Short description of results:	There were no deaths during the study and no signs of toxicity were observed. Laboratory investigations and pathological examinations did not reveal indications of adverse effects. According to the study scientists, alanine aminotransferase was increased in high dose animals, however, the respective mean values were exceptionally high at pretest already. The only findings that could be attributed to treatment were a reduction in body weight gain and, during the second part of the study, a decrease in food consumption. These effects were noted in both sexes but were confined to the highest dose level. Thus, the mid dose of 250 mg/kg bw/day was considered the NOEL in this study.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	Monograph (2000): The study was considered supportive only due to reporting deficiencies. For examples, the year when the study was performed was not indicated in the original report, test substance purity not reported, statistical analysis of the results was not reported. RAR (2015): The study was considered invalid due to serious reporting deficiencies, e.g., absence of information on batch and purity of the test material. Therefore and since the study report is not available, this study is not considered to be reliable.
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL.
Category study in AIR 5 dossier (L docs)	Category 4b

1. Information on the study

Data point	CA 5.3.2/029
Report author	[redacted]
Report year	1983
Report title	Six Month Study of Mon 0139 by Gelatin Capsule to Beagle Dogs
Report No	810166
Document No	Not reported
Guidelines followed in study	No guideline statement, but in general accordance with OECD 409 (1981)
Deviations from current test guideline (OECD 409, 1998; OECD 452, 2018)	Blood chloride and urine volume were not measured, unclear if a middle section of the spinal cord was observed microscopically. Deviations from the current version of OECD 409 (1998) are basically due to the fact that the study was aligned to an older version of the OECD test guideline 409.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

MON-0139 (aqueous solution of the isopropylamine salt of glyphosate) was administered orally by gelatin capsule to groups of six male and six female Beagle dogs at daily doses of 0, 10, 60 or 300 mg/kg bw/day for approximately six months.

Clinical observations were done twice daily. Weekly determinations of individual body weight and daily food consumption were performed. Ophthalmologic examinations were performed at pretest and prior to final necropsy on all animals. Haematological and blood biochemistry parameters were evaluated prior to start of treatment and monthly during treatment. Urinalysis was performed pre-test and during months 2, 4 and 6 of treatment. At the end of the scheduled dosing period, the animals were sacrificed and subjected to a full examination post mortem. Selected organs were weighed and specified tissues were taken for subsequent histopathology examination.

There were no mortalities in any of the dose groups. No unusual changes occurred in body weight, food consumption or clinical signs as a result of MON-0139 exposure. The only change which potentially related to MON-0139 administration was an elevation of serum alkaline phosphatase levels in males and females at all sampling intervals. There was no indication of the source of the increased levels of this enzyme as no microscopic evidence of lesions in the organs usually responsible for elevations in serum alkaline phosphatase levels were found. This, together with the generally small magnitude of these elevations and the lack of dose response in females makes the interpretation of this change equivocal as regards biological significance and correlation with MON-0139 administration. Changes in total LDH and LDH isoenzymes were identified but the occurrences were erratic. Total LDH levels were depressed in males especially from higher dosage levels at 4, 5 and 6 months of treatment primarily from decreases in LDH 5. Other changes in LDH isoenzymes included mild elevations of LDH 2 and LDH 3 in males and decreases of these isoenzymes in females. This lack of consistency in the direction of change between males and females and a lack of consistent response from one sampling period to another, along with the lack of correlation of

these changes with microscopic lesions or other serum chemistry changes, suggested an unlikely relationship to MON-0139 exposure. Other changes in serum chemical and changes in haematological and urinalysis parameters were isolated events and/or were within the range of normal values and were not considered related to administration of the test substance. *Post mortem*, there were no gross lesions, organ weight changes or microscopic findings that were considered associated with administration of MON-0139.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	MON-0139 (aqueous solution of the isopropylamine salt of glyphosate)
Description:	Amber liquid
Lot/Batch #:	LURT-12011
Purity:	62.49 % for isopropylamine salt of glyphosate
Stability of test compound:	Shown stable during the dosing period

2. Vehicle and/or positive control: Empty gelatin capsule

3. Test animals:

Species:	Dog
Strain:	Beagle
Source:	[redacted]
Age:	Approx. 6 months
Sex:	Male and female
Weight at dosing:	♂ 6.3 – 10.6 kg; ♀ 5.4 – 8.1 kg
Acclimation period:	Approx. 6 weeks
Diet/Food:	Purina Certified Dog Chow® 5007 limited to a 2 – 3 hour period
Water:	Tap water, *ad libitum*
Housing:	Individually in stainless steel dog cages
Environmental conditions:	Temperature: 20 – 22 °C (68 – 72 °F) Humidity: Not reported Air changes: Not reported, assume standard 12 hours light/dark cycle

B: Study design and methods

In life dates: 1982-01-26 to 1982-08-13

Animal assignment and treatment:
Six male and six female dogs per dose level received MON-0139 orally, by gelatin capsule administration, once daily for approximately 6 consecutive months. The liquid MON-0139 was placed into empty gelatin capsules (size 1/8 oz.). Doses were adjusted weekly to correspond with each animal's body weight. Capsules were prepared daily. Each dog received one capsule approximately one to four hours after removing its food each day. Control animals were each administered one empty gelatin capsule daily. Animals were acclimated to the laboratory for approximately 6 weeks and passed a veterinary health check prior to

assignment to the study. Animals were individually housed in stainless steel dog cages.
Analyses after the completion of the study indicated 63.2 % MON-0139 compared to an assay (conducted prior to the study) provided by the sponsor of 62.49 % MON-0139. This +0.7 % variation of analyses was within normal limits and no decomposition of MON-0139 were demonstrated.

Table 5.3.2-102: Six Month Study of Mon 0139 by Gelatin Capsule to Beagle Dogs ([redacted] 1983): Study design

Test group	Dose Level [mg/kg bw/day]	Males	Females
Control	0	6	6
Low	10	6	6
Mid	60	6	6
High	300	6	6

Mortality
Each animal was checked for mortality or signs of morbidity at least twice daily during the treatment period.

Clinical observations
A check for clinical signs of toxicity was made at least twice daily (morning and afternoon) on all animals.

Body weight
Weekly determinations of individual body weight were performed.

Food consumption and utilisation
Daily determinations of food consumption were performed.

Ophthalmoscopic examination
Ophthalmologic examinations were performed at pretest and prior to final necropsy on all animals.

Haematology and clinical chemistry
Laboratory investigations of haematology and clinical chemistry were performed after overnight fasting on all the dogs before dosing started and approximately monthly during the treatment period. The blood samples were taken from the jugular vein.

EDTA was used as an anti-coagulant for evaluation of all haematology parameters with the exception of prothrombin time for which citrate was used. The following haematological parameters were measured: Haemoglobin, haematocrit, red blood cell count, mean cell volume (MCV), mean cell haemoglobin (MCH), mean cell haemoglobin concentration (MCHC), reticulocyte count, total white blood cell and differential counts, platelet count and prothrombin time.

For clinical chemistry evaluations, serum was harvested from whole blood and analysed for the following parameters: Blood urea nitrogen, glucose, alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, lactic dehydrogenase (total and isozyme determination), sodium, potassium, calcium, creatinine, total protein, albumin, globulin (calculated), cholesterol, phosphorus, direct and total bilirubin.

Urinalysis
Urinalysis was performed on all the dogs before dosing started and again during months 2, 4, and 6 of treatment. Urine was collected using metabolism cages. The following parameters were measured: Appearance, pH, specific gravity, proteins, glucose, ketones, blood pigments, bilirubin and urobilinogen. Microscopic examination of the spun urine deposit was performed.

Sacrifice and pathology
After 6 months of consecutive treatment, all surviving animals were fasted overnight, sacrificed by

intravenous sodium pentobarbital followed by exsanguination and subjected to a gross pathological examination. Terminal body weights were recorded immediately prior to sacrifice.

The following organ weights were determined: Adrenals, thyroids with parathyroids, pituitary, brain, heart, liver, kidneys, testes with epididymides and ovaries.

Tissue samples were taken from the following organs and preserved in buffered formalin: All gross lesions, adrenals, aorta, brain (cerebrum, cerebellum, medulla), caecum, colon, duodenum, epididymides, eyes, heart, ileum, jejunum, kidneys, liver, gallbladder, lungs, lymph nodes (mesenteric), mammary gland, oesophagus, ovaries, pancreas, pituitary gland, prostrate, rib with marrow, salivary gland (mandibular), spinal cord (cervical, lumbar), sciatic nerve, skeletal muscle, skin, spleen, stomach, testes, thymus, thyroid/parathyroids, trachea, urinary bladder, and uterus. All tissues above from the control and high dose groups were examined histopathologically. Only tissues with gross lesions were microscopically observed from the mid and low dose groups as no target organs were identified in the high dose animals.

Statistics
Non-categorical data from haematological, serum chemical and urinalysis were statistically examined by Dunnett's test for the comparison of multiple treatments with a control, and/or by inspection. Categorical data were examined to determine any remarkable group differences. Statistical evaluation of differences in body weights, food consumptions, terminal body weights and absolute organ weights between treated and control groups was accomplished by the use of Dunnett's test. The Mann-Whitney test with Bonferroni's Inequality was used to assess the organ/body weight ratios. A comparison of the frequency of microscopic lesions between treated groups and controls was evaluated by the use of Fisher's Exact Test with Bonferroni's Inequality.

II. RESULTS AND DISCUSSION

A. MORTALITY
There were no mortalities.

B. CLINICAL OBSERVATIONS
No unusual clinical signs were noted that could be attributed to MON-0139 exposure.

C. BODY WEIGHT
No significant body weight changes occurred between any of the dose groups.

D. FOOD CONSUMPTION AND TEST SUBSTANCE INTAKE
There were no treatment-related effects. Food consumption in treatment groups was comparable to controls. Test compound was administered by gelatine capsule with dosages adjusted according to individual animal weight. Determination of the degree of absorption of the test item following dosing was not performed.

E. OPHTHALMOSCOPIC EXAMINATION
There were no test substance-related ophthalmological findings at the end of the treatment period.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY
Haematology
Statistically significant changes were observed in several haematological parameters. However, the only parameter in which changes occurred in the same sex at several different sampling periods was mean cell haemoglobin concentration (MCHC).

** Statistically significant from controls ($p < 0.01$)

Blood clinical chemistry

Statistically significant changes were observed in several serum chemistry parameters. The only parameters in which changes occurred in the same sex at several different sampling periods were total LDH and LDH isoenzymes.

Alkaline phosphatase (ALP) levels were generally slightly elevated in both males and females at all sampling periods, although it was statistically significant only in males from Group 3 at 5 months of treatment. This change in males was most evident at the highest dosage level while in females it was usually present among all treated groups often with no dose response. This effect was considered as possibly related to administration of the test substance. Changes in other clinical chemistry parameters had no biological significance and were apparently unrelated to compound administration.

G. URINALYSIS

Statistically significant changes were observed in several urinalysis parameters. However, there were no parameters in which changes occurred in the same sex at several different sampling periods.

H. NECROPSY

Organ weights

The only mean absolute organ weight value that was statistically different from the control value was a decreased mean thyroid gland weight in males from the intermediate dosage group. This change was not present in the highest dosage group, therefore, it was not considered to have resulted from MON-0139 administration. The mean right testicular weight of the highest dosage group was increased (not statistically significant) due to an increase in the recorded testicular weight of one animal. There were, however, no gross or microscopic lesions recorded for the right testis of that animal. The only changes in organ to body weight ratios were increases in heart and thyroid weights relative to terminal body weights. The increased relative heart weights occurred in females from the intermediate dosage level and the increased relative thyroid weights occurred in females from the lowest dosage level, both of which resulted from non-significant increases in the absolute organ weights that were apparently unrelated to chemical administration.

Gross pathology

There were no gross lesions that were associated with administration of MON-0139.

Histopathology

There were no microscopic lesions that were associated with administration of MON-0139.

III. CONCLUSIONS

There were no mortalities in any of the dose groups. No unusual changes occurred in body weight, food

consumption or clinical signs as a result of MON-0139 exposure. The only change which potentially related to MON-0139 administration was an elevation of serum alkaline phosphatase levels in males and females at all sampling intervals. There was no indication of the source of the increased levels of this enzyme as no microscopic evidence of lesions in the organs usually responsible for elevations in serum alkaline phosphatase levels were found. This, together with the generally small magnitude of these elevations and the lack of dose response in females makes the interpretation of this change equivocal as regards biological significance and correlation with MON-0139 administration. Other changes in serum chemical and changes in haematological and urinalysis parameters were isolated events and/or were within the range of normal values and were not considered related to administration of the test substance. *Post mortem*, there were no gross lesions, organ weight changes or microscopic findings that were considered associated with administration of MON-0139.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study, the test item MON-0139 (aqueous solution of the isopropylamine salt of glyphosate) was administered orally by gelatin capsule to groups of six male and six female Beagle dogs at daily doses of 0, 10, 60 or 300 mg/kg bw/day for approximately six months according to a testing regime similar to OECD 409 (1981) and in compliance with GLP (no certificate of the competent authority was provided).

All animals survived until termination of the study. There were no clinical signs of toxicity. There were no effects on body weight, food consumption, ophthalmoscopy, haematology, urinalysis, gross postmortem findings, organ weights or microscopic pathology considered biologically adverse or related to administration of MON-0139. An apparent increase in alkaline phosphatase activity potentially associated with treatment was observed in top dose males from the second measurement onwards reaching statistical significance in month five only. Changes in total LDH and LDH isoenzymes were identified but the occurrences were erratic. No other clinical chemistry parameters were considered adversely affected. As the increase in alkaline phosphatase activity was not accompanied by any other indication of organ or tissue damage, the highest dose of 300 mg/kg bw/day can be considered the NOAEL.

Assessment and conclusion by RMS:
.

1. Information on the study

Data point	CA 5.3.2/030
Report author	[redacted]
Report year	1981 (Hungarian report, Revised and English version 1991)
Report title	3 Month Oral Dietary Toxicity Study with Glyphosate in Dogs
Report No	8011
Document No	Not reported
Guidelines followed in study	None indicated, study preceded OECD 409 guideline, but the study design was similar to OECD 409 (1981)
Deviations from current test guideline (OECD 409, 1998)	Not all required haematological, clinical chemistry, urinalysis parameters were evaluated; some organs were not weighed or microscopically examined. Formulated diets were not analysed for concentration, homogeneity or stability. Purity of the test substance not stated in the revised report since the respective supplement to the original report was missing to the author of the revised report.

	Deviations from the current version of OECD 409 (1998) are basically due to the fact that the study was aligned to an older version of the OECD test guideline 409.
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory when study was performed
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary

This is a revised and English report version of the 1981 Hungarian report. The revision was regarded as necessary by the study sponsor in order to eliminate slight deficiencies and to analyse more deeply the obtained experimental data. For this revision, none of the original data of the study were modified or omitted according to the best of the revision author's knowledge.

