krüger *et al.* (2013, ASB2013-11599) reported the abundance of glyphosate in the urine of a total of 240 cows from Danmark. From each of eight dairy farms, the same number of 30 cows (15 fresh calving, 15 high yielding cows, i.e., at the top level of milk production) was selected. All these 240 cows excreted glyphosate in the urine, however, at very different concentrations. Urine samples were diluted 1:20 with distilled water and tested for glyphosate by means of an ELISA kit (Abraxis, USA). The limit of detection (LOD) or a limit of quantification (LOQ) were, unfortunately, not mentioned. However, it is stated in the paper that validation of test results had been done by a comparison with GC-MS which is considered a more suitable method. It was mentioned that the correlation coefficient between the two methods was 0.96 and, thus, sufficiently high but this validation data was not shown in this paper. However, for further interpretation of the results, it is assumed that the method was in fact valid and that the measured values were reliable.
It is worth mentioning that the cows (breed not given) were 4 to 7 years old and had an average body weight between 550 – 600 kg and that the total number of cows in the farms ranged from 140 to 400 animals. The average daily milk yield in the different farms ranged from 8.6 to 11.2 kg

Mean urinary glyphosate concentrations differed very much among the eight farms, ranging from 10 µg/L up to 103.3 µg/L. It is a reasonable assumption that urinary excretion of glyphoate was due to dietary exposure and, thus, detection of glyphosate in the urine of cattle is not surprising. Residues of glyphosate may occur in feedstuffs for ruminants and, so far the maximum residue limits (MRLs) are not exceeded, are allowed by law and of no concern. (Therefore, the word “contamination” as used by the authors is not correct and somehow misleading.) The reason for the remarkable differences between the farms is unknown but most probably the diet was different, including a high variability in glyphosate residues. It is one of the main deficiencies of the publication that no details on feeding regime have been given and that the diets were not analysed for glyphosate content.
It is interesting to note that the mean urinary concentrations in cows exceeded the mean value in human urines of 0.2 µg/L as found by Hoppe (2013, ASB2013-8037, see B.6.9.3) by more than 500 times suggesting higher residues of glyphosate in cattle rations than in human diet. This big difference is also confirmed by comparison to further data on glyphosate findings in human urine samples (see B.6.9.3)

The maximum mean value of *ca* 103 µg/L can be used to calculate a systemic dose to which the cows in that farm had been exposed to since glyphosate does not accumulate but is rapidly excreted. The study authors have estimated a maximal glyphosate excretion via urine of 3.1 mg/day. If an oral absorption rate of only 20% is assumed instead of 30% as used by the study authors (for justification, see B.6.1), the maximum daily oral intake should have been in the magnitude of 15 – 16 mg. This dose might be compared either to the ADI (even though but it is not clear if a reference dose established for humans is per se also applicable to farm animals) and in particular to ruminants.

Thus, the maximum expected systemic dose was better compared to the NOAELs in subacute studies with either the isopropylamine salt of glyphosate (540 mg/kg bw/day according to Rowe *et al.*, 1987, TOX9552424) or a Roundup formulation (400 mg/kg bw/day according to Rowe *et al.*, 1987, ASB2010-8131). For a cow of 550 kg, the latter NOAEL would correspond to a daily intake of 220 g. In the study description (see above), a glyphosate content of 30.5% is mentioned. Thus, a daily glyphosate intake of 67 g can be calculated. If this amount of 67000 mg is compared to the expected maximum systemic exposure of 15 or 16 mg per day in the study in Danish cows, a margin of safety of about 1:4200 would result. Based on these considerations, an impairment of animal health in the Danish cows is very unlikely.

In contrast, the authors reported increased activities of the enzymes creatine kinase (CK), glutamate oxaloacetate transaminase (GOT, synonymous to ASAT), and glutamate dehydrogenase (GLDH) in blood serum but also changes in cholesterol levels and an increase in blood urea concentrations. values of unknown origin. For this comparison, they used reference values of unknown origin with the most of them not precisely mentioned. A relationship with the detection of glyphosate in urine was postulated interpreting the alterations in laboratory parameters as indicative for liver damage and neprhrotoxicity.

Leaving aside the serious methodical deficiencies of the study (*e.g.*, the absence of a control group with no glyphosate residues in the urine), there is no evidence that the altered clinical chemistry parameters in cows were indicative of any health deterioration. There could be many different reasons of such alterations and, taking into account the very low glyphosate concentrations (see above), exposure to glyphosate is not a likely one. Moreover, the statistical correlation between glyphosate excretion in urine and changed clinical chemistry parameters as claimed by the autors was in fact rather poor. (Thus, for the comparison of glyphosate with creatine kinase, an R value of 0.135 was considered in the articleas indicative of "positive correlation" which in fact is not the case. In contrast, higher R values of up to 0.809 were obtained when two different clinical chemistry parameters such as zinc and cobalt concentrations were measured and may indicate some correlation between them but apparently not with glyphosate excretion. Unfortunately, due to the way of reporting, the reader may be misleaded here to assume correlation with glyphosate.)

Since, in parallel, the authors claimed very low serum levels of several trace elements such as cobalt or manganese, a possible chelating mode of action of glyphosate was suspected. However, these considerations appear purely speculative, in particular against the background of the very low exposure. Even if glyphosate would have chelating properties, the ingested and absorbed amount is not expected to bind trace elements to such an extent that clinical signs might be expected to occur even though such an effect was suspected by scientists from the Aarhus university uin Danmark (Sørensen *et al.*, 2014, ASB2014-5761).

Again, statistical correlation was rather weak. Indeed, the almost complete absence of the two elements in cattle from all farms rather points to either an analytical problem or to a deficiency in the diet.

Thus, to conclude, the urinary levels in Danish cows might well reflect the abundance of glyphosate residues in their feed. The systemic exposure that may be calculated is very low and no health concern is anticipated. Final conclusion on the clinical chemistry findings is not possible but, on one hand, it seems not proven that they were adverse and, on the other, it is very unlikely that they might be related to glyphosate.

In a second paper dealing with determinations of glyphosate in the urine of cattle, Krüger *et al.* (2014, ASB2014-5024) reported, again, data from Danmark. The sample number was 242. It is not clearly stated but can be assumed that the 240 cows mentioned in the first paper were completely or at least partly included. These urine measurements were compared to samples from Germany. The German urine samples were collected from 343 cows from "conventional husbandry" and from 32 cows of which husbandry was

not described but which were kept in so-called "GM free" regions. (There are regions in Germany where farmers try to avoid feed that is or might be produced abroad on the basis of genetically modified crops.) The samples were analysed by means of a not further specified ELISA (Abraxis, USA) but, again, an LOD or LOQ were not mentioned. Instead, a comparison between values obtained by this ELISA and GC-MS was provided and, this time, explained in greater detail. The comparison revealed a very good correlation (R2 of 0.96 for cattle urine, based on 21 samples that were measured in parallel by both methods). Neither individual numeric values for urine concentrations nor statistical parameters such as the mean, median or standard deviation are given in this very brief paper but only figures. It seems from these printed figures that the mean urinary concentration in Danish cows was slighly above 40 µg/L as compared to only ca 20 µg/L in the German cows from conventional husbandry. This difference was statistically significant. The German cows from "GM free" regions had hardly any glyphosate in their urines. In contrast to what is said in the article, this finding is not surprising since imported feedstuffs will most certainly contain higher residues of glyphosate.
As discussed above with regard to Krüger *et al.* (2013, ASB2013-11599), urinary concentrations in this magnitude are of no health concern for cattle.

Furthermore, glyphosate was found in the urine of fattening rabbits (n = 77) in the magnitude of about 60 µg/L (mean value, standard deviation showing values ouf up to ca 120 µg/L). Less glyphosate (mean of 20-30 µg/L) was determined in the urine of hares (n = 193). Nothing is known on the origin of these samples and no conclusions can be drawn.
(In human samples that were analysed by the same group, the mean concentration was nearly 2 µg/L with a maximum in the magnitude of 5 µg/L. For details, see section B.6.9.3.) Information on glyphosate residues in the organs of slaughtered cows was also given in this paper and is reported in chapter B.7.