Glyphosate (purity and manufacturer not stated since the respective supplement as mentioned in the original study report was not included in the revised report) was administered to groups of four male and four female Beagle dogs for three months via food at target dietary concentrations of 0, 200, 600 or 2000 ppm (equivalent to 0, 9.08, 24.92 or 77.43 mg/kg bw/day).

All animals survived the dosing period and there were no clinical signs of toxicity. Body weight and food consumption were overall not affected. Haematology, clinical chemistry, urinalysis and gross pathological examination did not reveal adverse effects. Liver weight (values not reported in the revised report) was marginally lower at the highest dose level (2000 ppm). In two high dose males and in all high dose females, a histopathological feature called "indistinct structure" was described. This was also seen at the mid dose (600 ppm) level in a smaller number of dogs (2 males and one female). This change was characterised by round shaped and enlarged hepatocytes and occasionally also by the narrowing of some of the hepatocytic trabeculae and slight dissociation of the liver structure. In addition, congestion of the liver was noted in three males and all female dogs in the highest dose group.

II. MATERIALS AND METHODS

A: Materials

1. **Test material:** Glyphosate
   - Identification: 14/980
   - Description: Not reported
   - Lot/Batch #: 03090380
   - Purity: Purity not stated since the respective supplement mentioned in the original study report was not provided in the revised report
   - Stability of test compound: Not reported
2. **Vehicle and/or positive control:** Plain diet / none
3. **Test animals:**
   - Species: Dog
   - Strain: Beagle

Source:	[redacted]
Age:	9 – 11 months
Sex:	Male and female
Weight at dosing:	Body weight data at test start not included in revised report
Acclimation period:	3 weeks
Diet/Food:	Composition not provided in the revised report.
Water:	Tap water, *ad libitum*
Housing:	Individually in kennels (1 square meter)
Environmental conditions:	Temperature: 18 ± 2 °C Humidity: 50 ± 5 % Air changes: 5-7 /hour Light/dark cycle: Not reported

B: Study design and methods

In life dates: 1980-11-24 to 1981-02-26

Animal assignment and treatment:
The test material was offered daily in diet to groups of 4 males and 4 females Beagle dogs for 13 weeks. Target dietary concentrations were 0, 200, 600 or 2000 ppm (equivalent to 0, 9.08, 24.92 or 77.43 mg/kg bw/day). Food was mixed with appropriate amounts of test substance one week before the start of the study and monthly thereafter. Food was provided to the animals for 3 hours each day between 0900 and 1200 hours and unconsumed food was weighed and food consumption calculated weekly. The report does not indicate that formulated diet was analysed for concentration, homogeneity or stability. The study design is summarised in the table below:

Table 5.3.2-105: 3 Month Oral Dietary Toxicity Study with Glyphosate in Dogs ([redacted], 1981): Study design

Test group	Dietary concentration [ppm]	Males	Females
Control	0	4	4
Low	200	4	4
Mid	600	4	4
High	2000	4	4

Mortality
Animals were observed daily.

Clinical observations
Animals were observed daily.

Body weight
Body weight measurement was done weekly.

Food consumption and utilisation
Each day, unconsumed food was weighed and food consumption calculated weekly. Chemical intake [mg/kg bw/day] was calculated weekly from food consumption and body weight data and the nominal dose level.

Ophthalmoscopic examination
Not performed.

Haematology and clinical chemistry
Blood samples were collected from the antebrachial vein prior to initiation of treatment and on study days 42 and 85±2 days. The following haematology parameters were measured: haematocrit, haemoglobin, erythrocyte count, and total and differential leukocyte counts.

The following clinical chemistry parameters were measured: Alkaline phosphatase, glutamic oxaloacetic transaminase, glutamic pyruvic transaminase, creatinine, blood urea nitrogen, total protein, albumin, globulin, albumin/globulin ratio, glucose, bilirubin, potassium and sodium.

Urinalysis
Urine was collected using metabolic cages at termination of the dosing period. The following urine parameters were evaluated: specific gravity, pH, protein, glucose and microscopic examination of sediment was performed.

Sacrifice and pathology
After 13 weeks of treatment, all animals were subjected to a complete necropsy and all gross findings were recorded. Animals were anaesthetised with phenobarbital and euthanised by exsanguinations from the carotid artery before necropsy. At necropsy, the organs and tissues were removed and preserved in 8 % formalin.

Weights of the following organs were recorded for all animals and the ratios to the final body weight were calculated: Brain, pituitary, heart, adrenals, thyroids, liver, gonads, and kidneys.

The following organs and tissues from all animals were examined microscopically: Brain (cerebrum, cerebellum pons), spinal cord, peripheral nerve, pituitary, thyroids, adrenals, spleen, lymph nodes (cervical, mesenteric), heart, aorta (thoracic, abdominal), salivary gland (submandibular), oesophagus, stomach (cardiac, fundus, pylorus), liver, gall bladder, pancreas, duodenum, jejunum, ileum, large intestine, trachea, lungs, kidneys, urinary bladder, testes, prostate, ovaries, uterus, eyes, femoral muscle, and all gross lesions.

Statistics
Differences between the control and treated groups were analysed using Student's two samples t-test.

II. RESULTS AND DISCUSSION

A. MORTALITY
All animals survived the study.

B. CLINICAL OBSERVATIONS
No signs of toxicity were observed during the study.

C. BODY WEIGHT
There were no statistically or biologically significant differences in weight variations occurring during the study between control and glyphosate treated animals. The supplement containing the data was not included in the revised study report.

D. FOOD CONSUMPTION AND TEST SUBSTANCE INTAKE
There was an isolated reduction in food consumption in some of the high dose (2000 ppm) group animals at or around study week 9 primarily associated with 3 dogs. Reduced food intake occurred at other times during the study similarly in controls and treated dogs but these reductions were no longer observed by the end of the study period. However, food intake was reduced in all study groups at the end of the dosing period causing a moderately lower substance intake. The supplement containing the food consumption data

was not included in the revised study report.

The overall group mean chemical intakes [mg/kg bw/day] over the whole treatment period were calculated from food consumption, body weights and the nominal dose levels. The results are shown in the table below:

Table 5.3.2-106: 3 Month Oral Dietary Toxicity Study with Glyphosate in Dogs ([redacted], 1981): Summary of mean group compound uptake, selected weeks [mg/kg bw/day]

Study Week	Dose levels for both sexes combined [mg/kg bw/day]			
	Dose group [ppm]			
	0	200	600	2000
1	-	9.07	25.9	83.85
3	-	10.54	25.86	91.88

E. OPHTHALMOSCOPIC EXAMINATION

Not performed.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

There were no significant differences in haematology values in measured parameters between control and treated dogs during the study. The supplement containing the data was not included in the revised study report.

Blood clinical chemistry

There were no significant differences in clinical chemistry values in measured parameters between control and treated dogs during the study. The supplement containing the data was not included in the revised study report.

G. URINALYSIS

There were no significant differences in clinical chemistry values in measured parameters between control and treated dogs during the study. The supplement containing the data was not included in the revised study report.

H. NECROPSY

Organ weights

Marginally lower absolute liver weights resulted in lower relative liver weights for high dose animals. There were no differences in weights of the other organs between controls and treated animals. The supplement containing the data was not included in the revised study report.

Gross pathology

The revised report indicates that the findings at necropsy were rare, slight and nonspecific to treatment with glyphosate with no differences observed between control and treated groups. The report indicates a "weaker general condition of the animals at necropsy" that did not correlate with the clinical laboratory and pathology findings. One 600 ppm group female and one 2000 ppm group female were graded as in poor general condition at necropsy.

Histopathology
No findings considered indicative of severe toxicity were observed in any of the organs examined. Alterations considered mild were found only in the livers of some higher dose group dogs that were described as "indistinct structure" that did "not transfer to degeneration and was regarded as fully reversible". The revised report presents a histopathology report indicated to be prepared from the primary histopathology findings from 1981. The changes observed in the livers of the high dose group dogs (2000 ppm) were described in the revised report as round shaped, enlarged hepatocytes and occasionally narrowing of some of the hepatocytic trabeculae and slight dissociation of the structure. Non-pathologic congestions seen the liver of one lower dose animal was more pronounced in the animals with "indistinct liver structure". The abnormal presence or localisation of connective tissue or fibrosis were not observed. No other changes observed were considered attributable to treatment with glyphosate. It was concluded that treatment-related findings occurred only in the liver of the high dose group animals in the form of increased congestion and "indistinct structure". These liver lesions were considered functional and reversible. No other findings were considered of toxicological or pathological significance.

Table 5.3.2-107: 3 Month Oral Dietary Toxicity Study with Glyphosate in Dogs ([redacted], 1981): Summary incidence of liver histopathological findings

Finding	Dietary Concentration [ppm]							
	Males				Females			
	0	200	600	2000	0	200	600	2000
Focal subacute inflammation	4/4	1/4	2/4	3/4	4/4	2/4	1/4	3/4
Congestion	0/4	1/4	0/4	3/4	0/4	0/4	0/4	4/4
Indistinct structure	0/4	0/4	2/4	2/4	0/4	0/4	1/4	4/4

III. CONCLUSIONS

All animals survived the dosing period and there were no clinical signs of toxicity. Body weight and food consumption were overall not affected. Haematology, clinical chemistry, urinalysis and gross pathological examination did not reveal adverse effects. Liver weight (values not reported in the revised report) was marginally lower at the highest dose level (2000 ppm). In two high dose males and in all high dose females, a histopathological feature called "indistinct structure" was described. This was also seen at the mid dose (600 ppm) level in a smaller number of dogs (2 males and one female). This change was characterised by round shaped and enlarged hepatocytes and occasionally also by the narrowing of some of the hepatocytic trabeculae and slight dissociation of the liver structure. In addition, congestion of the liver was noted in three males and all female dogs in the highest dose group.
None of the parameters recorded or measured revealed treatment related changes, except histopathology, where more or less functional type morphological changes were described in the livers of some dogs of the highest dose group.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Groups of four male and four female Beagle dogs were treated for three months with glyphosate via their food at target dietary concentrations of 0, 200, 600 or 2000 ppm (equivalent to 0, 9.08, 24.92 or 77.43 mg/kg bw/day). All animals survived the dosing period and there were no clinical signs of toxicity. Body weight and food consumption were not affected. Haematology, clinical chemistry, urinalysis and gross pathological examination did not reveal adverse effects. Liver weight (value not reported in the revised

report) was marginally lower at the highest dose level (2000 ppm). In two high dose males and in all high dose females, a histopathological feature called "indistinct structure" was described. This was also seen at the mid dose (600 ppm) level in a smaller number of dogs (2 males and one female). This change was characterised by round shaped and enlarged hepatocytes and occasionally also by the narrowing of some of the hepatocytic trabeculae and slight dissociation of the liver structure. In addition, congestion of the liver was noted in three male and all female dogs in the highest dose group. The toxicological significance of these findings is equivocal. Based on these results, an average daily glyphosate intake of approximately 25 mg/kg bw/day calculated from the 600 ppm mid-dose target concentration can be considered a NOAEL for dogs under the conditions of this study.

Assessment and conclusion by RMS:
.

Oral 1 year toxicity (dog)

Table 5.3.2-108 summarises the oral 1-year studies performed in dogs previously assessed in the 2001 and 2015 EU glyphosate evaluations.

Table 5.3.2-108: Studies on oral 1-year repeated-dose toxicity with glyphosate in non-rodents

Table 5.3.2-108: Studies on oral 1-year repeated-dose toxicity with glyphosate in non-rodents

Annex Point	Study	Species Study type	Substance(s)	Reference list-related category§	Result
CA 5.3.2/037	[redacted], 1982 (Revised and English version of Hungarian report 1992)	Beagle dog 12-month, oral diet (0, 30, 100, 300 ppm)	Glyphosate (Purity: not reported)	Invalid, Category 4b	NOAEL = 300 ppm (equivalent to approx. 8 mg/kg bw/day for the sexes combined)

§: The category describes the acceptability/reliability of the study within the AIR 5 submission. This category does not describe hazard classification. (for details please refer to the Doc ID: 110054-B-GRG_Jun_2020)

There are five valid 1-year studies available in which Beagle dogs were administered glyphosate in the diet or via capsule ([redacted], 2007; [redacted], 1997; [redacted], 1996; [redacted], 1990; [redacted], 1985). These studies were previously assessed in the 2001 and 2015 EU glyphosate evaluations.

In all of these studies only non-specific signs of toxicity (slight effect body weight and an increase in clinical signs of soft, liquid stools) were observed at or close to limit dose (1000 mg/kg bw/day). These effects were characterised as reduction in body weight gain, reduction in urinary pH and minor effects on clinical pathology parameters. An increase in focal pneumonia and focal granulomatous pneumonia in the lung in all females dosed at 1259 mg/kg bw/day was observed in the study by [redacted] (1997). In the other female groups, this lesion was observed in only one out of four dogs each. However, the extent of this lesion was very focal and the degree of intensity was slight in all cases. Statistically, no significant differences between control and dose groups were found in the incidence of this lesion. In this study no treatment-related effects were observed.

Overall, the lowest dose level where treatment-related effects were observed was 926 mg/kg bw/day in female dogs in the study by [redacted] (1996). The lowest one-year oral dog NOAEL for glyphosate technical is 182 mg/kg bw/day for males and 184 mg/kg bw/day for females ([redacted] 1997). But since in this study the dose levels were set at wide intervals, this rather low NOAEL seems to be an artefact of dose selection. The most relevant one-year oral dog NOAEL for glyphosate technical is 500 mg/kg bw/day ([redacted], 2007; [redacted], 1985).

The additional study by [redacted] (1992; revised and English version of 1982 hungarian report) was considered invalid due to serious reporting deficiencies.

1. Information on the study

Data point	CA 5.3.2/031
Report author	[redacted]
Report year	2007
Report title	Glyphosate technical: 52-week Toxicity Study by Oral Route (Capsule) in Beagle Dogs
Report No	29647 TCC
Document No	Not reported
Guidelines followed in study	OECD 452 (1981); JMAFF 2-1-14 (2001)
Deviations from current test guideline (OECD 452, 2018)	None
Previous evaluation	Yes, accepted in RAR (2015)

GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The toxicity potential of glyphosate technical was assessed in a 1-year oral toxicity study in male and female Beagle dogs. Groups of four dogs per sex received daily doses (capsules) of 0, 30, 125, or 500 mg/kg bw/day for 52 consecutive weeks (dose level selection was based on the results of a 13-week study run in the same laboratory). Observations covered mortality, clinical signs, body weight, food consumption, ophthalmological examinations, haematology, clinical chemistry, urine analysis, organ weights, necropsy and histopathological examination.