Possible impact on the microflora in ruminant's GIT
A number of papers has been published recently in which a possible causal link of glyphosate exposure and subsequent Clostridium botulinum (C. botulinum) overgrowth with a new disease in cattle is suggested. The scientific background of this assumption is the herbicidal mode of action of glyphosate. In plants, the enzyme 5-enolpyruvylshikimic acid-3-phosphate synthase (EPSP synthase) is inhibited resulting in a lack of formation of aromatic amino acids by the shikimate pathway that is common in the plant kingdom but not does not occur in animals. However, this pathway is operative in most bacteria and yeast and many protozoan species. Thus, an impact of glyphosate on microflora, e.g., in the intestines, is at least conceivable. In line with that, concern on this issue was expressed by scientists from the Aarhus University in Denmark (Sørensen *et al.*, 2014, ASB2014-5761).

Rodloff and Krüger (2012, ASB2013-13311) hypothesised that an emerging new disease in cattle but also symptoms in a small number of farmers might be caused by Clostridium botulinum. This animal disease of so far unknown etiology and pathogenesis was reported to have occurred from the late 1990ies onwards in cattle mainly from some parts of Germany but, according to the authors, cases had been observed also in France, the Netherlands, and the U.K. even though references were not given. Clinical signs in cattle are predominately seen in the perinatal period and comprise indigestion with alternating constipation and diarrhea, apathy, ataxia, paralysis, retracted abdomen, breathing difficulties, a decrease in milk yield, and death. In some farmers taking care of affected herds, symptoms such as dizziness, weakness, fatigue, blurred vision, nausea, and difficulties to speak, to swallow and to breathe have been occasionally reported. The authors suggested a causal link to Clostridium botulinum because these signs and symptoms appear similar to what is known from the rarely occurring cases of botulism in animals and man that are not food-borne (i.e., not caused by acute intoxication with the bacterial toxin). By means of an ELISA (no details given), they have detected Clostridium botulinum neurotoxin (BoNT) in fecal samples (in total in 16 out of 33) obtained from cattle on six German farms where the suspicious clinical signs or even fatalities had been noted but not in a total of 10 samples from two farms without any evidence of this disease. Toxin types were different (A, B, C, D, and E, in various combinations). Health state of the donor animals was not reported. In addition, neurotoxin of different types was found in various organs such as the rumen and the liver in 15 sick cows after slaughter. However, it is not known howmany cows were examined in total

post mortem and by which method and if they belonged to the group of which fecal samples had been taken before.
In man, 16 out of 77 fecal samples were positive for BoNT that were taken from humans who were reported to have been in close contact with diseased cows. It is not clear if one or more samples were obtained from the same person and, thus, the total number of humans under investigation is not known. Again, health status of the involved people was not reported. With regard to neurotoxin types, mainly type E had been found.
Unfortunately, these numbers do not completely match with a table in the paper in which 12 BoNT-positive human fecal samples in a total number of 33 and 29 BoNT-positive bovine fecal samples out of 118 under examination were mentioned to be obtained from 7 "selected" German cattle farms.

Conclusion by RMS:
This paper does not contribute anything to risk assessment of glyphosate and, in fact, this herbicidal active ingredient was not mentioned therein. However, it is important for understanding of subsequent publications and, therefore, is referred to in this RAR.
In itself, this paper is adequate to suggest a scientific hypothesis, based on some data that might require further research. However, no causal relationship between a new disease in cattle and C. botulinum has been established. C. botulinum neurotoxin could not be quantified. Qualitative detection of the neurotoxin might be also a random co-incidence. The publication is flawed by many reporting deficiencies. In particular, the method by which the neurotoxin was detected and its different types were distinguished, is not described.

In a similar paper, Krüger *et al.* (2012, ASB2013-13312) reported the abundance of (different types) of the micro-organism *C. botulinum* itself in 44 out of 196 bovine fecal samples (22.5%) and in 17 out of 77 human fecal samples (22%) but also in silages (9 / 21 = 47%), concentrate feed specimens (4 / 14 = 28.6%), and in all 7 tested house dust specimens from a total of 41 dairy farms in the German Federal State of Schleswig-Holstein. This finding was based on the immunological detection of antigens of *C. botulinum* by an ELISA technique using polyclonal antibodies. All the cattle had been reported to have shown clinical signs as described above. In addition, in four of the involved humans, symptoms were claimed to have occurred but without further specification or medical confirmation.

Conclusion by RMS:
Again, this paper, in principle, is not relevant for risk assessment of glyphosate but it is mentioned therein that ingested spores might germinate in the intestinal tract if protective indigenous bacterial flora is lacking (as observed in cases of infant botulism) or altered and this might be linked to the glyphosate hypothesis explained below. Therefore, it is mentioned here despite its many reporting deficiencies. The findings rather point to ubiquitious occurrence of C. botulinum but are not suitable to prove a causal relationship of its abundance to clinical signs or symptoms.

By the same group, it was published that different bacteria such as *Enterococcus faecalis*, *Enterococcus faecium* or *Bacillus badius* were able to inhibit growth of *C. botulinum* and/or the production of its neurotoxins *in vitro* whereas other bacterial species did not exhibit such an effect (Shehata *et al.*, 2012, ASB2013-8529). Subsequently, Krüger *et al.* (2013, ASB2013-8527) reported that glyphosate (analytical grade) and the herbicide Roundup UltraMax® containing 450 glyphosate/mL was able to suppress this antagonizing effect of *Enterococcus* species on *C. botulinum in vitro*. What they actually observed was a growth inhibition of both *C. botulinum* (and a reduction in neurotoxin type B production) and *Enterococcus faecalis* by glyphosate and Roundup herbicide but at different concentrations. While growth of *E. faecalis* was completely inhibited by 0.1 mg glyphosate or Roundup/mL, the same effect on *C. botulinum* was seen only at a concentration of 1 mg Roundup/mL or of 10 mg glyphosate/mL.

Conclusion by RMS:
This data suggests a different susceptibility of E. faecalis and C. botulinum to cytotoxic effects of glyphosate and a glyphosate-based herbicide in vitro. With regard to C. botulinum, the Roundup UltraMax formulation was more toxic than the active ingredient confirming similar evidence from various fields of toxicological

testing. No conclusions can be drawn if similar effects might occur in vivo because the situation in, e.g., the GITs of ruminants or monogastric animals is different with hundreds or thousands of mirobial species co-existing. In any case, even the lowest tested concentration of 0.1 mg/mL appears extremely high if a (maximum) systemic dose of 15 or 16 mg per cow is assumed to result from feeding the animals with a ration containing glyphosate residues (based on Krüger et al., 2013, ASB2013-11599, see above). Thus, the possible impact of glyphosate (herbicides) on bacteria due to inhibition of the enzyme EPSP was somehow confirmed in vitro but there is no health concern and no impact on realistic risk assessment.

A different toxicity of Roundup UltraMax® to various microbial species was also observed by Shehata *et al.* (2013, ASB2012-16301) who measured the effect of different concentrations on 23 bacterial species and strains mostly of chicken origin and also on sporulated *Eimeria tenella* (*i.e.*, a protozoon in poulty) oocytes *in vitro*. It is not clear whether the mentioned concentratios ranging from 0.075 mg to up to 5 (bacteria) or 1.2 (*Eimeria tenella*) mg per mL are related to the herbicide formulation or had been adjusted to the active ingredient. In general, the authours found lower minimum inhibitory concentrations (0.075 – 0.6 mg/mL) for beneficial bacteria whereas, in contrast, some pathogenic germs such as *Clostridium perfringens* or several *Salmonella* species appeared much less sensitive with growth inhition seen only at the highest tested concentration of 5 mg/mL. With regard to *Eimeria tenella*, the threshold for an effects was around 0.3 mg/mL with a clear effect to be seen at 0.6 mg/mL.

Conclusion by RMS:
Different cytototoxicity of a glyphosate-based herbicide to micro-organisms was confirmed once more and might be due to either the active ingredient or, e.g., a surfactant. (It is not known whether a tallowamine surfactant was contained.) However, antibiotic activity of the herbicide (expressed in the minimum inhibitory concentrations) was lower than that of known antibiotics that are used in veterinary medicine. Even the lowest effect concentrations in this study were by far higher than the expected glyphosate concentrations in poultry feed (GTF, 2013; ASB2013-11007) and, thus, must be considered unrealistically high. Furthermore, in vitro exposure of selected individual species and strains to a herbicide might be not a good model for complex interactions in GIT of poultry when residues are ingested.