No unscheduled deaths or premature sacrifices occurred during the study. There were no treatment-related effects on clinical signs, eyes, body weight, body weight gain, food consumption, haematology, clinical chemistry or urine analysis parameters in both sexes. Gross pathology, organ weight data and histopathological examination demonstrated no treatment-related effects.

I. MATERIALS AND METHODS

A: Materials

1. Test material: Glyphosate technical

Identification:	Glyphosate tech
Description:	White crystalline powder
Lot/Batch #:	H05H016A
Purity:	95.7 %
Stability of test compound:	Expiry date: 2008-03-25

2. Vehicle and/ or positive control: Gelatine capsules size 12 (Torpac, New York, USA) / none

3. Test animals:

Species:	Dog
Strain:	Beagle
Source:	[redacted]
Age:	Approx. 6 months
Sex:	Males and females
Weight at dosing:	7.8 – 8.9 kg (males); 7.2 – 7.9 kg (females)
Acclimation period:	13 days + 20 days pre-treatment period
Diet/Food:	125 C3 pelleted diet (SAFE, Villemoisson, Epinay-sur-Orge, France), approx. 300 g per day. Due to weight loss in three animals the amount for these dogs was increased to 350 g/day from day 149, 180, and 185, respectively. From day 191 onwards all animals received 350 g/day. One male received 400 g from day 221 onwards
Water:	Tap water, *ad libitum*

Housing:	Individually in pens containing wood shavings for bedding, except when a urine sample was required. The dogs were group-housed once a week, by sex and dose group, after the last recording of clinical signs in the afternoon, until the next morning
Environmental conditions:	Temperature: 20 ± 5 °C Humidity: 50 ± 20 % Air changes: approx. 12 / hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 2005-09-27 to 2006-10-17

Animal assignment and treatment:
In a chronic oral toxicity study groups of four Beagle dogs per sex received daily doses of 0, 30, 125 or 500 mg/kg bw/day glyphosate technical in gelatine capsules for 52 consecutive weeks. The dose levels were selected based on results of a 13-week oral (capsule) toxicity study in dogs. Dose formulations were prepared weekly by adding the required amount to the capsules. The dosages were calculated based on minimum nominal active substance content of 950 g/kg glyphosate in the test item. Analyses of the test item showed a glyphosate content consistently above 95 %. Thus, no adjustment was considered necessary. Since the test item was added under GLP conditions, no additional analyses of dose formulations were deemed necessary.

Administrations of dose capsules were done approximately the same daily time each day. The low and mid-dose animals received one capsule per day, the high-dose and control dogs received three capsules per day. The quantity of dosage form applied to each animal was adjusted weekly based on the most recently recorded body weight.

Clinical observations
Observations for morbidity, and mortality were made twice daily. A check for clinical signs of toxicity was made at least once daily on all animals. In addition, a detailed clinical examination was performed once before start of treatment and weekly thereafter until termination.

Body weight
Individual body weights were recorded three times before group allocation, on day 1 (prior to treatment) and weekly thereafter during the conduct of study and at termination.

Food consumption and compound intake
Food consumption of each animal was estimated daily by noting the difference between the amount provided and the remaining amount on the next morning. Food consumption was expressed as percentage of quantity provided. Whenever fasting was required, food was removed at the end of the day and estimation of food consumption was made at that time.

Ophthalmological examination
Ophthalmological examinations were performed on all dogs prior to start and at the end of the treatment period. Pupillary light and blink reflexes were evaluated first. Mydriasis was then induced by adding Tropicamide solution into the eyes and the appendages, optic media and fundus were examined by indirect ophthalmoscopy.

Haematology and clinical chemistry
Blood samples were collected from all dogs prior to treatment, in week 25 and at the end of the treatment period in week 51. For sampling dogs were fasted overnight for at least 14 hours. The following haematological parameters were examined: Haemoglobin concentration (HB), erythrocyte count (RBC),

mean cell volume (MCV), packed cell volume (PCV), mean cell haemoglobin concentration (MCHC), mean cell haemoglobin (MCH), thrombocytes (PLAT), leukocytes (WBC), differential white cell count with cell morphology, neutrophils (N), eosinophils (E), basophils (B), lymphocytes (L), monocytes ♂, reticulocytes (RETIC), prothrombin time (PT) and activated partial thromboplastin time (APTT). The following clinical chemistry parameters were examined: Alkaline phosphatase (ALP), alanine aminotransferase activity (ALAT), aspartate amino transferase (ASAT), albumin, albumin/globulin ratio, total bilirubin, glucose, urea, calcium, chloride, total cholesterol, creatinine, γ-glutamyl-transferase (GGT), inorganic phosphorus, total protein, sodium, potassium and triglycerides.

Urinanalysis
Individual urine samples were collected from all dogs prior to treatment, in week 25 and at the end of the treatment period in week 51. For sampling dogs were fasted overnight for at least 14 hours. Urine was collected in the presence of thymol crystals. The following examinations were made: Appearance, colour, specific gravity, pH, volume, proteins, glucose, ketones, bilirubin, nitrites, blood and urobilinogen. The sediment was examined microscopically for leukocytes, erythrocytes, cylinders, magnesium ammonium phosphate crystals, calcium phosphate crystals, calcium oxalate crystals and cells.

Sacrifice and pathology
All surviving dogs were killed after completion of 52 weeks treatment and were subjected to a gross pathological examination. The following organs were weighed: Adrenals, brain, epididymides, heart, kidneys, liver, spleen, thymus, uterus, pituitary, prostate, ovaries, testes and thyroids with parathyroid. Organ to body weight ratios were calculated.

Tissue samples were taken from the following organs of all dogs and preserved in 10 % buffered formalin (except for the eyes with the optic nerve which were fixed in Davidson´s fixative, and testes and epididymides which were preserved in Bouin´s fluid): Adrenals, aorta, brain, caecum, colon, duodenum, oesophagus, eyes and optic nerve, epididymides, femur with articulation, gall bladder, heart, ileum, jejunum, kidneys, larynx, liver, lungs with bronchi, mammary gland, mandibular lymph node, mesenteric lymph node, skeletal muscle, ovaries, oviducts, parathyroid, pancreas, pituitary, prostate, rectum, salivary glands (parotid and submandibular), skin, spinal cord (cervical, thoracic and lumbar), spleen, sternum with bone marrow, stomach, sciatic nerve, testes, thymus, thyroids with parathyroid, tongue, trachea, urinary bladder, ureters and uterus (horns and cervix).

A detailed histopathological examination was performed on all sampled tissues of all dogs, except for femur, larynx, oviducts, tongue, ureter and vagina.

Statistics
Statistical analysis of body weight, haematology, blood biochemistry, urinalysis and organ weight data was done according to the statistical decision tree shown in "*Guidance Notes for Analysis and Evaluation of Chronic Toxicity and Carcinogenicity Studies*" (OECD, 2002), summarising the most common statistical procedures used for analysis of data in toxicology studies, together with their most likely outcomes.

II. RESULTS AND DISCUSSION

A. MORTALITY
No mortalities or premature sacrifices occurred during the treatment period.

B. CLINICAL OBSERVATIONS
There were no treatment-related clinical signs observed during the study period.

Observed clinical signs consisted of vomiting or soft faeces, thin appearance, hyperactivity, ptyalism, skin findings (scabs and erythema, generally localized on the ear(s)) and nodules on the ears. These clinical observations were seen transiently, and were encountered with a similar incidence in both control and treated animals and/or were independent to the administered dose-level and/or were already present before

the beginning of the treatment period.

C. BODY WEIGHT

There was no treatment-related effect on body weight development. The lower mean body weight recorded in high dose males at the end of the treatment period was due to the lower mean body weight gain during the first month of the study (see Table 5.3.2-109**Error! Reference source not found.** below). Individual body weight changes were within the range of physiological variations. In addition, such body weight changes were observed in both control and treated dogs.

Table 5.3.2-109: Glyphosate technical: 52-week Toxicity Study by Oral Route (Capsule) in Beagle Dogs ([redacted] 2007): Mean body weight and body weight changes [kg]

Dose level [mg/kg bw/day]	Males				Females			
	0	30	125	500	0	30	125	500
Mean bw prior to start (day -1)	8.2	8.3	8.3	8.3	7.4	7.4	7.6	7.4
Weeks 1 – 4	+0.6	+0.3	+0.5	**+0.2***	+0.3	+0.3	+0.3	+0.3
Weeks 4 – 26	+1.4	+0.9	+1.4	+1.1	+1.2	+1.1	+1.5	+1.6
Weeks 26 – 52	+0.9	+1.4	+1.1	+0.8	+0.6	+0.2	+0.5	+1.1
Weeks 1 – 52/53	+2.8	+2.6	+2.9	+2.0	+2.1	+1.6	+2.3	+3.0
Mean bw in week 52/53	11.2	11.0	11.2	10.5	9.6	9.2	10.0	10.6

* Statistically significant from control ($p < 0.05$)

The weight loss of some dogs observed in the control, and low-dose group during some periods of the study were resolved when the daily food quantity was increased. Therefore, these changes were considered not test substance related.

D. FOOD CONSUMPTION

There was no treatment-related effect on food consumption noted during the study.

The reduced food consumptions noted during the study were not considered test substance related, since they occurred only on some occasions and in control and treated dogs.

Due to weight loss one male each of the low and mid dose group, and one control female received 350 g/day from day 149, 180 and 185, respectively. From day 191 onwards all animals received 350 g/day. One male received 400 g from day 221 onwards.

E. OPHTHALMOLOGY

There were no ophthalmological findings observed at the end of the study period.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

There were no treatment-related effects noted in the haematological parameters.

The differences observed for the activated partial thromboplastin time, MCHC and eosinophil counts in the treated animals when compared to control dogs were only slight and/or not dose-related.

Table 5.3.2-110: Glyphosate technical: 52-week Toxicity Study by Oral Route (Capsule) in Beagle Dogs ([redacted], 2007): Results of haematological examinations week 51 (mean ± SD)

G. URINANALYSIS

There were no findings among the quantitative or semi-quantitative and qualitative parameters during the treatment period.

H. NECROPSY

Organ weights

The statistically significant lower brain weight (see table below Table 5.3.2-112) observed in males at 125 mg/kg bw/day was dose-independent. In addition, there were no macroscopic or histopathological findings noted in this organ. Thus, this finding is considered incidental.
There were no other statistically significant differences in organ weights and organ to body weight ratios between control and treated dogs.

Table 5.3.2-112: Glyphosate technical: 52-week Toxicity Study by Oral Route (Capsule) in Beagle Dogs ([redacted], 2007): Body/Brain weights of male dogs

Dose group [mg/kg bw/day]	0	30	125	500
No of animals	4	4	4	4

** DUNNETT'S TEST based on pooled variances at 1 % level; assigned control group(s): 1.

Gross pathology
There were no test substance related macroscopic findings observed in any animal of all dose groups.

Histopathology
There were no test substance related microscopic findings observed in any tissue sample of any dose group.

III. CONCLUSIONS

No unscheduled deaths or premature sacrifices occurred during the study. There were no treatment-related effects on clinical signs, eyes, body weight, body weight gain, food consumption, haematology, clinical chemistry or urine analysis parameters in both sexes. Gross pathology, organ weight data and histopathological examination demonstrated no treatment-related effects.

The test item was clinically well tolerated and did not result in any laboratory or histological changes.
In conclusion under the experimental conditions of this study, the NOEL for oral toxicity of glyphosate technical was established at 500 mg/kg bw/day by the study authors.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The toxicity potential of glyphosate technical was assessed in a 1-year oral toxicity study in male and female Beagle dogs. Groups of four dogs per sex received daily doses (capsules) of 0, 30, 125, or 500 mg/kg bw/day for 52 consecutive weeks. The study was conducted according to OECD 452 (1981) and in compliance with GLP regulations

Glyphosate technical was well tolerated and did not produce any laboratory or histological effects in Beagle dogs when administered daily for 52 weeks by the oral route at all dose levels. Based on these results, the NO(A)EL in Beagle dogs after 1 year of oral exposure was 500 mg/kg bw/day.

Assessment and conclusion by RMS:
.

1. Information on the study

Data point	CA 5.3.2/032
Report author	[redacted]
Report year	1997
Report title	HR-001: 12-Month Oral Chronic Toxicity Study in Dogs
Report No	[redacted] 94-0157
Document No	Not reported
Guidelines followed in study	Japan MAFF Guidelines 59 NohSan No.4200, 1985; U.S. EPA FIFRA Guidelines Subdivision F, 1984; OECD 409 (1981; in general compliance to OECD 452, 1981)
Deviations from current test guideline (OECD 409, 1998; OECD 452, 2018)	Blood clotting time parameters not evaluated; epididymis and uterus weights not reported. Deviations from the current versions of OECD 409 (1998) and OECD 452 (2018) are basically due to the fact that the study was aligned to older versions of the OECD test guidelines.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

An oral 12-month toxicity study of HR-001 (Glyphosate technical) was conducted in Beagle dogs of both sexes. Groups of 4 males and 4 females each were given the test substance by incorporating it into basal diet at a level of 0, 1600, 8000 or 50000 ppm (equivalent to 0, 34.1, 182 or 1203 mg/kg bw/day for males and 0, 37.1, 184 or 1259 mg/kg bw/day for females) for a period of 12 months. Animals were checked daily for general conditions. Body weights and food consumption were measured periodically. All animals were subjected to urinalysis at weeks 25 and 51 and to haematology and blood chemistry at weeks 26 and 52. Ophthalmological examinations were performed at week 52. At termination of treatment, animals were euthanised and subjected to organ weight analysis and necropsy. Histopathological examinations were performed on representative organs/tissues from all animal used.

Findings related to the treatment were demonstrated in clinical observation, body weight, urinalysis, haematology and blood chemistry.

50000 ppm group: Loose stool was observed in 3 of 4 males and 4 of 4 females. These animals frequently showed this clinical sign through the treatment period, whereas in the control group, only one animal in each sex showed the sign over a limited period during treatment. Body weight gain was retarded gradually with progression of the treatment in both sexes, when compared to the controls. Consequently, the difference in mean body weight between the 50000 ppm and control groups became great with time, although statistical significance was not observed. Haematologically, slight anaemic changes were noted for females at weeks 26 and 52. Females also showed significantly increased plasma level of chloride at week 26 and significantly decreased plasma levels of albumin and inorganic phosphorous at week 52. Significantly lowered urine pH values were continuously observed in males and females. However, this finding was not recognised as a toxic change since it is known that the test substance is secreted with little metabolism into urine, is degraded to a free acid in urine, and consequently, makes the urine acidic.

8000 and 1600 ppm groups: There were no treatment-related abnormalities in either sex.