To conclude, a link of glyphosate residues in ruminant's diet to a new disease in cattle has not been established and is not likely. Furthermore, there is no convincing proof that clinical signs in cattle (of which the occurrence cannot be doubted) were indeed caused by *C. botulinum* or its toxins. Meanwhile, a comprehensive case-control study on a possible causal relationship between C. botulinum and that chronic disease in cattle has been conducted in Germany. Preliminary results suggest that this was not the case even though further investigations have been considered necessary. In addition, use of glyphosate on the included farms had no impact on the occurrence of clincial signs (Seyboldt and Hoedemaker, 2014, ASB2014-10736).

However, because of the growing public concern about this cattle disease especially in Germany and because an effect on micro-organisms due to EPSP inhibition cannot be excluded, the German Federal Institute for Risk Assessment (BfR) has commisioned a study with a glyphosate-based herbicide (containing a tallowamine surfactant) in an artifical rumen system (RUSITEC) to investigate wheter (1) quantitative composition of ruminal microflora might be compromised and (2) there is evidence of *C. botulinum* overgrowth. Unfortunately, results of this project have not been published so far. However, an internal research report of the Veterinary High School in Hannover (Riede *et al.*, 2013; ASB2013-14684) has been submitted to the Federal Institute for Risk Assessment and is reported here in brief. Two different experiments were performed. In the first one, the effects of a glyphosate-based herbicide (Plantaclean® XL; 360 g/l glyphosate, containing a tallowamine surfactant) on rumen fermentative parameters were studied. Total glyphosate doses per day were 0.26 or 2.31 mg per fermentation vessel. No major changes in rumen parameters were detected except slight decreases in NH3-N concentrations and increases in isovalerate production in response to the high dosage. There was an increase in (beneficial) Bifidobacterium spp. but, in general, the microbial communities were not affected. In the second trial, no effects of the herbicide on the growth of C. sporogenes was found that had been artificially added to serve as a surrogate for C. botulinum.

Malformations in piglets with suspected correlation with glyphosate

Krüger *et al.* (2014, ASB2014-8935) reported glyphosate residues in different organs/tissues (brain, gut wall, heart, kidneys, liver, lungs, and muscle tissue) from a total of 38 malformed one-day old piglets (breed not specified) which had been brought in by a Danish farmer. The same farmer had complained about reproduction and developmental problems already in the past, e.g., in an Internet publication by the NGO "GM-Free Cymru (Wales)" in which health effects in pigs including malformations were mainly ascribed to the feeding of genetically modified soy (Anon., 2012, ASB2014-3921) and, apparently, his observations have been also referred to by Sørensen *et al.* (2014, ASB2014-5761). The malformations were very much different including craniofacial but also visceral and leg anomalies. For determination of glyphosate, apparently the same ELISA as for urine measurements (Abraxis, USA) was used after mincing and diluting tissue samples from the various organs. Mean glyphosate concentrations between 2.1 ppm (liver) and 12.9 ppm (heart) were found. In most organs, standard deviation was extremely large and individual values in single animals ranged from 0 (liver) and 0.1 ppm (kidney) to occasional findings as high as 80 ppm (in lung and heart). The authors speculated if there was a correlation between the malformations and intake of glyphosate residues to which the piglets might have become exposed via the placenta. The farmer claimed that the rate of malformed piglets had increased from 1:1432 when the sows had been fed a diet containing 0.25 ppm glyphosate to 1:260 when the sows received a diet with a glyhosate content of 0.87-1.13 ppm during the first 40 days of pregnancy.

Conclusion by RMS:

This publication cannot be considered to describe a reliable scientific study. First, the analytical data obtained from the piglets appear questionable since no information was given whether the ELISA had been modified for these investigations or validated for analysing tissue samples. No LOD or LOQ was mentioned. For the changing glyphosate content in the diet as claimed by the farmer, there is no confirmation in the publication.

The second main weakness of the study is that only malformed piglets had been investigated for glyphosate concentrations in their organs. Thus, there was no control group to (possibly) prove the hypothesis of a potential correlation.

For the following considerations, such a correlation is unlikely:

-In a multitude of developmental studies and multi-generation studies in rats, no evidence of teratogenicity was obtained. Even in rabbits which proved more vulnerable, developmental effects were confined to exaggerated dose levels causing also clear maternal toxicity (see sction B.6.6). It is very unlikely that pigs, receiving much lower amounts of glyphosate by ingestion of residues in the diet, should be that much more sensitive and, if so, it is hardly conceivable that such effects would not have become apparent before and also in other countries and on other farms.

-Many different malformations were reported. However, most chemical teratogens produce a specific teratogenic effect or a certain pattern of findings. Moreover, teratogenic effects usually follow a dose response. In this case, the glyphosate concentrations in the organs and tissues were so variable that such a dose response may be excluded.

-Malformations in piglets are quiet frequent and have often a genetic background. Infectious diseases may also play a role. There is no indication in the paper that a differential diagnosis has been considered.

B.6.5.1 Further published data (released since 2000)

Introduction by RMS:

A large number of studies on toxicity of glyphosate and its formulations was published since 2000. Most of these studies are presented in the chapters on genotoxicity, carcinogenicity, reproductive toxicity and neurotoxicity of this report because they are discussed there in context with these endpoints. However, some additional studies are presented below that could not be allocated to these endpoints.

Additionally to the reviews reported above in the chapters on different end points of this RAR some further toxicological reviews on glyphosate have been published since 2000. The content of these reviews is a

broad range of possible effects which are attributed by the authors to glyphosate, glyphosate formulations or generally to pesticides. However, some reviewers summarised effects described in the original studies without to differentiate between clearly evidenced effects and questionable or highly doubtful effects. The quality of the reviewed literature is in many cases not sufficiently discussed. On this basis some autors come to conclusions which deviate from conclusions of the rapporteur of this RAR.

Samsel and Seneff, 2013 (ASB2013-8535) reviewed toxicological literature on glyphosate and concluded that glyphosate inhibits cytochrome P450 enzymes. The authors believe that this activity would result in nearly all diseases as inflammatory diseases, obesity, depression, ADHD, autism, Alzheimer`s disease, Parkinson`s disease, ALS, multiple sclerosis, cancer, cachxia, infertility, developmental diseases, gastrointestinal disorders, heart disease, diabetes. Antoniou *et al.* (2011, ASB2011-7202) reviewed toxicological literature on Roundup and glyphosate. The authors conclude that Roundup and glyphosate would cause endocrine disruption, damage to DNA, reproductive developmental toxicity, neurotoxicity and cancer as well as birth defects. Many of these effects would be found at very low doses, comparable to levels of pesticide residues found in food and the environment. Mostafalou and Abdollahi (2013, ASB2014-9618) published a review on the relation between pesticides and elevated ranges of a broad range of different diseases. According to the authors pesticides cause diseases as different types of cancers, diabetes, neurodegenerative disorders like Parkinson, Alzheimer and amyotrophic lateral sclerosis, birth defects, and reproductive disorders, resipiratory problems, cardiovascular diseases, chronic nephropaties, autoimmune diseases, chronicfatique syndrome and aging.

Mesnage and Seralini (2014, ASB2014-9616) submitted a review on pesticide toxicity and genetically modified organisms (GMOs) which are used in agriculture. The authors propose to pay more attention on the mixtures of pesticides with further substances and to test relevant combinations of pesticides at levels which occur in genetically modified plants. NABU (2011, ASB2012-8016) reviewed some ecological and toxicological literature on glyphosate and formulations. The active substance, metabolites and further substances in the formulations are considered toxic especially for aquatic organisms. They would disturb human cells and the development of vertebrates. In result of resistance of wild plants the amount of glyphosate products is expected to grow in the future. PANAP (2009, ASB2012-8017) reviewed literature on toxicity, environmental effects and environmental fate of glyphosate. The authors conclude that independent scientific studies and poisonings in Latin America are beginning to reveal that use of glyphosate would not be safe.

Antoniou *et al.* (2010, ASB2012-803) reviewed toxicological and ecological literature on glyphosate and genetically modified Soya. The authors conclude that the toxic activity of glyphosate is increased by the combination with further substances in the formulations. Toxicity was already observed at concentrations which occur in agriculture and environment. The authors conclude that there would be a relation between glyphosate and increased malformations. Furthermore, epidemiologicas studies would demonstrate a relation between glyphosate use and carcinogenicity and genotoxicity.

Brändli and Reinacher (2012, ASB2012-804) submitted a short survey on use and health effects of glyphosate. The authors conclude that the use of glyphosate for siccation would be a scandal and would be considered to be bodily injury by negligence.

Greenpeace (2013, ASB2012-810) reviewed literature on ecological and health effects of glyphosate. The authors conclude that the submitted evidence in this report demonstrates that glyphosate-based products can have advers impacts on human and animal health, and that a review of their safety for human and animal health is urgently needed. The authors demand that no genetically modified glyphosate-tolerant crops should be authorised. They would be linked to unsustainable farming practices that damage the basic natural resources food production is based upon, and their cultivation should be banned.

Altenburger *et al.* (2012, ASB2014-9176) submitted a review that provides an overview on experimental studies from the past decade that address diagnostic and/or mechanistic questions regarding the combined effects of chemical mixtures using toxicogenomic techniques. By joining established mixture effect models with toxicokinetic and –dynamic thinking the authors suggest a conceptual framework that may help to overcome the current limitation of providing mainly anecdotal evidence on mixture effects.

Furthermore, some studies have been published in which the authors investigate the activity of glyphosate

and/or glyphosate formulations on selected biochemical or morphological structures. However, based on the provided information the impact of these results for the in vivo situation of the whole organism of animals or humans with autoregulation and feedback mechanisms is questionable. The dose dependency of the described effects and their importance for real life situations is often not sufficiently discussed by the authors. Many authors conclude that further studies would be necessary.
In some cases the authors compare the toxicity of glyphosate with the toxicity of glyphosate formulations or of surfactants. A frequent result in these cases is a higher toxicity of the formulations or the surfactants. In some further cases only glyphosate formulations have been used in the studies. Some authors use these results for a conclusion concerning the toxicity of the active substance glyphosate but do not consider the activity of surfactants or further substances in the formulation.

Chaufan *et al.*, 2014 (ASB2014-7616) examined the effects of glyphosate, AMPA and the formulation Roundup Ultra Max on oxidative balance and cellular endpoints in HepG2 cells. Only the formulation Roundup Ultra Max had toxic effects while no effects were found with glyphosate and AMPA. The formulation produced an increase in reactive oxygen species, nitrotyrosine formulation, superoxide dismutase activity and glutathione levels.
In an in in vivo study (Larsen *et al.*, 2012, ASB2014-6905) Wistar rats were exposed during 30 or 90 days to low levels of 0.7 and 7 mg/L glyphosate in drinking water. Only 4 animals per dose and sex were used. Levels of glutathione and glutathione peroxidase have been increased which was considered as a protective mechanism by the authors. George *et al.*, 2013 (ASB2014-8034) studied the effects of glyphosate on HaCaT cell proliferation. The authors concluded that glyphosate promotes proliferation in HaCaT cells probably by disrupting the balance between Ca^{2+}-levels and oxidative stress. However, in the study the commercial formulation Roundup was used. Therefore, the results can not be attributed to the substance glyphosate only. Hedberg et Wallin, 2010 (ASB2014-7494) studied the effects of glyphosate, Roundup and further substances on intracellular transport in Xenopus laevis. The chemicals inhibited retrograde transport of melanosomes in the range of 0.5 – 5 mM. Cellular morphology and localization of microtubules and actin filamentes were affected. The effects are pH-dependent. El-Shenawy, 2009 (ASB2012-11611) compared the cytotoxicity of Roundup and the active substance glyphosate. Male rats were i. p. treated with Roundup or glyphosate. The results characterize Roundup as a stronger antioxidant than the active substance glyphosate itself. Caglar and Kolankaya, 2008 (ASB2012-11580) treated rats with formulation Roundup orally during 5 and 13 weeks and studied hepatotoxicity. The authors concluded that high doses of Roundup can be a potential riks for human health. Modesto and Martinez (2010, ASB2012-811) studied effects of Roundup Transorb on fish. They observed haematologic alterations and effects on antioxidant defenses and on acetylcholinesterase activity.
Zhao *et al.* (2013, ASB2014-9645) investigated the effect of different doses of glyphosate on apoptosis and expression of androgen-binding protein and vimentin mRNA in mouse Sertoli cells. The authors conclude that glyphosate can cause cellular damages, inhibit cell proliferation, induce cell apoptosis, and decrease expression of ABP and vimentin mRNAs in mouse Sertoli cells in vitro. Xia *et al.* (2013, ASB2014-9642) studied the induction of vitellogenin gene expression in the fish medaka exposed to glyphosate and potential molecular mechanism. While glyphosate markedly up-regulated VTG transcription levels in both female and male fish, the upward trend was inhibited at the high glyphosate concentrations. Wunnapak *et al.* (2014, ASB2014-9638) used Roundup to induce nephrotoxicity in rats. A panel of kidney injury biomarkers was evaluated in terms of suitability to detect acute kidney injury and dysfunction. Martini *et al.* (2012, ASB2014-9613) used 3Z3-L1 fibroblasts to investigate the effect of a commercial formulation of glyphosate on proliferation, survival and differentiation. According to the results, a glyphosate-based herbicide inhibits proliferation and differentiation in this mammalian cell line and induces apoptosis suggesting GF-mediated cellular damage.

Larsen *et al.* (2014, ASB2014-9606) evaluated the activities of different xenobiotic- metabolizing enzymes in liver subcellular fractions from Wistar rats exposed to a glyphosate based herbicide. The results demonstrated certain biochemical modifications after exposure to a GLP-based herbicide. The authors conclude that the pharmacotoxicological significance of these findings remains to be clarified. Belle *et al.* (2012, ASB2014-9251) write in a letter to the editor that Williams *et al.* (2012, ASB2012-12052) analyzed five of their articles. Williams *et al.* (2012, ASB2012-12052) would minimize

the experimental evidence that glyphosate plays a role in toxicity and would discredit their findings.The article of Williams *et al.* (2012, ASB2012-12052) would contain several errors. Williams *et al.* (2012, ASB2012-12052) have not evidenced that the experiments of Belle *et al.* have been incorrect or biased.

Kim *et al.* (2013, ASB2014-9591) investigated the mechanism of the additive effect of glyphosate and TN-20, a common surfactant in glyphosate herbicides. The results support the possibility that mixtures of glyphosate and TN-20 aggrevate mitochondrial damage and induce apoptosis and necrosis. Throughout this process, TN-20 seems to disrupt the integrity of the cellular barrier to glyphosate uptake, promoting glyphosate-mediated toxicity.

Kilinc *et al.* (2013, ASB2014-9588) studied the influence of pesticide exposure on carbonic anhydrase II from sheep stomach. The authors conclude that both glyphosate isopropylamine and dichlorvos inhibited CA-II isoenzym in a noncompetetive manner.

Jasper *et al.* (2012, ASB2014-9583) evaluated the toxicity of hepatic, haematological, and oxidative effects of glyphosate Roundup on male and female albino Swiss mice. The results of this study indicate that glyphosate-Roundup can promote haematological and hepatic alterations, even at subacute exposure, which could be related to the induction of reactive oxygen species.

Chaufan *et al.* (2014, ASB2014-9314) studied the effects on oxidative formulation in HepG2 cells. The authors conclude that the results confirm that G formulations have adjuvants working together with the active ingredient and causing tolxic effects that are not seen with acid glyphosate.

Gencer *et al.* (2012, ASB2014-9481) studied in vitro effects of Imazethapyr, 2,4-D, glyphosate and propanocarb on human erythrocyte carbonic anhydrase activity. Imazethapyr was the most effective inhibitor for CA-H isoencyme. The lowest inhibition was caused by glyphosate.

Campo *et al.* (2009, ASB2014-9281) evaluated the toxicity of ten pesticides used in the municipality of Popayan., Colombia, using bioassay with Bacillus subtilis. Glyphosate was slightly toxic in this test.