I. MATERIALS AND METHODS

A: Materials

1. **Test material:** Glyphosate technical

Identification:	HR-001
Description:	White crystals
Lot/Batch #:	T-950308
Purity:	94.61 %
Stability of test compound:	Not mentioned in the report

2. **Vehicle and/or positive control:** None

3. **Test animals:**

Species:	Dog
Strain:	Beagle
Source:	[redacted]
Age:	5 months
Sex:	Males and females
Weight at dosing:	7.8 – 8.9 kg (males); 7.2 – 7.9 kg (females)
Acclimation period:	23 and 31 days for males and females, respectively
Diet/Food:	Solid diet DS (Oriental Yeast, Co.) restricted at 250 g/dog/day
Water:	Tap water, *ad libitum*
Housing:	Individually in stainless steel cages 83.5 × 90.0 × 80.0 cm
Environmental conditions:	Temperature: 24 ± 2 °C Humidity: 55 ± 10 % Air changes: 15 / hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1996-03-05 to 1997-04-03

Animal assignment and treatment:
Groups of 4 males and 4 females Beagle dogs received the test material by incorporating it into the basal diet at a level of 0, 1600, 8000 or 50000 ppm for a period of 12 months.

Clinical observations
All animals were observed daily for clinical signs. Detailed clinical observations were performed at least once per week.

Body weight
Individual body weights were recorded at initiation of treatment, weekly from weeks 1 to 13, and every 4 weeks from weeks 16 to 52. In addition, final body weight was measured before necropsy.

Food consumption and compound intake
Food consumption of each animal was recorded weekly from week 1 to 13 and every 4 weeks from week

16 to 52. Food residues, if any, were collected and weighed every morning. Daily food consumption by each animal was calculated as follows:

$$Food\ consumption = \frac{[Feeding\ amount\ (250\ g\ diet + 250\ g\ water) - food\ residue]}{2}$$

Chemical intake (mg/kg bw/day) was calculated weekly from food consumption and body weight data and the nominal level.

Ophthalmological examination
Ophthalmological examinations were performed on all dogs prior to start of the treatment period and at week 52. The following items were examined: eyeball, eyelid, conjunctiva, cornea, anterior chamber, pupil, iris, lens, vitreous body and fundus.

Haematology and clinical chemistry
Blood samples were collected from all dogs prior to treatment, in weeks 25 and 52. The following haematological parameters were examined: Haematocrit, haemoglobin concentration, erythrocyte count, mean corpuscular volume, mean corpuscular haemoglobin, mean corpuscular haemoglobin concentration, platelet count and total leukocyte count.

All animals were subjected to blood biochemical examinations at weeks 26 and 52.

The following clinical chemistry parameters were examined: Alkaline phosphatase (ALP), glutamic oxaloacetic transaminase (GOT), glutamic pyruvic transaminase (GPT), γ-glutamyl transpeptidase (GGTP), creatine phosphokinase (CPK), creatinine (Creat.), blood urea nitrogen (BUN), total protein (TP), albumin (Alb), globulin (Glob.), albumin/globulin ratio (A/G ratio), glucose (Gluc.), total cholesterol (T. Chol.), triglyceride (TG), total bilirubin (T. Bil.), calcium (Ca), inorganic phosphorus (P), sodium (Na), Potassium (K) and chloride (Cl).

Urinalysis
Prior to initiation of treatment and at weeks 25 and 51, all animals were subjected to urinalysis on the following parameters: Appearance, colour, specific gravity, pH, volume, proteins, glucose, ketones, bilirubin, nitrites, blood and urobilinogen.

Sacrifice and pathology
All surviving dogs were killed after completion of 52 weeks treatment and were subjected to a gross pathological examination. The following organs were weight: Adrenals, brain, epididymides, heart, kidneys, liver, spleen, thymus, uterus, pituitary, prostate, ovaries, testes, thyroids with parathyroid. Organ to body weight ratios were calculated.

Tissue samples were taken from the following organs of all dogs and preserved in 10 % buffered formalin (except for the eyes with the optic nerve which were fixed in Davidson´s fixative, and testes and epididymides which were preserved in Bouin´s fluid): Brain, spinal cord, peripheral nerve, pituitary, thymus, thyroids with parathyroids, adrenals, tonsil, spleen, bone with marrow, lymph nodes, heart, aorta, tongue, buccal mucosa of oral cavity, pharynx, salivary glands, oesophagus, stomach, liver with gallbladder , pancreas, duodenum, jejunum, ileum, caecum, colon, rectum, nasal cavity, larynx, trachea, lung, kidneys, urinary bladder, testes, prostate, penis, epididymides, ovaries, oviducts, uterus, vagina, diaphragm, eyes, femoral muscle, skin, mammary gland and all gross lesions.

A detailed histopathological examination was performed on all sampled tissues of all dogs, except for femur, larynx, oviducts, tongue, ureter and vagina.

Statistics
Statistical analysis of body weight, haematology, blood biochemistry, urinalysis and organ weight data was done according to the statistical decision tree shown in "*Guidance Notes for Analysis and Evaluation of Chronic Toxicity and Carcinogenicity Studies*" (OECD, 2002), summarising the most common statistical procedures used for analysis of data in toxicology studies, together with their most likely outcomes.

II. RESULTS AND DISCUSSION

A. MORTALITY
There were no deaths in any dose groups of either sex.

B. CLINICAL OBSERVATIONS
In the 50000 ppm group, loose stool was observed in 3 of 4 males and 4 of 4 females. The animals in the 8000 and 1600 ppm groups did not show the clinical sign at all. In the control group, only one animal in each sex showed it. Most of the animals in the 50000 ppm group frequently showed the sign throughout the treatment period, whereas the occurrence in the suffering animals of the control group was restricted to a limited period.

For other clinical signs observed, the occurrence was sporadic in all dose groups, or the incidence was almost comparable among the dose groups.

C. BODY WEIGHT
In the 50000 ppm group of both sexes, retarded body weight gain became evident gradually as the study progressed. Consequently, the mean body weights in this group at termination of treatment were 6 % in males and 11 % in females lower than those in the controls. However, statistically significant differences in mean body weights were not observed throughout the treatment between the control and treated groups including the 50000 ppm.

Table 5.3.2-113: HR-001: 12-Month Oral Chronic Toxicity Study in Dogs ([redacted], 1997): Mean body weight and body weight changes [kg]

Dose level [ppm]	Males				Females			
	0	1600	8000	50000	0	1600	8000	50000
Mean bw prior to start (day -1)	8.4	8.3	8.3	8.3	8.2	8.2	8.2	8.2
Weeks 0 – 4	+1.1	+1.2	+1.1	+0.9	+1.0	+0.9	+0.8	+0.6
Weeks 4 – 24	+2	+2.7	+1.8	+1.5	+1.9	+1.7	+2	+1.3
Weeks 24 – 52	0	+0.6	+0.5	+0.1	+0.8	+0.8	+1.4	+0.5
Weeks 0 – 52	+3.1	+4.5	+3.4	+2.5	+3.7	+3.4	+4.2	+2.4
Mean bw in week 52/53	11.5	12.8	11.7	10.8	11.9	11.6	12.4	10.6

* Statistically significant from control ($p < 0.05$)

D. FOOD CONSUMPTION
Decreased food consumption was noted for one female in the 1600 ppm group at weeks 24, 28 and 52 and for another female in the same group at week 32. Consequently, group mean food consumption in this group was decreased at those weeks. However, food consumption in this group recorded at other weeks was comparable to that of the controls. Moreover, the averaged group mean food consumption through the treatment period was almost comparable between the 1600 ppm and control groups of females.

All males in all dose groups and females except the above 2 animals in the 1600 ppm group consumed whole amount of diet offered every day.

Group mean chemical intakes were calculated from group mean values of food consumption and body weight, and the nominal dose levels. The overall group mean chemical intakes [mg/kg bw/day] through the whole treatment period are presented in the table below:

Table 5.3.2-114: HR-001: 12-Month Oral Chronic Toxicity Study in Dogs ([redacted], 1997): Mean test substance intake

Dose level [ppm]	Test substance intake [mg/kg bw/day]	
	Males	Females
1600	34.1	37.1
8000	182	184
50000	1203	1259

E. OPHTHALMOLOGY

No remarkable ocular changes were detected in animals in any dose group at week 52.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

Statistically significant changes in haematology that were observed in treated groups are presented in the following table:

Table 5.3.2-115: HR-001: 12-Month Oral Chronic Toxicity Study in Dogs ([redacted], 1997): Results of haematological examination – selected parameters (mean ± SD)

Parameter	Week	Dose level [ppm]							
		Males				Females			
		0	1600	8000	50000	0	1600	8000	50000
Haematocrit (Ht) [%]	0	41.5 ± 1.7	↓40.9 ± 2.9	↓38.2 ± 1.4	↓39.5 ± 3.0	45.6 ± 0.6	↓42.1 ± 3.8	45.6 ± 1.8	**↓41.8* ± 1.2**

	52	7.68 ± 0.35	↑8.05 ± 0.63	↓7.31 ± 0.52	↓7.13 ± 0.71	8.40 ± 0.42	↓7.86 ± 0.62	↓7.46 ± 1.03	**↓6.87* ± 0.42**

* Statistically significant from controls ($p < 0.05$)

Male groups showed no significant changes in any parameters.

Female in the 50000 ppm group showed significantly decreased values of haematocrit (Ht), haemoglobin concentration (Hb), and erythrocyte count (RBC) at week 52. Haemoglobin concentration in this group was also significantly lower at week 26. This group had already showed lower values for these 3 parameters than the controls before initiation of treatment (at week 0). In particular, the differences from the control values in haematocrit and erythrocyte count at week 0 were statistically significant. However, the rates of deviation from the control values were, though slightly, augmented in the treatment period when compared to those at week 0.

Females in the 8000 and 1600 ppm groups showed no significant changes in haematological examinations.

Clinical chemistry
Statistically significant changes in blood biochemistry that were observed in treated groups are presented in the table hereafter:

Table 5.3.2-116: HR-001: 12-Month Oral Chronic Toxicity Study in Dogs ([redacted] 1997): Results of week 52 clinical chemistry examination- selected parameters (mean ± SD)

Parameter	Dose level [ppm]							
	Males				Females			
	0	1600	8000	50000	0	1600	8000	50000
Creatine phosphokinase (CPK) [U/L]	111 ± 21	↓93 ± 7	**↓82* ± 8**	↑121 ± 16	78 ± 14	↑96 ± 9	↑103 ± 22	↑100 ± 20
Albumin (Alb) [g/dL]	3.07 ± 0.19	↑3.22 ± 0.18	↓2.99 ±0.26	↓2.88 ± 0.09	3.19 ± 0.14	↓3.04 ± 0.20	↓3.13 ± 0.12	**↓2.84* ± 0.17**
Calcium (Ca) [mg/dL]	10.2 ± 0.2	↑10.4 ± 0.3	↓10.0 ± 0.3	↓9.8 ± 0.2	10.2 ± 0.1	**↓10.0* ± 0.1**	↑10.3 ± 0.2	**↓9.7** ± 0.1**
Inorganic phosphorus (P) [mg/dL]	3.8 ± 0.9	↑3.9 ± 0.6	↓3.3 ± 0.3	↓2.8 ± 0.2	3.9 ± 0.3	3.9 ± 0.3	↑4.2 ± 0.5	**↓2.8* ± 0.5**
Chloride (Cl) [mEq/L]	112.3 ± 1.3	↓110.2 ± 1.8	↑112.5 ± 2.2	↑114.0 ± 1.0	112.0 ± 1.3	↑112.4 ± 1.5	↓109.3 ± 2.0	↑114.0 ± 1.7

* Statistically significant from controls ($p < 0.05$);
** Statistically significant from controls ($p < 0.01$)

Females in the 50000 ppm group showed a significant increase in chloride (Cl) at week 26 and significant decreases in albumin (Alb), calcium (Ca) and inorganic phosphorous (P) at week 52. A significant decrease in calcium was also noted for females in the 1600 ppm group at 52 weeks.

For male groups, the 8000 ppm group showed a significant decrease in creatine phosphokinase (CPK) at week 52. But this change was not observed in the 50000 ppm group.

G. URINALYSIS
There were no findings among the quantitative or semi-quantitative and qualitative parameters during the treatment period.

H. NECROPSY
Organ weights
Males in the 1600 ppm group showed statistically significant increases in both absolute and relative weights of the pituitary. However, these changes were not observed in the 50000 or 8000 ppm groups of males.

In the 50000 or 8000 ppm groups, neither males nor females showed statistically significant changes in any organ weights.

Gross pathology
The macroscopic lesions observed in the present study were all sporadic in nature and there were no statistically significant differences in the incidence between the control and treated groups.

Histopathology
In the 50000 ppm group, focal pneumonia / focal granulomatous pneumonia in the lung was observed in all females. In the other female groups including the control group, the lesion was observed in only one of 4 animals each. However, the extent of the lesions was very focal and the degree of intensity was slight in all cases including those of the 50000 ppm group. Statistically, no significant differences between the control and dose groups were found in incidence of any histological lesions, including the pulmonary lesion.

III. CONCLUSIONS

Findings related to the treatment were demonstrated in clinical observation, body weight, urinalysis, haematology and blood chemistry.

50000 ppm group: Loose stool was observed in 3 of 4 males and 4 of 4 females. These animals frequently showed this clinical sign through the treatment period, whereas in the control group, only one animal in each sex showed the sign over a limited period during treatment. Body weight gain was retarded gradually with progression of the treatment in both sexes, when compared to the controls. Consequently, the difference in mean body weight between the 50000 ppm and control groups became great with time, although statistical significance was not observed. Haematologically, slight anaemic changes were noted for females at weeks 26 and 52. Females also showed significantly increased plasma level of chloride at week 26 and significantly decreased plasma levels of albumin and inorganic phosphorous at week 52. Significantly lowered urine pH values were continuously observed in males and females. However, this finding was not recognised as a toxic change since it is known that the test substance is secreted with little metabolism into urine, is degraded to a free acid in urine, and consequently, makes the urine acidic.

8000 and 1600 ppm groups: There were no treatment-related abnormalities in either sex.

Based on the results, the no-observable-effect level, minimum toxic level and sure toxic level of HR-001 to Beagle dogs under the conditions of the present study were determined as follow.

	Males	Females
No observable effect level	8000 ppm (182 mg/kg bw/day)	8000 ppm (184 mg/kg bw/day)
Minimum toxic level	50000 ppm (1203 mg/kg bw/day)	50000 ppm (1259 mg/kg bw/day)
Sure toxic level	≥50000 ppm (≥1203 mg/kg bw/day)	≥50000 ppm (≥1259 mg/kg bw/day)

3. Assessment and conclusion

Assessment and conclusion by applicant:
This oral 12-month toxicity study with glyphosate technical (HR-001) was conducted in Beagle dogs of both sexes. Groups of 4 males and 4 females each were given the test material via the diet at dose levels of 0, 1600, 8000 or 50000 ppm (equivalent to 0, 34.1, 182 or 1203 mg/kg bw/day for males and 0, 37.1, 184 or 1259 mg/kg bw/day for females) for a period of 12 months. The study was conducted according to OECD 409 (1981) and in general accordance with OECD 452 (1981).
Based on the study results the NOAEL in Beagle dogs after 1-year oral exposure to HR-001 is 8000 ppm (equivalent to 182 and 184 mg/kg bw/day for males and females, respectively).