Kwiatkowska *et al.* (2014, ASB2014-9603) published a study that was undertaken to evaluate toxic potential of glyphosate, ist metabolites AMPA, methylphosphonic acid and its impurities N-(phosphonomethyl)iminodiacetic acid (PMIDA), N-methylglyphosate, hydroxymethylphosphonic acid and bis-(phosphonomethyl)amine. The authors evaluated the effect of those compounds on haemolysis, haemoglobin oxidation, reactive oxygen species (ROS) formation and changes in morphology of human eythrocytes. Glyphosate, its metabolites and impurities induced a little haemolysis and haemoglobin oxidation. All changes were very low, even after 24 h incubation. Most of the investigated compounds induced reactive oxygen species formation from 0.25 mM, except the N-methylglyphosate wich caused an increase in ROS formation from 0.5 mM. Moreover, the investigated xenobiotics did no change the size and shape (except bis-(phosphonomethyl)amine) of the human erythrocytes. Changes in human erythrocytes were observed only when high concentrations of the compounds were applied. Some investigated metabolites and impurities caused a slight stronger damage to human erythrocytes than glyphosate.

Mesnage *et al.* (2013, ASB2014-1755) studied the toxicity on human cells in vitro for glyphosate-based formulations and also for polyethoxylated tallowamine POE-15, glyphosate alone and a formulation without glyphosate. Hepatic (HEPG2), embryonic (HEK293) and placental (JEG3) cells were exposed 24 h. POE-15 was the most toxic of the tested substances and combinations. The authors conclude that pesticide formulations should be studied as mixtures for toxic effect with mammals over a 2-year period. They question the use of ethoxylated substances in herbicide formulations, since they appear as active principle for human sell toxicity. The results would challenge guidance values as the ADI because they are only derived from results of studies with the active substance.

Mesnage *et al.* (2012, ASB2012-13917) tested the toxicity of 9 active pesticide substances including glyphosate, comparing with the toxicity of their formulations, including Roundup. The tests have been performed in vitro with 3 human cell lines. The authors conclude that Roundup was found in this experiments to be 125 times more toxic than glyphosate. These results would challenge the relevance of the ADI because this is only based on the toxicity ofthe active substance. Therefore, an additional adjuvant factor of at least 100 could be applied to the present calculation of the ADI. However, this calculation

would never replace the direct study of the commercial formulation with its adjuvants in regulatory tests. Coalova *et al.* (2014, ASB2014-7615) studied the influence of spray adjuvant on the toxicity effects of a glyphosate formulation in Hep-2-cell line. They determined the median lethal concentration of Atanor (glyphosate formulation), Impacto (spray adjuvant) and a mixture of both agrochemicals. The substances and mixtures induced dose- and time-dependent cytotoxicity. The toxicity of a mixture of Atanor and Impacto was additive in Hep2-cells. The authors conclude that the addition of adjuvant to glyphosate formulation would increase the toxicity of the mixture in cell culture. Kwiatkowska *et al.* (2014, ASB2014-8085) investigated the effect of glyphosate, its metabolites and impurities on acetylcholinesterase (AchE) activity (in vitro) in human erythrocytes. The authors conclude that the compounds studied (used in concentrations that are usually determined in the environment) do not disturb function of human erythrocyte acetylcholinesterase.

Hoare (2014, ASB2014-9157) submitted a QSAR assessment on the toxicological properties of glyphosate and its impurities. To assess the toxicological properties of glyphosate and five impurities (AMPA, IBMPA, MAMPA, NMG and IDA) present in the technical grade of material, the QSAR models ACD labs, DEREK NEXUS, TOXTREE, EPA T.E.S.T. VEGA and OECD Toolbox were employed. None of the structures analysed triggered any alerts on DEREK NEXUS for carcinogenicity, chromosome damage, genotoxicity or mutagenicity. Eye and skin irritation were not anticipated in any of the QSAR models evaluated. No alert for skin sensitisation was triggered in DEREK NEXUS for any compound. Equivocal alerts for nephrotoxicity and plausible alerts for hepatotoxicity were triggered by DEREK NEXUS for glyphosate, NMG, MAMPA and AMPA.

A further study was published which describes cases of intoxication in dogs and cats:

Bates and Edwards (2013, ASB2014-9249) inform in a letter about cases of intoxication of dogs and cats by glyphosate in UK, registered by the Veterinary Poisons Information Service. Vomiting, diarrheoea and lethargy were the most common signs in dogs. Vomiting, anorexia and lethargy were the most common signs in cats.

Two further studies have been submitted which investigated ecotoxicological effects of glyphosate:

Relyea (2005, ASB2012-204) examined the impact of four globally common pesticides including glyphosate on the biodiversity of aquatic communities containing algae and animals. In a further study Relya (2012, ASB2012-2791) created wetland communities including water plants and animals and exposed thes communities to Roundup. The author reports different effects on nontarget species.

Further studies are presented in detail below:

Abstract*

Sea urchin embryo, DNA-damaged cell cycle checkpoint and the mechanisms initiating cancer development (translation from original article)

Cell division is an essential process for heredity, maintenance and evolution of the whole living kingdom. Sea urchin early development represents an excellent experimental model for the analysis of cell cycle

checkpoint mechanisms since embryonic cells contain a functional DNA-damage checkpoint and since the whole sea urchin genome is sequenced. The DNA- damaged checkpoint is responsible for an arrest in the cell cycle when DNA is damaged or incorrectly replicated, for activation of the DNA repair mechanism, and for commitment to cell death by apoptosis in the case of failure to repair. New insights in cancer biology lead to two fundamental concepts about the very first origin of cancerogenesis. Cancers result from dysfunction of DNA-damaged checkpoints and cancers appear as a result of normal stem cell (NCS) transformation into a cancer stem cell (CSC). The second aspect suggests a new definition of "cancer", since CSC can be detected well before any clinical evidence. Since early development starts from the zygote, which is a primary stem cell, sea urchin early development allows analysis of the early steps of the cancerization process. Although sea urchins do not develop cancers, the model is alternative and complementary to stem cells which are not easy to isolate, do not divide in a short time and do not divide synchronously. In the field of toxicology and incidence on human health, the sea urchin experimental model allows assessment of cancer risk from single or combined molecules long before any epidemiologic evidence is available. Sea urchin embryos were used to test the worldwide used pesticide Roundup that contains glyphosate as the active herbicide agent; it was shown to activate the DNA-damage checkpoint of the first cell cycle of development. The model therefore allows considerable increase in risk evaluation of new products in the field of cancer and offers a tool for the discovery of molecular markers for early diagnostic in cancer biology. Prevention and early diagnosis

Abstract*

To assess human health risk from environmental chemicals, we have studied the effect on cell cycle regulation of the widely used glyphosate-conaining pesicide Roundup. As a model system we have used sea urchin embryonic first divisions following fertilization, which are appropriate for the study of universal cell cycle regulation without interference with transcription. We show that 0.8% Roundup (containing 8 mM glyphosate) induces a delay in the kinetic of the first cell cleavage of sea urchin embryos. The delay

is dependent on the concentration of Roundup. The delay in the cell cycle could be induced using increasing glyphosate concentrations (1-10 mM) in the presence of a subthreshold concentration of Roundup 0.2%, while glyphosate alone was ineffective, thus indicating synergy between glyphosate and Roundup formulation products. The effect of Roundup was not lethal and involved a delay in entry into M-phase of the cell cycle, we analysed CDK1/cyclin B activation during the first division of early development. Roundup delayed the activation of CDK1/cyclin B *in vivo*. Roundup inhibited also the global protein synthetic rate without preventing the accumulation of cyclin B. In summary, Roundup affects cell cycle regulation by delaying activation of the CDK1/cyclin B complex, by synergic effect of glyphosate and formulation products. Considering the universality among species of the CDK1/cyclin B regulator, our results question the safety of glyphosate and Roundup on human health.