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

In a toxicity study, groups of four male and four female Beagle dogs were fed diets containing 0 (control), 3000, 15000 or 30000 ppm glyphosate acid (equivalent to 0, 90.9, 440.3 or 906.5 mg/kg bw/day for males and 0, 92.1, 447.8 or 926.2 mg/kg bw/day for females) for a period of at least 1 year.

Clinical observations and veterinary examinations (including ophthalmoscopy) were made and body weights, food consumption and clinical pathology parameters were measured and at the end of the

scheduled period, the animals were killed and subjected to a full examination *post mortem*. Selected organs were weighed and specified tissues were taken for subsequent histopathology examination.

Mild toxicity was evident at 30000 ppm glyphosate acid, as a slight reduction in body weight in females throughout the latter half of the study. This reduction was generally independent of any reduction in food consumption and does not, therefore, reflect a palatability effect. There were no other toxicologically significant effects and the pathological no-effect level was 30000 ppm glyphosate acid.

Oral administration of 0, 3000, 15000 or 30000 ppm glyphosate acid in the diet for 52 weeks caused minimal toxicity at 30000 ppm, evident as a slight reduction in body weight in females. This dose level was equivalent to an overall mean dose of 906 mg/kg bw/day for males and 926 mg/kg bw/day for females.

B: Study design and methods

In-life dates: 1995-04-11 to 1996-04-12

Animal assignment

In a chronic toxicity study, groups of four male and four female Beagle dogs were fed diets containing 0 (control), 3000, 15000 or 30000 ppm glyphosate acid (equivalent to 0, 90.9, 440.3 and 906.5 mg/kg bw/day for males and 0, 92.1, 447.8 and 926.2 mg/kg bw/day for females) for a period of at least 1 year. A randomisation procedure was used which resulted in the even distribution of dogs (16 males and 16 females) to treatment groups according to body weight ensuring that litter mates were in different groups. Each morning, male dogs received 400 g and female dogs received 350 g of their appropriate experimental diet.

Table 5.3.2-117: Glyphosate Acid: 1 Year Dietary Toxicity Study in Dogs ([redacted], 1996): Study design

Test group	Dietary concentration [ppm]	Dose to animal (Males / Females) [mg/kg bw/day]	Males	Females
Control	0	0 / 0	1 – 4	5 – 8
Low	3000	90.9 / 92.1	9 – 12	13 – 16
Mid	15000	440.3 / 447.8	17 – 20	21 – 24
High	30000	906.5 / 926.2	25 – 28	29 – 32

Diet preparation and analysis

The experimental diets were made in 60 kg batches, by direct addition of glyphosate acid (allowing for purity) to ground Laboratory A diet, and mixed thoroughly. Water was then added to each batch and mixed prior to pelleting. The pellets were dried in the residual heat of an autoclave, allowed to cool and were then stored in bins at room temperature.

Samples from all dietary levels (including controls) were taken at approximately two-monthly intervals throughout the study and analysed quantitatively for glyphosate acid. The homogeneity of glyphosate acid in Lab diet A was determined by analysing samples from the low and high dose levels. The chemical stability of glyphosate acid in diet was determined over a period of up to 10 weeks (69 days) for these same diets.

Samples were extracted with water. Portions of the supernatant were diluted with water to give sample solution concentrations within the range of the calibration standards. These were derivatised using 9-fluorenylmethylchloroformate (FMOCCL) and analysed by High Performance Liquid Chromatography (HPLC).

Concentration analysis results: The mean achieved concentrations of glyphosate acid in analysed dietary preparation were typically within 12 % of nominal concentration.
The overall mean concentrations were within 9 % of target.

Homogeneity results: The homogeneity of glyphosate acid in diet at concentrations of 3000 ppm and 30000 ppm for a batch size of 60 kg was determined and considered satisfactory; percentage deviations from the overall mean where within 11 %.

Stability results: The chemical stability of glyphosate acid in experimental diets (determined at concentrations of 3000 ppm and 30000 ppm) when stored at room temperature, was shown to be satisfactory for 69 days. This covered the period of usage on the present study.

Observations

All dogs were observed at least three times daily for clinical behavioural abnormalities (at dosing, after dosing and at the end of the working day) and, on a weekly basis, they were given a thorough examination. Individual, daily assessments of gastro-intestinal findings were made for up to 5 hours post dosing: any subsequent assessments were made on a group basis. All dogs were also given a full clinical examination by a veterinarian pre-study, during weeks 13, 26, 39 and prior to termination. The examination included cardiac and pulmonary auscultation.

Body weight

All dogs were weighed weekly, before feeding, throughout the pre-study period, on day 1 and thereafter at weekly intervals until termination.

Food consumption and test substance intake
Food residues were recorded daily, approximately 4 hours after feeding and any residual food was discarded. These measurements were made for at least 2 weeks pre-study and throughout the treatment period.

Ophthalmoscopic examination
The eyes of all dogs were examined pre-study, during weeks 13, 26, 39 and prior to termination.

Haematology and clinical chemistry
Blood was collected from all dogs in weeks -1, 4, 13, 26 and prior to termination into tubes containing EDTA or trisodium citrate and the following parameters measured: Haemoglobin, haematocrit, red blood cell count, mean cell volume, mean cell haemoglobin, prothrombin time, blood cell morphology, mean cell haemoglobin concentration, platelet count, total white cell count, differential white cell count, red cell distribution width activated partial thromboplastin time and bone marrow smears (taken but not examined).

Clinical chemistry
Blood was collected from all dogs in weeks -1, 4, 13, 26 and prior to termination into tubes containing lithium heparin and the following parameters measured: Urea, creatinine, glucose, albumin, total protein, cholesterol, triglycerides, total bilirubin, creatine kinase activity, alkaline phosphatase activity, aspartate aminotransferase activity, alanine aminotransferase activity, gamma-glutamyl transferase activity, calcium, phosphorus (as phosphate), sodium, potassium and chloride.

Urinalysis
Urine was collected by catheterisation, pre-experimentally, in week 26 and during the week prior to termination. The following parameters were measured and recorded on each urine sample: Volume, colour (if abnormal), specific gravity, pH, glucose, ketones, protein, bilirubin and blood.
In addition, each urine sample was centrifuged and the sediment stained and examined microscopically to identify the components.

Investigations *post mortem*

Macroscopic examination
All animals were killed by exsanguination under terminal anaesthesia induced by intravenous administration of sodium pentobarbitone and examined *post mortem*.

Organ weights
From all animals surviving to scheduled termination, the following organs were removed, trimmed free of extraneous tissue and weighed: Adrenal glands, brain, epididymides, thyroid glands, kidneys, liver and testes.

The left and right components of paired organs were weighed separately.

Tissue submission
The following tissues were examined *in situ*, removed and examined and fixed in an appropriate fixative: Gross lesions including masses, adrenal gland, aorta, brain (cerebrum, cerebellum and brainstem), bone marrow (sternum), caecum, colon, duodenum, epididymides, eyes (retina, optic nerve), femur (including stifle joint, stored not examined), gall bladder, heart, ileum, jejunum, kidney, larynx, liver, lung, lymph node – prescapular, lymph node – mesenteric, mammary gland (females only), peripheral nerve (sciatic), oesophagus, ovary, pancreas, parathyroid gland, pituitary gland, prostate gland, rectum, salivary gland, spinal cord (cervical, thoracic, lumbar), skin, spleen, sternum, stomach, testis, thymus, thyroid gland, trachea, urinary bladder, uterus (with cervix) and voluntary muscle.

Microscopic examination
All processed tissues were examined by light microscopy.

Statistics
All data were evaluated using analysis of variance and / or covariance for each specified parameter using the GLM procedure in SAS (1989).

II. RESULTS AND DISCUSSION

A. MORTALITY
None of the dogs died.

B. CLINICAL OBSERVATIONS
There were no toxicologically significant findings. Salivation at dosing was observed in individual dogs in all treatment groups throughout the study. The apparent increased incidence in two top dose males and one female was considered to be related to anticipation of feeding and not to treatment with glyphosate acid. There was also a low incidence of scrotal skin reddening seen in one male in each treatment group; this was considered to be incidental to treatment with glyphosate acid.

There was no increased incidence of faecal abnormalities in dogs treated with glyphosate acid.

C. BODY WEIGHT AND BODY WEIGHT GAIN
There was a slight body weight effect evident in females fed 30000 ppm glyphosate acid with a maximum reduction of 11 % (compared to controls) in week 51. These dogs showed a gradual reduction in growth rate, compared to the controls, which was consistently statistically significant from week 23 onwards. One female lost 0.6 kg during week 32 but this was related to a loss of appetite during this time. There were no effects in males at any dose level or in females at 15000 ppm but females fed 3000 ppm glyphosate acid also showed slightly poorer growth than the controls, with a maximum reduction of 8 % in week 51. However, this effect only achieved statistical significance on occasions during the study and is considered attributable to the poorer growth of two females and not an effect of glyphosate acid, since there was no effect at 15000 ppm.

Table 5.3.2-118: Glyphosate Acid: 1 Year Dietary Toxicity Study in Dogs ([redacted] 1996): Intergroup comparison of body weights [kg] (selected time points; adjusted mean values shown for weeks 2-53)

Week	Dietary Concentration of Glyphosate acid [ppm]							
	Males				Females			
	0	3000	15000	30000	0	3000	15000	30000
1	11.40 ± 1.19	↑11.53 ± 0.83	↓11.33 ± 0.95	↑11.45 ± 0.83	9.60 ± 0.80	↓9.55 ± 0.69	↓9.48 ± 0.55	↓9.58 ± 0.99
8	12.66 ± 0.92	↓12.40 ± 0.49	↓12.48 ± 0.82	↓12.37 ± 0.88	10.74 ± 0.88	**↓10.40* ± 0.66**	↓10.68 ± 0.73	**↓10.42* ± 0.81**
16	13.35 ± 0.99	↓12.97 ± 0.92	↓13.28 ± 0.83	↓12.95 ± 0.79	11.46 ± 0.94	**↓11.03* ± 0.61**	↑11.50 ± 0.96	**↓10.99* ± 0.87**
32	14.19 ± 0.94	↓13.69 ± 1.48	↓13.93 ± 1.15	↓13.69 ± 0.85	12.28 ± 0.80	**↓11.63* ± 0.49**	↑12.59 ± 1.35	**↓11.46** ± 1.17**

* Statistically significant difference from control group mean ($p < 0.05$; Student's t-test, 2-sided);
** Statistically significant difference from control group mean ($p < 0.01$ Student's t-test, 2-sided)

D. FOOD CONSUMPTION AND COMPOUND INTAKE
There was no effect on food consumption but 3 dogs (one male mid dose and 2 females top dose) left food on occasions which affected the group mean values. Dose rates (based on nominal dietary levels of glyphosate acid) were calculated in terms of mg/kg bw/day. Mean values are shown below:

Table 5.3.2-119: Glyphosate Acid: 1 Year Dietary Toxicity Study in Dogs ([redacted], 1996): Mean Dose Received [mg/kg bw/day]

Glyphosate acid [ppm]	3000	15000	30000
Males	90.9	440.3	906.5
Females	92.1	447.8	926.2

E. OPHTHALMOSCOPIC EXAMINATION

There was a very low incidence of corneal or lenticular opacities but these were seen both in control animals as well as those fed glyphosate acid. There were no treatment related abnormalities.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

There were no differences in haematological parameters which were considered to be related to treatment.

Blood clinical chemistry

There were no toxicologically significant findings.

Plasma cholesterol levels were increased slightly in the treated groups of both sexes at weeks 26 and 52 but there was no evidence of any dose relationship.

Plasma phosphorus levels were lower in the male treated groups at week 52 but this was due, in part, to slightly higher individual control values. Similarly, the reduced sodium value in males fed 30000 ppm at week 52 was due solely to one male.

Various animals in all groups (including controls) showed evidence of higher plasma alanine aminotransferase, aspartate aminotransferase and creatine kinase activities throughout the study as well as pre-experimentally, but there was little evidence of any conclusive group effects.

Other statistically significant differences were minor and/or not dose related and were considered to be of no toxicological significance.

Table 5.3.2-120: Glyphosate Acid: 1 Year Dietary Toxicity Study in Dogs ([redacted], 1996): Intergroup comparison of blood clinical chemistry selected parameters and time points (adjusted mean values)

Parameter	Week	Dietary Concentration of Glyphosate acid [ppm]							
		Males				Females			
		0	3000	15000	30000	0	3000	15000	30000
Cholesterol [mmol/L]	26	3.78 ± 0.34	↑**4.48* ± 0.31**	↑3.96 ± 0.26	↑**4.40* ± 0.65**	4.28 ± 0.96	↑4.59 ± 0.70	↑**4.88* ± 0.60**	↑4.86 ± 0.36

* Statistically significant from controls ($p < 0.05$);
** Statistically significant from controls ($p < 0.01$)

G. URINALYSIS

There were no differences in urine clinical chemistry parameters which were considered to be related to treatment.

H. SACRIFICE AND PATHOLOGY

Organ weights

There were no treatment related effects on any organ weights. Adrenal weights were slightly raised in the male 3000 ppm group but this was exaggerated by a low value for one male in the control group.

Macroscopic findings

Several treated females showed red areas in or diffuse reddening of the urinary bladder mucosa. The incidence was not clearly related to dose and in the absence of a similar effect in males it was considered unlikely that the lesion is related to the administration of glyphosate acid.

Microscopic findings

It was considered unlikely that any of the lesions confined to the treated groups were related to the administration of glyphosate acid as they were either of low incidence or the incidence was not related to dose. The pathological no-effect level for glyphosate acid was 30000 ppm.

III. CONCLUSIONS

Mild toxicity was evident at 30000 ppm glyphosate acid, as a slight reduction in body weight in females throughout the latter half of the study. This reduction was generally independent of any reduction in food consumption and does not, therefore, reflect a palatability effect. There were no other toxicologically significant effects and the pathological no-effect level was 30000 ppm glyphosate acid.

Oral administration of 0, 3000, 15000 or 30000 ppm glyphosate acid in the diet for 52 weeks caused minimal toxicity at 30000 ppm, evident as a slight reduction in body weight in females. This dose level was equivalent to an overall mean dose of 906 mg/kg bw/day for males and 926 mg/kg bw/day for females.

There were no other treatment related findings and the pathological no-effect level was 30000 ppm glyphosate acid.