Abstract*

Cell cycle mechanisms are highly conserved from unicellular eukaryotes to complex metazoans including humans. Abnormalities in the regulation of the cell cycle result in death or diseases such as cancer. Early development of sea urchin has proved to be a powerful model for cell division studies and offers the opportunity to study synchronous cell divisions in the absence of transcriptional control. We have analyzed pesticide induced dysfunctions in the first cell division following fertilization in sea urchin embryos, using Roundup, a widely used pesticide formulation containing isopropylamine glyphosate as the active substance. The pesticide induced cell cycle dysfunction by preventing the *in vivo* activation of the universal cell cycle regulator CDK1/cyclin B. We further show that synthesis of the regulator protein, cyclin B, as well as its association to the catalytic protein, CDK1, were not affected by the pesticide. Therefore, our results suggest that the pollutant impedes the processing of the CDK1/cyclin B complex, which is required in its physiological activation. Our studies demonstrate the relevance of sea urchin embryonic cells as a sensitive model to assess pesticide toxicity at the level of the universal cell cycle checkpoints.

Marc, J. Mulner-Lorillon, O. Belle, R.	2004	Glyphosate-based pesticides affect cell cycle regulation Biology of the Cell Volume: 96, Pages: 245-249, ASB2009-9014

Abstract*
Cell-cycle dys-regulation is a hallmark of tumor cells and human cancers. Failure in the cell- cycle checkpoints leads to genomic instability and subsequent development of cancers from the initial affected cell. A worldwide used product Roundup 3plus, based on glyphosate as the active herbicide was suggested to be of human health concern since it induced cell cycle dysfunction as judged from analysis of the first cell division of sea urchin embryos, a recognized model for cell cycle studies. Several glyphosate-based pesticides from different manufacturers were assayed in comparison with Roundup 3plus for their ability to interfere with the cell cycle regulation. All the tested products, Amega, Cargly, Cosmic, and Roundup Biovert induced cell cycle dysfunction. The threshold concentration for induction of cell cycle dysfunction was evaluated for each product and suggests high risk by inhalation for people in the vicinity of the pesticide handling sprayed at 500 to 4000 times higher dose than the cell- cycle adverse concentration.

Marc, J. Belle, R. Morales, J. Cormier, P. Mulner-Lorillon, O.	2004	Formulated glyphosate activates the DNA-response checkpoint of the cell cycle leading to the prevention of G2/M transition. Toxicological Sciences, Volume: 82, Pages: 436-442 ASB2012-11894

Abstract*
A glyphosate containing pesticide impedes at 10 mM glyphosate the G2/M transition as judged from analysis of the first cell cycle of sea urchin development. We show that formulated glyphosate prevented dephosphorylation of Tyr 15 of the cell cycle regulator CDK1/cyclin B in vivo, the end point target of the G2/M cell cycle checkpoint. Formulated glyphosate had no direct effect on the dual specific cdc25 phosphatase activity responsible for Tyr 15 dephosphorylation. At a concentration that efficiently impeded the cell cycle, formulated glyphosate inhibited the synthesis of DNA occurring in S phase of the cell cycle. The extent of the inhibition of DNA synthesis by formulated glyphosate was correlated with the effect on the cell cycle. We conclude that formulated glyphosate's effect on the cell cycle is exerted at the level of the DNA-response checkpoint of S phase. The resulting inhibition of CDK1 cyclin B Tyr 15 dephosphorylation leads to prevention of the G2/M transition and cell cycle progression.

Heu, C., Berquand, A., Elie-Caille, C., Nicod, L.	2012	Glyphosate-induced stiffening of HaCat keratinocytes, a Peak Force Tapping study on living cells. Journal of Structural Biology Volume: 178, Number: 1, Pages: 1-7 ASB2012-11843

Abstract*
The skin is the first physiological barrier, with a complex constitution, that provides defensive functions against multiple physical and chemical aggressions. Glyphosate is an extensively used herbicide that has been shown to increase the risk of cancer. Moreover there is increasing evidence suggesting that the mechanical phenotype plays an important role in malignant transformation. Atomic force microscopy (AFM) has emerged within the last decade as a powerful tool for providing a nanometer-scale resolution imaging of biological samples. Peak Force Tapping (PFT) is a newly released AFM-based investigation technique allowing extraction of chemical and mechanical properties from a wide range of samples at a relatively high speed and a high resolution. The present work uses the PFT technology to investigate HaCaT keratinocytes, a human epidermal cell line, and offers an original approach to study chemically-induced changes in the cellular mechanical properties under near-physiological conditions. These experiments indicate glyphosate induces cell membrane stiffening, and the appearance of cytoskeleton structures at a subcellular level, for low cytotoxic concentrations whereas cells exposed to IC_{50} (inhibitory concentration 50%) treatment exhibit control-like mechanical behavior despite obvious membrane damages. Quercetin, a well-known antioxidant, reverses the glyphosate-induced mechanical phenotype.

Heu, C., Elie-Caille, C., Mougey, V., Launay, S., Nicod, L.	2012	A step further towards glyphosate-induced epidermal cell death: Involvement of mitochondrial and oxidative mechanisms. Environmental Toxicology and Pharmacology Volume: 34, Number: 2, Pages: 144-153 ASB2012-11844

Abstract*
A deregulation of programmed cell death mechanisms in human epidermis leads to skin pathologies. We previously showed that glyphosate, an extensively used herbicide, provoked cytotoxic effects on cultured human keratinocytes, affecting their antioxidant capacities and impairing morphological and functional cell characteristics. The aim of the present study, carried out on the human epidermal cell line HaCaT, was to examine the part of apoptosis plays in the cytotoxic effects of glyphosate and the intracellular mechanisms involved in the apoptotic events. We have conducted different incubation periods to reveal the specific events in glyphosate-induced cell death. We observed an increase in the number of early apoptotic cells at a low cytotoxicity level (15%), and then, a decrease, in favour of late apoptotic and necrotic cell rates for more severe cytotoxicity conditions. At the same time, we showed that the glyphosate-induced mitochondrial membrane potential disruption could be a cause of apoptosis in keratinocyte cultures.

Klimisch evaluation

Reliability of study: Not reliable

Comment: Non-guideline *in vitro* tests with no control for low pH effects. Minor reporting deficiencies (source and purity of glyphosate, replicates per dose level)

Relevance of study: Not relevant (*in vitro* data on the effects on an immortalized epidermal cell-line does consider low exposure potential due to *stratum cornea* protection. Inappropriate test substance if not adjusted for pH; low pH glyphosate acid is not contained in formulated glyphosate based products)

Klimisch code: 3

Additional comments:
Glyphosate technical acid evaluated was not reported to be pH adjusted and therefore does not reflect real world exposures to the more neutral pH formulations, which contain glyphosate salts, not glyphosate acid. The pH range of test concentrations (850 - 1150 mg/L) is very acidic, approximately 1.7-2.2 pH units. Keeping in mind the pH scale is logarithmic, these values are substantially lower than those of viable skin and *in vitro* cell cultures.

Exposure potential to live human epidermal skin cells in the field is likely to be considerably lower than the authors have considered. The epidermis is protected by the *stratum cornea*. Human *in vitro* dermal absorption studies for a range glyphosate formulated products are presented in the chapter on dermal absorption, showing a very low dermal absorption of glyphosate; nearly all of the glyphosate is washed off the skin surface after 24 hour exposures (88% to >99% before *stratum cornea* removal). Therefore, the studies of Heu *et al.*, while representative of glyphosate spray concentrations, are approximately two or more orders of magnitude higher of those which may result for 8-24 hour dermal exposures.

Axelrad, J.C. Howard, C.V. McLean, W.G.	2003	The effects of acute pesticide exposure on neuroblastoma cells chronically exposed to diazinon Toxicology, Volume: 185, Pages: 67-78 ASB2012-11553

Abstract*
Speculation about potential neurotoxicity due to chronic exposure to low doses of organophosphate (OP) pesticides is not yet supported by experimental evidence. The objective of this work was to use a cell culture model of chronic OP exposure to determine if such exposure can alter the sensitivity of nerve cells to subsequent acute exposure to OPs or other compounds. NB2a neuroblastoma cells were grown in the presence of 25 µM diazinon for 8 weeks. The OP was then withdrawn and the cells were induced to differentiate in the presence of various other pesticides or herbicides, including OPs and OP-containing formulations. The resulting outgrowth of neurite-like structures was measured by light microscopy and quantitative image analysis and the IC_{50} for each OP or formulation was calculated. The IC_{50} values in diazinon-pre-exposed cells were compared with the equivalent values in cells not pre-exposed to diazinon. The IC50 for inhibition of neurite outgrowth by acute application of diazinon, pyrethrum, glyphosate or a commercial formulation of glyphosate was decreased by between 20 and 90% after pre-treatment with diazinon. In contrast, the IC_{50} for pirimiphos methyl was unaffected and those for phosmet or chlorpyrifos were increased by between 1.5- and 3-fold. Treatment of cells with chlorpyrifos or with a second glyphosate-containing formulation led to the formation of abnormal neurite-like structures in diazinon-pre-exposed cells. The data support the view that chronic exposure to an OP may reduce the threshold for toxicity of some, but by no means all, environmental agents.

Benedetti, A. L. Vituri, C.D. Trentin, A.G. Domingues, M.A.C. Alvarez-Silva, M.	2004	The effects of sub-chronic exposure of Wistar rats to the herbicide Glyphosate-Biocarb® Toxicology Letters, Volume: 153, Pages: 227-232 ASB2012-11562

Abstract*
The object of this study was to analyze the hepatic effects of the herbicide Glyphosate-Biocarbo (as commercialized in Brazil) in Wistar rats. Animals were treated orally with water or 4.87, 48.7, or 487 mg/kg of glyphosate each 2 days, during 75 days. Sub-chronic treatment of animals starting from the lowest dose of glyphosate induced the leakage of hepatic intracellular enzymes, alanine aminotransferase (ALT) and aspartate aminotransferase (AST), suggesting irreversible damage in hepatocytes. We observed the increase of Kupffer cells in hepatic sinusoid of glyphosate-treated animals. This was followed by large deposition of reticulin fibers, composed mainly of collagen type III. We may conclude that Glyphosate-Biocarbo may induce hepatic histological changes as well as AST and ALT leaking from liver to serum in experimental models.

Mesnage, R. Clair, E. Gress, S. Then, C. Szekacs, A. Seralini, G.E.	2012	Cytotoxicity on human cells of Cry1Ab and Cry 1Ac *Bt* insecticidal toxins alone or with a glyphosate-based herbicide. Journal of Applied Toxicology doi: 10.1002/jat.2712. [Epub ahead of print] ASB2012-11900

Abstract*
The study of combined effects of pesticides represents a challenge for toxicology. In the case of the new growing generation of genetically modified (GM) plants with stacked traits, glyphosate-based herbicides (like Roundup) residues are present in the Roundup-tolerant edible plants (especially corns) and mixed with modified *Bt* insecticidal toxins that are produced by the GM plants themselves. The potential side effects of these combined pesticides on human cells are investigated in this work. Here we have tested for the very first time Cry1Ab and Cry1Ac *Bt* toxins (10 ppb to 100 ppm) on the human embryonic kidney cell line 293, as well as their combined actions with Roundup, within 24 h, on three biomarkers of cell death: measurements of mitochondrial succinate dehydrogenase, adenylate kinase release by membrane alterations and caspase 3/7 inductions. Cry1Ab caused cell death from 100 ppm. For Cry1Ac, under such conditions, no effects were detected. The Roundup tested alone from 1 to 20 000ppm is necrotic and apoptotic from 50 ppm, far below agricultural dilutions (50% lethal concentration 57.5 ppm). The only measured significant combined effect was that Cry1Ab and Cry1Ac reduced caspases 3/7 activations induced by Roundup; this could delay the activation of apoptosis. There was the same tendency for the other markers. In these results, we argue that modified *Bt* toxins are not inert on non-target human cells,

and that they can present combined side-effects with other residues of pesticides specific to GM plants.

Relevance of study:	Relevant with restrictions (Due to reliability. The assessed combinatory effects are of limited relevance)
Klimisch code:	3

Additional comments:

Direct exposure to cells in culture bypasses normal processes limiting absorption and cellular exposure and avoids normal metabolism, excretion, serum protein binding, and other factors that would protect cells in the intact organism. Anadon *et al.* (2009, ASB2012-11542) dosed rates with 400 mg/kg of glyphosate, a massive dose relative to any environmental exposure, and achieved peak modeled plasma concentrations of glyphosate of approximately 5 µg/mL (5 mg/L or 5 ppm). Assuming linear kinetics, the maximum allowable US daily intake (2 mg/kg/day) would give an approximated blood concentration of 0.025 ppm (25 ppb). McQueen *et al.* (2012, ASB2012-11898) recently evaluated glyphosate exposure to pregnant women and concluded that estimated exposures based on actual measurements in food were only 0.4% of the acceptable daily intake.

The "Roundup" LC_{50} concentration used (57.5 ppm) is more than 2000-fold higher than the anticipated concentration (based on Anadon *et al.*, 2009, ASB2012-11542) following maximum allowable intake.

The co-application of Cry protein with the glyphosate-surfactant reduces the apparent degree of cellular injury (as measured by induction of caspase levels). This occurs even at concentrations of Cry1Ab which the authors report to cause cellular injury and membrane disruption. This is worth noting for several reasons:

First, it brings into question the toxicity observations with Cry1Ab, as the argument that membrane disruption and impaired mitochondrial function should be protective seems to be highly untenable, especially in view of the studies (Levine et al, 2007, ASB2009-9030) demonstrating the mitochondrial membrane activity of surfactants.

Second, it should take off the table any implications of a "synergistic effect" of Cry proteins and glyphosate-surfactant herbicides. (The direction is, if anything, antagonistic, but the entire system is fundamentally irrelevant.)

Third, this probably is demonstrating the artificiality of the system itself. As noted above, this is a protein-free medium. Protein protects cells in culture by multiple mechanisms- binding to toxic materials, binding to potential receptor sites, or other non-specific surface-stabilisation effects. It appears from Mesnage's own data that simple addition of protein to their system, even at low concentrations (and even if that protein is a Cry protein) protects from toxicity.

Clair E., Linn, L., Travert, C., Amiel, C., Seralini, G.E	2012	Effects of Roundup® and Glyphosate on Three Food Microorganisms: *Geotrichum candidum*, *Lactococcus lactis* subsp. *cremoris* and *Lactobacillus delbrueckii* subsp. *bulgaricus* Current Microbiology, Volume: 64, Number: 5, Pages: 486-491 ASB2012-11592

Abstract*
Use of many pesticide products poses the problem of their effects on environment and health. Amongst them, the effects of glyphosate with its adjuvants and its by-products are regularly discussed. The aim of the present study was to shed light on the real impact on biodiversity and ecosystems of Roundup®, a major herbicide used worldwide, and the glyphosate it contains, by the study of their effects on growth and viability of microbial models, namely, on three food microorganisms (*Geotrichum candidum*, *Lactococcus lactis* subsp. *Cremoris delbrueckii* subsp. *bulgaricus*) widely used as starters in traditional and industrial dairy technologies. The presented results evidence that Roundup® has an inhibitory effect on microbial growth and a microbicide effect at lower concentrations than those recommended in agriculture. Interestingly, glyphosate at these levels has no significant effect on the three studied microorganisms. Our work is consistent with previous studies which demonstrated that the toxic effect of glyphosate was amplified by its formulation adjuvants on different human cells and other eukaryotic models. Moreover, these results should be considered in the understanding of the loss of microbiodiversity and microbial concentration observed in raw milk for many years.

Klimisch evaluation

Reliability of study:	Not reliable
Comment:	Non-validated, non-guideline test with methodological and reporting deficiencies (e.g. dose concentrations in media not specified, no positive controls or controls that show the validity of the test system /and concentration range tested). Inappropriate test system for formulations containing surfactant; cytoxic membrane disruption potential of surfactants are well known for in vitro test systems.
Relevance of study:	Not relevant (Due to reliability)
Klimisch code:	3

Additional Comments
Glyphosate at 1% had no effect on lactobacilli but did impair *Geotrichum*, which is unsurprising as glyphosate at herbicidal concentrations will impact metabolism of many fungi, which (like plants) use the shikimate pathway for aromatic amino acid production.
Surfactants are known to be bacteriostatic, with (for example) quaternary ammonium compounds typically being active in the 30-150 ppm range.