The no-observed adverse effect level (NOAEL) for toxicity over 1 year for females was 15000 ppm glyphosate acid (equivalent to an overall mean dose of 447 mg/kg bw/day). The no-observed adverse effect level (NOAEL) for toxicity over 1 year for males was 30000 ppm glyphosate acid (equivalent to an overall mean dose of 906 mg/kg bw/day).

3. Assessment and conclusion

Assessment and conclusion by applicant:

In this toxicity study, groups of four male and four female Beagle dogs were fed diets containing 0 (control), 3000, 15000 or 30000 ppm glyphosate acid (equivalent to 0, 90.9, 440.3 or 906.5 mg/kg bw/day for males and 0, 92.1, 447.8 or 926.2 mg/kg bw/day for females) for a period of at least 1 year. The study was conducted according to OECD 452 (1981) and in compliance with GLP (no certificate of the competent authority was provided).

Oral administration of glyphosate acid in the diet for 52 weeks caused minimal toxicity at 30000 ppm, evident as a slight reduction in body weight in females. This dose level was equivalent to an overall mean dose of 906 mg/kg bw/day for males and 926 mg/kg/ bw/day for females.

There were no other treatment-related findings and the pathological no-effect level was 30000 ppm glyphosate acid.

The NOAEL for toxicity over 1 year for females was 15000 ppm glyphosate acid (equivalent to an overall mean dose of 447 mg/kg bw/day). The NOAEL for toxicity over 1 year for males was 30000 ppm glyphosate acid (equivalent to an overall mean dose of 906 mg/kg bw/day).

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.3.2/035
Report author	[redacted]
Report year	1990
Report title	Glyphosate: 52 Week Oral Toxicity Study in Dogs
Report No	7502
Document No	Not reported
Guidelines followed in study	OECD 409 (1981), FIFRA 83-1, in general compliance with OECD 452 (1981)
Deviations from current test guideline (OECD 409, 1998; OECD 452, 2018)	Activated partial thromboplastin time not measured. Clinical signs poorly reported in the report. Deviations from the current versions of OECD 409 (1998) and OECD 452 (2018) are basically due to the fact that the study was aligned to older versions of the OECD test guidelines.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
In a 52-week oral study, groups of four male and four female Beagle dogs were administered glyphosate daily via capsule at dose levels of 0, 30, 300 or 1000 mg/kg bw/day.

Clinical observations were made daily. Body weights and food consumption were assessed in weekly intervals. Ophthalmoscopic examination was performed pre-test and during weeks 13, 29, 39 and 51. Haematological, blood biochemistry parameters, as well as urine and faecal analysis for occult blood were conducted prior to start of treatment and at weeks 13, 26, 39 and 51 of treatment. Plasma levels of glyphosate were determined after weeks 1, 12 and 51 of treatment. Red blood cell and plasma cholinesterase activity were measured at weeks 13, 26, 39 and 51 and brain cholinesterase measured at termination. At the end of the scheduled period, the animals were sacrificed and subjected to a full examination *post mortem*. Selected organs were weighed and tissues were taken for subsequent histopathology examination.

There were no mortalities in any of the dose groups. Changes in faecal consistency (soft/loose/liquid) were recorded more frequently for the animals in the high dose group throughout the dosing period. This finding was observed 4 – 6 h after dosing and was also recorded on isolated occasions for a few animals of the intermediate dose group. A reduction in body weight gain was recorded for all treated groups males (low

dose: approximately 17 % of control, intermediate and high dose: approximately 25 % of control). In the females, only the high dose group showed a reduction in body weight gain of approximately 19 % of control. These body weight differences did not achieve statistical significance and may have been a chance effect. The mean food consumption in treatment groups was not significantly different from controls. Ocular examinations revealed no treatment related abnormalities. There were no haematological or clinical chemistry changes observed that could be associated with treatment with glyphosate. Red blood cell, plasma, and brain cholinesterase activity was similar between all groups. There were no changes in any urinalysis parameters examined to indicate a treatment-related effect. Occult blood determinations performed on faecal samples obtained at the time of urine collections were negative for all animals throughout the study. There were no significant in absolute or relative (to body weight) organ weight differences between groups for either sex attributable to treatment with glyphosate. No pathologically significant gross or microscopic findings in any group could be related to treatment.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	Not reported
Lot/Batch #:	206-Jak-25-1; 206-Jak-59-3; 229-Jak-5-1;
Purity:	98.6 %; 99.5 %; 98.9 %
Stability of test compound:	Shown stable in capsule for at least 7 days

2. Vehicle and/or positive control: Clear gelatine capsule (empty)

3. Test animals:

Species:	Dog
Strain:	Beagle
Source:	[redacted]
Age:	Approx. 5 – 6 months
Sex:	Male and female
Weight at dosing:	♂ 8.2 – 12.1 kg; ♀ 6.7 – 11.7 kg
Acclimation period:	3-weeks
Diet/Food:	SDS Dog Diet A, 400 g/day.
Water:	Tap water, *ad libitum*
Housing:	Paired in custom-designed pens
Environmental conditions:	Temperature: ~19 °C (12 – 25 °C) Humidity: ~50 % (30 – 83 %) Air changes: Not reported 12 hours light/dark cycle

B: Study design and methods

In life dates: 1989-08-29 to 1990-08-30

Animal assignment and treatment:
Four male and four female dogs per dose level received glyphosate technical (source Cheminova A/S, Lemvig, Denmark) orally, by capsule administration, once daily for 52 consecutive weeks. Three batches

of the test material (206-Jak-25-1, purity: 98.6 %; 206-Jak-59-5, purity: 99.5 % and 229-Jak-5-1, purity: 98.9 %) were used during the course of the study. The bulk powder was encapsulated in hard, clear gelatin capsules. The individual test substance amount to be given was calculated weekly on the basis of each dog's most recently recorded body weight. Multiple-capsule administration was necessary in the high dose groups and, to ensure equal conditions, in the controls. The dose levels of 0 (vehicle control group receiving empty capsules), 30, 300 and 1000 mg/kg bw/day were selected on the basis of the results from a previous maximum tolerated dose study ([redacted], 1989). Regular analyses of the capsule preparations performed at 3 monthly intervals revealed deviations of the actual from the nominal compound weight varying within tolerable limits (<5 %). Encapsulated Glyphosate was shown to be stable for at least 7 days in the capsules.

Table 5.3.2-121: Glyphosate: 52 Week Oral Toxicity Study in Dogs ([redacted], 1990): Study design

Test group	Dose Level [mg/kg bw/day]	Males	Females
Control	0	4	4
Low	30	4	4
Intermediate	300	4	4
High	1000	4	4

Mortality
Each animal was checked for mortality or signs of morbidity during the daily clinical observations.

Clinical observations
A check for clinical signs of toxicity was made once daily.

Body weight
The body weight of each animal was recorded weekly starting two weeks before the start of treatment.

Food consumption and utilisation
Individual food consumption was recorded daily starting two weeks before the start of treatment.

Ophthalmoscopic examination
Ophthalmoscopy was performed at pre-test and again during weeks 13, 29, 39 and 51 of treatment.

Haematology and clinical chemistry
Laboratory investigations of haematology and clinical chemistry were performed on all the dogs before dosing started and again during weeks 13, 26, 39 and 51 of treatment. The blood samples were taken from the jugular vein after the dogs had been fasted overnight, any food residues being withdrawn at approximately 1400 hours on the day before sampling.

EDTA was used as an anti-coagulant for evaluation of all parameters with the exception of prothrombin time for which citrate was used. The following haematological parameters were measured: Haemoglobin, haematocrit, red blood cell count, mean cell volume (MCV), mean cell haemoglobin (MCH), mean cell haemoglobin concentration (MCHC), reticulocyte count, total white blood cell and differential counts, platelet count and prothrombin time. Femoral bone marrow smears were taken at necropsy, air-dried and methanol-fixed but were not evaluated as there were no changes in peripheral blood or red cell morphology.

For clinical chemistry evaluations, heparin was used as an anti-coagulant and plasma analysed for the following parameters: Blood urea nitrogen, glucose, aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, sodium, potassium, calcium, chloride, creatinine, total protein, protein electrophoresis, albumin, albumin/globulin ratio, cholesterol, triglycerides, alkaline phosphatase, gamma

glutamyl transpeptidase, phosphate, total bilirubin, red blood cell, plasma and brain cholinesterase.

Whole blood was collected from all the animals via the jugular vein into lithium heparinised tubes after 1, 12 and 51 weeks of treatment. Immediately after collection, the samples were centrifuged, the plasma separated and stored deep frozen (-20 °C) until subsequent analysis for plasma levels of glyphosate.

Urinalysis/Faecal analysis
Urine samples were collected from all dogs housed in metabolism cages over the final 17 hours of a 21 hour period of water deprivation during weeks 13, 26, 39 and 51 of treatment. The following parameters were measured: Appearance, volume, pH, specific gravity, proteins, glucose, ketones, blood pigments, bilirubin and urobilinogen. Microscopic examination of the spun urine deposit was performed for the presence of epithelial cells, white blood cells, red blood cells, crystals, organisms and abnormal constituents.
Faecal analysis for occult blood was performed at the time of the urine collections.

Sacrifice and pathology
After 52 weeks of consecutive treatment, all surviving animals were sacrificed by intravenous pentobarbitone followed by exsanguination and subjected to a gross pathological examination. Any macroscopic findings were recorded. Terminal body weights were recorded immediately after sacrifice.
The following organ weights were determined: Adrenals, thyroids with parathyroids, pituitary, brain, heart, liver and gallbladder (drained), kidneys, lungs, spleen, pancreas, thymus, testes with epididymides, prostate, uterus, ovaries and salivary gland (submaxillary, sublingual and parotid).

Tissue samples were taken from the following organs and preserved in buffered formalin: All gross lesions, adrenals, aortic arch, brain (3 sections), caecum, colon, duodenum, epididymides, eyes, heart, ileum, jejunum, kidneys, liver and gall bladder, lungs, lymph nodes (mandibular and mesenteric), mammary gland, oesophagus, ovaries, pancreas, pituitary gland, prostrate, rectum, salivary gland (submaxillary, sublingual and parotid), spinal cord, sciatic nerve, skeletal muscle, skin, spleen, stomach, sternum, testes, thymus, thyroid/parathyroids, tongue, trachea, urinary bladder and uterus. All tissues above from all groups were examined histopathologically.

Statistics
Haematology, clinical chemistry and body weight gain data were statistically analysed for homogeneity of variance using the 'F-max' test. If the group variance appeared homogeneous a parametric ANOVA was used and pairwise comparisons made via Student's t-test using Fisher's F-protected LSD. If the variance were heterogeneous, log or square root transformations were used in an attempt to stabilise the variances. If the variances remained heterogeneous then a non-parametric test such as Kruskal-Wallis ANOVA was used and pairwise comparisons made via the Dunn Z test where considered appropriate. Histological findings were analysed using Fisher's Exact Probability test. Organ weights were analysed relative to body weight.

II. RESULTS AND DISCUSSION

A. MORTALITY
There were no mortalities.

B. CLINICAL OBSERVATIONS
Changes in faecal consistency (soft/loose/liquid) were recorded more frequently for the animals in the high dose group throughout the dosing period. This finding was observed 4 – 6 h after dosing and was also recorded on isolated occasions for a few animals of the intermediate dose group. There were no other clinical signs related to treatment with Glyphosate. Numerical incidence and frequency are not provided in the study report.

C. BODY WEIGHT
A lower body weight gain was recorded for males in all treated groups (low dose: approximately 17 % of control, intermediate and high dose: approximately 25 % of control). In the females, only the high dose

group showed a lower body weight gain of approximately 19 % of control. These differences did not achieve statistical significance and may have been a chance effect.

Table 5.3.2-122: Glyphosate: 52 Week Oral Toxicity Study in Dogs ([redacted], 1990): Intergroup comparison of mean body weights and body weight gain – selected time points from start of study

Dose [mg/kg bw/day]	Initial body weight [kg]	Final body weight [kg]	Total weight gain [kg]	Total weight gain [% of controls]
Males				
0	10.1	14.9	4.8	-
10	↑10.3	↓14.3	↓4.0	83 %
300	↑10.2	↓13.8	↓3.6	75 %
1000	↑10.3	↓13.9	↓3.6	75 %
Females				
0	8.8	12.4	3.6	-
10	↓8.7	↑12.6	↑3.9	108 %
300	↑9.0	↑13.1	↑4.1	114 %
1000	↓8.7	↓11.6	↓2.9	81 %

D. FOOD CONSUMPTION AND TEST SUBSTANCE INTAKE

The mean food consumption in treatment groups was not significantly different from controls.

Analysis of glyphosate in the hard gelatin capsules showed an acceptable degree of accuracy in capsule preparation (<5 % deviation from nominal weight). There was no indication of degradation of encapsulated glyphosate over 7 days under the storage conditions employed. Plasma analysis indicated good proof of absorption and the levels of glyphosate in plasma were dose related. Plasma concentrations of glyphosate at week 1 ranged from 0.24 – 0.38, 1.29 – 2.17 and 5.44 – 10.23 µg/mL for low-, intermediate- and high dose males, respectively. Plasma concentrations of glyphosate at week 1 for females ranged from 0.16 – 1.01, 1.06 – 1.80 and 2.13 – 6.86 µg/mL for low-, intermediate- and high dose females, respectively. Plasma concentrations of glyphosate at week 52 ranged from 0.14 – 0.47, 0.99 – 2.64 and 3.18 – 9.49 µg/mL for low-, intermediate- and high dose males, respectively. Plasma concentrations of glyphosate at week 52 for females ranged from 0.24 – 0.63, 1.07 – 2.75 and 6.07 – 10.50 µg/mL for low-, intermediate- and high dose females, respectively.

E. OPHTHALMOSCOPIC EXAMINATION

Ocular examinations revealed no treatment-related abnormalities. There were incidental background observations which are commonly seen in dogs that were considered to be unrelated to treatment.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

All haematological parameters assessed gave values that were generally within the normal reference ranges for the species. There were no haematological changes observed that could be associated with treatment with glyphosate.

Blood clinical chemistry

There were no changes in the clinical chemistry parameters indicative of any treatment-related effects.

Red blood cell, plasma and brain cholinesterase activity was similar between all groups.

G. URINALYSIS AND FAECAL ANALYSIS

There were no changes in any of the parameters examined to indicate a treatment-related effect. Only the normal variations such as a few positive results for blood pigments and red blood cells were identified at pretrial and during the treatment period. In some instances, these positive results were attributable to the

animals being in oestrous.

Occult blood determinations performed on faecal samples obtained at the time of urine collections were negative for all animals throughout the study.

H. NECROPSY

Organ weights
There were no significant absolute or relative (to body weight) organ weight differences between groups for either sex attributable to treatment with glyphosate.

Gross pathology
Very few findings were noted and there were no significant differences between controls and glyphosate-treated animals.

Histopathology
No pathologically significant findings were recorded in any group and there were no differences in incidences which could be related to treatment.