Clair *et al.* demonstrate that surfactants are bacteriostatic for 3 microorganisms at concentration ranges well within the range of concentrations generally found to be useful for sanitation purposes. However, surfactant solutions are routinely used to sanitize food processing equipment at concentrations at or above those tested by Clair *et al.* (2012, ASB2012-11592).

B.6.5 Medical data and information (Annex IIA 5.9)
B.6.5.1 Toxicity of the metabolite AMPA
B.6.5.2 Reports on clinical cases and poisoning incidents

Glyphosate is worldwide used extensively as herbicide. According to this extensive use a large number of poisoning incidents happened and was published. An extensive review of clinical cases was submitted by Bradberry *et al.*, 2004, ASB2012-11576. Another review of cases was published by Lee *et al.*, 2008, ASB2012-11879.

Burger *et al.* (2009, ASB2013-11831) briefly mentioned a total of 60 reports by physicians from Germany on cases of poisoning with glyphosate herbicides since 1990. Without further specification, in the vast majority of 52 cases only slight health impairment was reported. In four cases, health disturbances were considered "moderate" whereas the only one actually life- threatening case was the result of ingestion of 200 mL of a herbicide containing glyphosate and a tallowamine surfactant with suicidal intent. In the three remaining cases, no symptoms were reported or their severity could not be evaluated.

More than 650 cases of intoxication/irritation ascribed to ingestion of contact to glyphosate- based herbicides are mentioned in an overview on poisoning incidents from Brazil that was just recently kindly provided to the RMS by the Brazilian National Health Surveillance Agency (Paumgartten/ANVISA, 2012, ASB2013-13413). This data was collected by up to 10 Brazilian poison centers between 2010 and 2012. It is not clear if it is representative for the whole huge country in which the agricultural conditions in general and also those of pesticide use are extremely different. In addition, there is even a higher number of poison information centers in Brazil that have not provided data and, thus, the number of incidents might underestimate the real incidence. On the first glance, the exposure routes, ingested amounts, circumstances (accident, suicidal attempt?), clinical signs and medical treatment are similar to what is known from Germany and from the literature. The much higher total number of cases (as compared to Germany) seems to reflect the applied amount of glyphosate and its formulations that is by orders of magnitude higher in Brazil. Unfortunately, severity of symptoms is not graded and vey often the final outcome was not reported. Another problem is that the product to which exposure was claimed is not specified. Frequently, "Roundup" is mentioned but different formulations are marketed under this name. In many other cases, the incident is ascribed to"glyphosate". However, this is not credible because there is no simple access to the active ingredient and a certain product must have been applied. Furthermore, it is not clear whether a causal relationship had been actually confirmed. Thus, this potentially most interesting data require further thorough analysis before it may be used for evaluation of health risks.

Jayasumana *et al.* (2014, ASB2014-3085) published a hypothesis on an association between glyphosate exposition, hard water and nephrotoxic metals in an epidemic of chronic kidney disease in Sri Lanka. The authors conclude that although glyphostate alone does not cause an epidemic of chronic kidney disease, it seems to have acquired the ability to destroy the renal tissues when forms complexes with localized geo environmental factor (hardness) and nephrotoxic metals. This conclusion is mainly based on a metal chelating property of glyphosate and the extensive use of glyphosate in Sri Lanka, and the occurance of hard water in the concerned areas. However, the hypothesis was not experimentally evidenced up to now. Sirinathsinghji (2014, ASB2014-10742) report that Sri Lanka is set to partially ban glyphosate-based herbicide use following a study linking it to a fatal chronic kidney disease epidemic affecting the country. This decision is also based on the above described publication of Jayasumana *et al.* (2014, ASB2014-3085).

Zouaoui *et al.* (2012, ASB2014-9734) reported 13 cases of acute intoxication with glyphosate (mostly suicidal). The most common symptoms were oropharyngeal ulceration, nausea and vomiting. The main altered biological parameters were high lactate and acidosis. We also noted respiratory distress, cardiac arrhythmia, hypercaleamia, impaired renal function, hepatic toxicity and altered consciousness. In fatalities, the common symptoms were cardiovascular shock, cardiorespiratory arrest, haemodynamic disturbance, intravascular disseminated coagulation and multiple organ failure. Concentrations of glyphosate and AMPA have been determined in blood and urine.

Sribanditmongkol *et al.* (2012, ASB2014-9731) report a case of a woman who died after ingestion of approximately 500 ml Roundup formulation. Toxic effects of the pesticide were caused by the abilitiy to erode tissues including mucous membranes and linings of the gastrointestinal and respiratory tracts.

A mild degree of pulmonary congestion and edema was observed in both lungs.
Mariager *et al.* (2013, ASB2014-9612) report the case of a 43-year-old man with a history of alcohol abuse. He had used a concentrated glyphosate herbicide and accidentally sprayed the liquid on himself. The patient developed local swelling, bullae and exuding wounds. Neurological impairment followed affecting finger flexion and sensation with reduced nerve conduction. Imaging revealed oedema of the soft tissue and juxta-articular osteopenia

Lee *et al.* (2012, ASB2014-9607) report the case of a 60-year orld patient who intentionally ingested 450 ml Roundup. He experienced cardiac arrest but was successfully resuscitated and treated with continuous venovenous haemodiafiltration.

Knezevic *et al.* (2012, ASB2014-9593) report the case of a 36 year old male patient who attemted suicide by drinking approximately 300 mL of glyphosate formulation. The patient became hypotensive, hypoxic with oliguric acute renal failure. After a single 27.5 hour treatment, clinical condition and renal function parameters did not require further dialysis.

Hour at al. (2012, ASB2014-9571) describe the case of a 66 year old man with a history of alcohol abuse who ingested 500 ml of rum and 350 ml of Roundup. He was hypotensive, diaphoretic and hypoxic. After veno-venous hemodiafiltration his condition improved within 24 hours.

Hinojosa *et al.* (2011, ASB2014-9566) submitted a retrospective study to identify substances involved in poisonings at Lariboisiere hospital. 315 patients were included with 891 announced substances. Only 1 case of glyphosate was identified.

Garlich *et al.* (2014, ASB2014-9480) report the case of a 62-year old man who drank a bottle of 41% glyphosae formulation. He was bradycardic and obtunded with respiratory depression. The patient underwent haemodialysis 16 h post ingestion after which he demonstrated improvement in clinical status.

A case of an inhalative intoxication by glyphosate is reported by BfR (2007, ASB2014-9290). A 59 years old farmer sprayed a glyphosate formulation without protective equipment over approximately 3 hours. He suffered from laboured breathing, cough and fever. A biopsy showed alveolitis and bronchiolitis.

Beswick and Millo (2011, ASB2014-9283) describe a fatal poisoning with a glyphosate surfactant herbicide. A 29-year old man was admitted following deliberate ingestion of approximatly 300 ml of Roundup Ace. He developed severe and persistent lactic acidosis, hyperkalaemia, hypotension, torrential watery diarrhoea and abdominal distension in the first 24 hours. The clinical course was complicated by cardiac arrhythmia and an episode of cardiac arrest. On day three following poisoning, the patient died.
Malhotra *et al.* (2010, ASB2012-11890) report a case of a 71-year old male who attempted suicide with a glyphosate formulation and developed a prolonged but reversible encephalopathy suggestive of acute CNS toxicity. He was in cardiogenic shock with severe metabolic acidosis. Neurologic investigations were performed to exclude structural pathology. CT brain scan was normal. An EEG reading on day 8 demonstrated generalised slow wave acitivity with triphasic sharp and slow wave complex consistent with an encephalopathy although non convulsive seizures could not be excluded.

B.6.5.1 Publications on dermal absorption of glyphosate

Wester *et al.* (2005, ASB2012-12050) compared dermal absorption through human skin *in vitro* after exposure either to a 1% solution (not further specified) or to cotton sheets that were treated with the same solution on the same day or up to 2 days before to reflect the abundance of glyphosate residues infabric that may occur due to applications of this active ingredient in cotton. The authors could show a lower absorption of glyphosate across the skin from the treated cotton as compared to the liquid solution itself but found also remarkable residues on and in the skin when the cotton sheets had been treated on

the same day. Adding of water to the cotton sheets resulted in an increase in absorption rate.