III. CONCLUSIONS

There were no mortalities in any of the dose groups. Changes in faecal consistency (soft/loose/liquid) were recorded more frequently for the animals in the high dose group throughout the dosing period. This finding was observed 4 – 6 h after dosing and was also recorded on isolated occasions for a few animals of the intermediate dose group. A reduction in body weight gain was recorded for all treated groups males (low dose: approximately 17 % of control, intermediate and high dose: approximately 25 % of control). In the females, only the high dose group showed a reduction in body weight gain of approximately 19 % of control. These body weight differences did not achieve statistical significance and may have been a chance effect. The mean food consumption in treatment groups was not significantly different from controls. Ocular examinations revealed no treatment related abnormalities. There were no haematological or clinical chemistry changes observed that could be associated with treatment with glyphosate. Red blood cell, plasma, and brain cholinesterase activity was similar between all groups. There were no changes in any urinalysis parameters examined to indicate a treatment-related effect. Occult blood determinations performed on faecal samples obtained at the time of urine collections were negative for all animals throughout the study. There were no significant in absolute or relative (to body weight) organ weight differences between groups for either sex attributable to treatment with glyphosate. No pathologically significant gross or microscopic findings in any group could be related to treatment.

Chronic oral administration of glyphosate at dose levels up to 1000 mg/kg bw/day in Beagle dogs did not cause systemic organ toxicity. However, the 1000 mg/kg bw/day dose level (highest dose tested) was considered to be the maximum tolerated dose in view of the effect on faecal consistency at this dose level.

The no-effect level (NOEL) was judged to be 300 mg glyphosate/kg bw/day.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this 52-week oral study, groups of four male and four female Beagle dogs were administered glyphosate daily via capsule at dose levels of 0, 30, 300 or 1000 mg/kg bw/day. The study was conducted according to OECD 409 (1981) and in general compliance with OECD 452 (1981).
Chronic oral administration of glyphosate over a period of 52 weeks at dose levels up to 1000 mg/kg bw/day in Beagle dogs was free of systemic organ toxicity. However, the 1000 mg/kg bw/day highest dose level tested was considered to be the maximum tolerated dose in view of an effect on faecal consistency at this dose level. Therefore, the NOAEL was judged to be the intermediate dose of 300 mg/kg bw/day.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.3.2/036
Report author	[redacted]
Report year	1985
Report title	Twelve Month Study of Glyphosate Administered by Gelatin Capsule to Beagle Dogs
Report No	[redacted]-4965
Document No	Not reported
Guidelines followed in study	No guideline statement, but in general accordance with OECD 452 (1981)
Deviations from current test guideline (OECD 452, 2018)	Urine volume not measured, spleen and uterus not weighed, unclear of number and location of brain sections observed microscopically. Deviations from the current version of OECD 452 (2018) are basically due to the fact that the study was aligned to an older version of the OECD test guideline 452.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
Glyphosate was administered orally by gelatin capsule to groups of six male and six female Beagle dogs at daily doses of 0, 20, 100 or 500 mg/kg bw/day for approximately twelve months.

Clinical observations were done twice daily. Weekly determinations of individual body weight were performed for fourteen weeks and bi-weekly determinations were made thereafter. Ophthalmologic examinations were performed at pretest and prior to final necropsy on all animals. Haematological, blood biochemistry parameters, as well as urine analysis, were conducted prior to start of treatment and during

months 3, 6, and 12 of treatment. At the end of the scheduled dosing period, the animals were sacrificed and subjected to a full examination post mortem. Selected organs were weighed and specified tissues were taken for subsequent histopathology examination.

There were no mortalities in any of the dose groups. Slightly higher incidences of abnormal excrement (bloody stool, yellow mucoid stool, diarrhoea, and emesis) were observed in low and high level females when compared to their control group. Approximately one-half of these observations were attributable to only one female dog from each of these groups of 6 animals per group. Females at the middle exposure level and males at all treatment levels had incidences of abnormal excrement similar to that of the control groups. One mid dose and one high dose female had localised skin redness with slight alopecia throughout most of the study. Body weight, food consumption and ophthalmologic findings were normal throughout the test duration. Haematology, clinical chemistry and urine pathologic parameters plus gross and microscopic findings revealed no changes attributable to glyphosate exposure.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate
Description:	White granular solid
Lot/Batch #:	NBP 2472136
Purity:	96.17 %
Stability of test compound:	Shown stable during the dosing period

2. Vehicle and/or positive control: Empty gelatin capsule

3. Test animals:

Species:	Dog
Strain:	Beagle
Source:	[redacted]
Age:	Approx. 6 months
Sex:	Male and female
Weight at dosing:	♂ 6.2 – 9.0 kg; ♀ 5.5 – 7.5 kg
Acclimation period:	Approx. 5 weeks
Diet/Food:	Purina Certified Dog Chow® 5007 (400 g available over 2 – 3 hour period)
Water:	Tap water, *ad libitum*
Housing:	Individually in stainless steel dog cages
Environmental conditions:	Temperature: 20 – 22 °C (68 – 72 °F) Humidity: Not reported Air changes: Not reported

B: Study design and methods

In life dates: 1983-09-20 to 1984-09-24

Animal assignment and treatment:

Six male and six female dogs per dose level received glyphosate orally by gelatin capsule administration, once daily for approximately 12 consecutive months. Dogs were dosed approximately one to six hours after food was removed each day. Doses were adjusted to correspond with each animal's most recent body weight. Capsules were prepared each week. The dose levels were 0 (vehicle control group receiving one empty capsule), 20, 100 and 500 mg/kg bw/day. The high dose was set based on the maximum capsule size and number of capsules (two 1/8 oz. capsules) that could be reasonably administered daily to dogs of this size over one year. Each capsule could hold a maximum of approximately 3 grams of packed glyphosate. Analyses after the completion of the study indicated 97.04 % glyphosate compared to an assay (conducted prior to the study) provided by the sponsor of 96.17 % glyphosate. The ± 0.87 % variation of analyses was within analytical limits and no decomposition of glyphosate was demonstrated.

Table 5.3.2-123: Twelve Month Study of Glyphosate Administered by Gelatin Capsule to Beagle Dogs ([redacted], 1985): Study design

Test group	Dose Level [mg/kg bw/day]	Males	Females
Control	0	6	6
Low	20	6	6
Mid	100	6	6
High	500	6	6

Mortality
Each animal was checked for mortality or signs of morbidity at least twice daily during the treatment period.

Clinical observations
A check for clinical signs of toxicity was made at least twice daily (morning and afternoon) on all animals.

Body weight
Weekly determinations of individual body weight were performed for fourteen weeks. Bi-weekly determinations were made thereafter.

Food consumption and utilisation
Weekly determinations of daily food consumption were performed for fourteen weeks. Bi-weekly determinations were made thereafter.

Ophthalmoscopic examination
Ophthalmologic examinations were performed at pretest and prior to final necropsy on all animals.

Haematology and clinical chemistry
Laboratory investigations of haematology and clinical chemistry were performed on all the dogs before dosing started and again during months 3, 6, and 12 of treatment. The blood samples were taken from the jugular vein after the dogs had been fasted overnight.

EDTA was used as an anti-coagulant for evaluation of all parameters with the exception of prothrombin time for which citrate was used. The following haematological parameters were measured: Haemoglobin, haematocrit, red blood cell count, mean cell volume (MCV), mean cell haemoglobin (MCH), mean cell haemoglobin concentration (MCHC), reticulocyte count, total white blood cell and differential counts, platelet count and prothrombin time.

For clinical chemistry evaluations, serum was harvested from whole blood and analysed for the following parameters: Blood urea nitrogen, glucose, aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, sodium, potassium, calcium, chloride, creatinine, total protein, albumin, globulin, cholesterol, alkaline phosphatase, gamma glutamyl transpeptidase, phosphorus, direct and total bilirubin.

Urinalysis
Urinalysis was performed on all the dogs before dosing started and again during months 3, 6, and 12 of treatment. Urine was collected using metabolism cages. The following parameters were measured: Appearance, pH, specific gravity, proteins, glucose, ketones, blood pigments, bilirubin and urobilinogen. Microscopic examination of the spun urine deposit was performed for the presence of bacteria, epithelial cells, white blood cells, red blood cells, crystals and abnormal constituents.

Sacrifice and pathology
After 12 months of consecutive treatment, all surviving animals were fasted overnight, sacrificed by intravenous sodium pentobarbital followed by exsanguination and subjected to a gross pathological examination. Terminal body weights were recorded immediately prior to sacrifice.

The following organ weights were determined: Adrenals, thyroids with parathyroids, pituitary, brain, heart, liver, kidneys, testes with epididymides and ovaries.

Tissue samples were taken from the following organs and preserved in buffered formalin: All gross lesions, adrenals, aorta, brain, caecum, colon, duodenum, epididymides, eyes, heart, ileum, jejunum, kidneys, liver, gallbladder, lungs, lymph nodes, mammary gland, oesophagus, ovaries, pancreas, pituitary gland, prostrate, rectum, rib, salivary gland (mandibular), spinal cord (cervical, mid-thoracic, lumbar), sciatic nerve, skeletal muscle, skin, spleen, stomach, testes, thymus, thyroid/parathyroids, trachea, urinary bladder and uterus. All tissues above from all groups were examined histopathologically.

Statistics
Non-categorical data from haematology, serum chemical and urinalysis were statistically examined by Dunnett's test for the comparison of multiple treatments with a control, and/or by inspection. Categorical data were examined to determine any remarkable group differences. Statistical evaluation of differences in body weights, food consumptions, terminal body weights and absolute organ weights between treated and control groups was accomplished by the use of Dunnett's test. The Mann-Whitney test with Bonferroni's inequality procedure was used to assess the organ/body weight ratios. Frequency of microscopic lesions between treated groups and controls was evaluated by the use of Fisher's Exact Test with Bonferroni's inequality procedure.

II. RESULTS AND DISCUSSION

A. MORTALITY
There were no mortalities.

B. CLINICAL OBSERVATIONS
Slightly higher incidences of abnormal excrement (bloody stool, yellow mucoid stool, diarrhoea, emesis) were observed in low and high level females when compared to their control group. Approximately one half of these observations were attributable to one female dog (approx. 17 %) from each of these groups. Females at the middle exposure level and males at all treatment levels had incidences of abnormal excrement similar to that of the control groups. One mid dose and one high dose female had localized skin redness with slight alopecia throughout most of the study. One low dose male had similarly reddened skin, but his condition lasted for a relatively short time. All other animals' skin was unaffected. These findings were considered of questionable relationship to Glyphosate administration due to a lack of apparent dose-relationship. The remaining observations were not unusual and were not attributed to glyphosate exposure.

C. BODY WEIGHT
No significant body weight changes occurred between any of the dose groups.

D. FOOD CONSUMPTION AND TEST SUBSTANCE INTAKE
There were no treatment-related effects. Food consumption in treatment groups was comparable to controls. Test compound was administered by gelatin capsule with dosages adjusted according to individual animal

body weight. Determination of the degree of absorption of the test item following dosing was not performed.

E. OPHTHALMOSCOPIC EXAMINATION

There were no test substance-related ophthalmological findings at the end of the treatment period.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

There were no changes in haematology parameters considered associated with glyphosate administration. Mild elevations in red blood cell counts (RBC), haemoglobin (HGB) and haematocrit (Hct) for low dose females at all test periods were similar to those observed at pretest. Mild changes in MCHC in males from the mid dose group (pretest and 12 months) and females from the low and mid dose groups (at 3 and 12 months) were not considered biologically significant.

Blood clinical chemistry

Phosphorus levels were statistically decreased in females from the low and high dose groups at 3 months and high dose group at 12 months when compared to controls. At 3 months, serum glutamic pyruvic transaminase (SGPT) values were significantly increased for high dose females. Sodium and potassium values were decreased in both sexes from high dose groups and for mid dose group males at 3 months, however this statistical difference was largely caused by slightly low control values at this time point. Statistically significant changes occurred in serum sodium (mid dose), glucose (mid dose) and calcium (low dose) values among males at 12 months. At 6 months, increased albumin values were statistically significant in females from the low dose group.

Decreased phosphorus levels, although statistically significant in females at 3 and 12 months, did not appear to be related to compound administration since the values were within the normal range. The changes in SGPT, sodium, potassium, calcium, glucose and albumin values were transient and/or within the normal range and were not considered an effect of glyphosate exposure.

** Statistically significant from controls ($p < 0.01$)

G. URINALYSIS

There were no urine abnormalities detected at any of the sampling periods.

H. NECROPSY

Organ weights

Absolute and relative (to body weight) pituitary weights for males from mid and high dose groups and absolute brain weights for males from mid dose group were statistically lower than controls at the terminal sacrifice. Reductions in pituitary weights were not conclusively associated with compound administration. There were no microscopic changes correlated with these reductions. Reduced brain weights did not follow a dose-related trend and were not considered a treatment effect. No other significant differences were observed in absolute organ weights or organ to body weight ratios.

Table 5.3.2-125: Twelve Month Study of Glyphosate Administered by Gelatin Capsule to Beagle Dogs ([redacted], 1985): Results from select absolute and relative organ weight determination

	Dose Level [mg/kg bw/day]							
	Males				Females			
	0	20	100	500	0	20	100	500

* Statistically significant from controls ($p < 0.05$);
** Statistically significant from controls ($p < 0.01$)

Gross pathology

There were no compound-related or biologically significant differences in the incidence of gross lesions between the glyphosate treated animals and controls.

Histopathology

There were no histopathological findings related to treatment.

III. CONCLUSIONS

There were no mortalities in any of the dose groups. Slightly higher incidences of abnormal excrement (bloody stool, yellow mucoid stool, diarrhoea, and emesis) were observed in low and high level females when compared to their control group. Approximately one-half of these observations were attributable to only one female dog from each of these groups of 6 animals per group. Females at the middle exposure level and males at all treatment levels had incidences of abnormal excrement similar to that of the control groups. One mid dose and one high dose female had localised skin redness with slight alopecia throughout most of the study. Body weight, food consumption and ophthalmologic findings were normal throughout the test duration. Haematology, clinical chemistry and urine pathologic parameters plus gross and microscopic findings revealed no changes attributable to glyphosate exposure.

Since there was no conclusive evidence of toxicity in this study, the highest dosage (500 mg/kg bw/day) was considered a no-effect level (NOEL) by the study authors.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study, glyphosate was administered orally by gelatin capsule to groups of six male and six female Beagle dogs at daily doses of 0, 20, 100 or 500 mg/kg bw/day for approximately twelve months. The study was conducted according to a testing regime in general accordance with OECD 452 (1981) and in compliance with GLP.

Although some unusual clinical observations (abnormal excrement, alopecia and skin redness) were noted among a few animals, these changes did not appear dose-dependent and were of questionable significance. Body weight, food consumption and ophthalmologic findings were normal throughout the test duration. All dogs survived the twelve months of testing. Clinical pathologic parameters plus gross and microscopic findings revealed no changes attributable to glyphosate exposure. Since there was no conclusive evidence of toxicity in this study, the highest dosage of 500 mg/kg bw/day is considered a no observed adverse effect level (NOAEL).

Assessment and conclusion by RMS:
.

1. Information on the study

Data point:	CA 5.3.2/037
Report author	[redacted]
Report year	1982 (Revision/ English version 1992)
Report title	12 month dietary toxicity study with glyphosate in dogs
Report No	8012
Document No	Not reported
Guidelines followed in study	Not known
GLP	Not known, GLP not compulsory when study was conducted
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Four Beagle dogs per sex and dose were fed diets for 12 months containing 0, 30, 100 or 300 ppm (equivalent to approx. 0, 0.75, 2.5 and 7.5 mg/kg bw/day based on application of diet conversion factor 40 for dogs published by Derelanko 2008) of glyphosate (purity and source not specified). Animals were observed for clinical signs. Body weights and food consumption were

	measured. Haematological and clinical chemistry evaluations were performed. The frequency of these observations and measurements are not known. All animals were subjected to gross pathological examination and histopathology. Organ weights were determined.
Short description of results:	There were no treatment-related clinical signs and no haematological, clinical chemistry, gross or histopathological changes with the possible exception of rounded hepatocytes and narrower sinusoids observed in the livers of some (2/4) high dose male dogs and mid (2/4) and high dose (3/4) females but not in the low dose and in the control groups. Since there was no further evidence of morphological or functional liver alterations, the reported findings while possibly treatment-related were not considered adverse effects. Thus, the NOAEL in this study was the highest dose of 300 ppm (approx. 8 mg/kg bw/day for the sexes combined).
Reasons for why the study is not considered relevant/reliable or not considered as key study:	Monograph (2000): The study was considered supplementary only due to reporting deficiencies (test substance purity missing, other deficiencies not specifically defined). The dates of the experimental work were not included in the report. RAR (2015): The study was considered unacceptable due to serious reporting deficiencies, e.g., absence of information on batch and purity of the test material. Therefore and since the study report is not available, this study is not considered invalid.
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL.
Category study in AIR 5 dossier (IUCLID docs)	Category 4b

CA 5.3.3 Other routes

No new subacute toxicity studies by the dermal and inhalation routes have been performed.

Table 5.3.3-1 summaries the studies performed in rats and rabbits by percutaneous application previously assessed in the 2001 and 2015 EU glyphosate evaluations.

Table 5.3.3-1: Studies on dermal 21-/28–day repeated-dose toxicity with glyphosate

§: The category describes the acceptability/reliability of the study within the AIR 5 submission. This category does not describe hazard classification. (for details please refer to the Doc ID: 110054-B-GRG_Jun_2020)

The short-term percutaneous toxicity of glyphosate has been investigated in the rat and rabbit.

In both Sprague-Dawley ([redacted] 1993) and Alpk:APfSD (Wistar derived) ([redacted], 1996) rats, no signs of systemic toxicity were noted following dosing for 21 days at 1000 mg/kg bw/day, the limit dose for this study type. Therefore, in both studies the NOAEL was set at 1000 mg/kg bw/day.

Three studies were conducted in New Zealand White rabbits ([redacted] 1985, [redacted] 1982 and [redacted] 1994) and doses ranged from 100 mg/kg bw/day to 5000 mg/kg bw/day. The study by [redacted] (1985) was considered supportive due to serious reporting deficiencies in the first EU evaluation (2001) and not accepted in the RAR (2015). Therefore and since the study report is not available, this study is not considered to be reliable. The other two subacute dermal studies were well conducted, in general compliance with OECD 410 (1981) and GLP and thus, considered acceptable. No signs of treatment-related systemic toxicity were noted in either study, the highest NOAEL being 5000 mg/kg bw/day.

In both the rat and the rabbit no signs of systemic toxicity were evident following repeated application of glyphosate to the skin. The NOAEL for short term percutaneous toxicity was 1000 mg/kg bw/day in the rat and 5000 mg/kg bw/day in the rabbit as previously concluded in the 2001 EU glyphosate evaluation. Based on the [redacted] (2012) *in vitro* dermal absorption of glyphosate through rabbit skin (CA 5.8.2/014), with 2.66 % bioavailability, the systemic NOAEL for rabbits exposed dermally to glyphosate is determined to be 133 mg/kg bw/day. When compared with the previous AOEL point of departure, 50 mg/kg bw/day (oral dose in rabbits), the systemic oral NOAEL based on 20 % gastrointestinal absorption is 10 mg/kg bw/day. The systemic oral NOAEL is over 10-fold lower than the dermal value, which highlights that the previous AOEL is overly conservative and based on non-systemic effects (gastrointestinal effects).

Table 5.3.3-2 summaries the studies performed in rats by inhalation previously assessed in the 2001 and 2015 EU glyphosate evaluations.

Table 5.3.3-2: Studies on 14-day repeated-dose toxicity by inhalation of glyphosate

Annex Point	Study	Species Study type	Substance(s)	Reliability/ GLP	Result
CA 5.3.3/009	[redacted], 1985	Wistar rat 14-day, inhalation (aerosol) (0, 0.28, 0.90, 0.93, 3.8 mg/L)	Glyphosate technical (Purity: not reported)	Not valid, Category 4b	NOAEC = 3.8 mg/L (aerosol)

Only one study on subacute inhalative toxicity (14 days) in rodents ([redacted], 1985) is available and was reviewed in the 2001 EU evaluation. The previous review concluded no treatment-related effects were observed and the NOAEC for inhalation of an aerosol was 3.8 mg/L. However, compared to modern regulatory standards, the study was considered unacceptable due to serious reporting deficiencies in the last evaluation (2015) (e.g. missing details on test substance batch and purity). Therefore and since the study report is not available, this study is invalid.

Since glyphosate is non-volatile (VP = 1.31×10^{-5} Pa (25 °C)) the conduct of a 28–day inhalation study is not needed according to EU requirements. Therefore, no further inhalation studies were conducted.

90–day inhalation studies are only required for volatile substances (i.e. substances with a vapour pressure (VP) $>10^{-2}$ Pa). Since glyphosate is non-volatile (VP = 1.31×10^{-5} Pa (25 °C)), no 90–day inhalation toxicity study was conducted.

Publications on repeated-dose toxicity via other routes

A literature search for the active substance glyphosate was performed in accordance to the provisions of the EFSA Guidance "Submission of scientific peer-reviewed open literature for the approval of pesticide active substances under Regulation (EC) 1107/2009" and updated Appendix to this Guidance document. The following publications were found relevant and reliable for this section and the summaries are thus presented below and are part of the general discussion at the beginning of the section.

Table 5.3.3-3 summarises the relevant publications.

Table 5.3.3-3: Publications on repeated-dose toxicity with glyphosate via other routes

Annex Point	Study	Species Study type	Substance(s)	Result	Comments
CA 5.3.3/010	Mesnage R. *et al.*, 2018	*In Vitro:* Differentiated HepaRG™ cells (HPR 116) (0.06 µM, 6 µM, 600 µM)	Glyphosate (Purity: ≥ 96 %)	No NOAEL derived Only weakly toxic *in vitro*	No positive control. No cytoxicity tests to determine appropriate concentration range tested.
CA 5.3.3/011	Kumar S. *et al.*, 2014	C57BL/6, TLR4–/–, IL-13–/– mouse Daily for 7 days or 3 times a week for 3 weeks, intranasal (100 ng, 1 µg, 100 µg)	Glyphosate reagent grade (Purity: not reported)	No NOAEL derived Pulmonary IL-13-dependent inflammation	Method for the collection and analysis of the air samples not validated.

In the study published by Mesnage *et al.* (2018), the effect of glyphosate on the transcriptome and metabolome profile of differentiated HepaRG cells was investigated at concentrations of 0.06, 6 and 600 µM *in vitro*. Glyphosate was found to be only weakly toxic inducing little change in transcriptome profiles when compared with the other herbicides tested in the same study.

The aim of the second study (Kumar S. *et al.*, 2014) was to explore the mechanisms of glyphosate-induced pulmonary pathology by utilizing murine models and real environmental samples. Mice of different strains inhaled extracts of glyphosate-rich air samples collected on farms during spraying of herbicides or inhaled different doses of glyphosate (100 ng, 1 µg, 100 µg applied intranasally to anesthetised mice). The cellular response, humoral response, and lung function of exposed mice were evaluated. Glyphosate-rich farm air samples as well as glyphosate alone were found to induce pulmonary IL-13-dependent inflammation and promote Th2 type cytokines, but not IL-4 for glyphosate alone. This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions since the method for the collection and analysis of the air samples was not validated.

2. Full summary

Executive Summary

In a dermal toxicity study groups of five male and five female Alpk:AP$_f$SD (Wistar-derived) rats received 6-hour dermal applications of 0 (control), 250, 500 or 1000 mg glyphosate acid/kg bw/day. Glyphosate acid was prepared as a paste using deionised water as the control substance and vehicle. A total of 15 applications were made over a 21 day period (5 applications per week).

Clinical observations were made and body weights and food consumption were measured, and at the end of the scheduled period, the animals were killed and subjected to an examination *post mortem*. Cardiac blood samples were taken for clinical pathology, selected organs were weighed and specified tissues were taken for subsequent histopathological examination.

There were no clinical signs of systemic toxicity at any dose level and no adverse compound related effects on body weight, food consumption, haematology, clinical chemistry or organ weights. There was no evidence of toxicity at histopathological examination.

There was no evidence of systemic toxicity or dermal irritation following 15 dermal applications over a 21 day period of up to 1000 mg glyphosate acid/kg bw/day.

I. MATERIALS AND METHODS

A: Materials

1. **Test material:** Glyphosate acid
   - Description: Technical, white solid
   - Lot/Batch number: P24
   - Purity: 95.6 % w/w a.s.
   - CAS#: Not reported
   - Stability of test compound: Not reported
2. **Vehicle and/or positive control:** Deionised water / none
3. **Test animals:**
   - Species: Rat
   - Strain: Alpk:APfSD
   - Age/weight at dosing: 6 – 8.5 weeks / males 214 – 249 g, females 193 – 227 g
   - Source: [redacted]
   - Housing: Individually, in cages on multiple rat racks suitable for animals of this strain and weight range expected during the course of the study.
   - Acclimatisation period: At least 5 days
   - Diet: Diet (PCD) supplied by Special Diet Services Limited, Witham, Essex, UK, *ad libitum*
   - Water: Mains water, *ad libitum*
   - Environmental conditions: Temperature: 21 ± 2 °C
     Humidity: 40 – 70 %
     Air changes: At least 15 changes / hour
     Photoperiod: 12 hours light / 12 hours dark

B: Study design and methods

In-life dates: 1996-01-10 to 1996-02-01

Animal assignment
The study was divided into ten (randomised blocks), each containing one cage per treatment group. The animals were randomly allocated to groups as shown below:

Table 5.3.3-4: Glyphosate Acid: 21 Day Dermal Toxicity Study in Rats ([redacted], 1996): Study design

Test group	Dose level of glyphosate acid [mg/kg bw/day]	Males	Females
Control	0	5	5
Low	250	5	5
Mid	500	5	5
High	1000	5	5

Preparation and treatment of animal skin
Sixteen to twenty-four hours before application of the test substance, the hair was removed with a pair of veterinary clippers from an area, approximately 10 cm × 5 cm, on the dorso-lumbar region of each animal. The rats were dosed dermally and the amount applied was calculated for each animal according to its weight at the time of dosing. The paste covered by a gauze patch (approximately 7 cm × 7 cm × 4-ply) was applied to the shorn back of each animal and was kept in contact with the skin for approximately 6 hours using an occlusive dressing. The gauze patch was covered by a patch of plastic film (7 cm × 7 cm) and was held in position using adhesive bandage (25 cm × 7.5 cm). This was secured by two pieces of PVC tape (approximately 2.5 cm × 20 cm) wrapped around the animal. The control animals were treated in a similar manner except that deionised water only was used. The rats were dosed sequentially in group order at approximately the same time each day.

At the end of each 6-hour contact period, the dressings were carefully removed. The skin, at the site of application, was cleansed using clean swabs of absorbent cotton wool soaked in clean warm water and was then dried gently with clean tissue paper.

A total of 15 six-hour applications were made during a period of 21 days. During this time there were three two-day periods when the animals were not dosed. Following each application there was an 18-hour 'rest' period during which the animals were fitted with plastic collars to prevent oral contamination.

Observations
Prior to the start of the study, all rats were examined to ensure that they were physically normal and exhibited normal activity. Detailed clinical observations were recorded daily and after decontamination. Cage-side observations were also made as soon as possible after dosing, and towards the end of the working day.

Body weight
The body weight of each rat was recorded daily, immediately prior to application of the test substance where applicable and prior to termination on day 22.

Food consumption and test substance intake
Food consumption was recorded continuously throughout the study for each rat and calculated as a weekly mean (g food/rat/day).

Haematology and clinical chemistry
Blood was collected at termination, by cardiac puncture and the following parameters were examined: Haemoglobin, haematocrit, red blood cell count, mean cell volume, mean cell haemoglobin, red cell distribution width, activated partial thromboplastin time, mean cell haemoglobin concentration, platelet count, total white cell count, differential white cell count, blood cell morphology and prothrombin time.

Clinical chemistry
Blood was collected at termination, by cardiac puncture and the following parameters were examined: Urea, creatinine, glucose, albumin, total protein, cholesterol, triglycerides, total bilirubin, creatine kinase activity, alkaline phosphatase activity, aspartate aminotransferase activity, alanine aminotransferase activity, gamma-glutamyl transferase activity, calcium, phosphorus (as phosphate), sodium, potassium and chloride.

Investigations *post mortem*
Macroscopic examination
All animals were examined *post mortem*. This involved an external observation and an internal examination of all organs and structures.

Organ weights
From all animals surviving to scheduled termination, the following organs were removed, trimmed free of extraneous tissue and weighed: Adrenal glands, kidneys, liver and testes.
Paired organs were weighed together.

Tissue submission
The following tissues were examined *in situ*, removed and examined and fixed in an appropriate fixative: Gross lesions including masses, testis*, kidney, liver, adrenal gland*, epididymis*, treated skin and untreated skin.
*: Tissues marked were stored and not examined microscopically

Microscopic examination
All selected tissues processed from the control and 1000 mg glyphosate acid/kg bw/day, together with macroscopic abnormalities from these groups, were examined by light microscopy.

Statistics
Haematology, clinical chemistry, organ weights and weekly food consumption were analysed using analysis of variance. Body weights, on initial (day 1) body weight, organ weights on final body weight were analysed using analysis of covariance. All data were analysed using *SAS (1989*).

II. RESULTS AND DISCUSSION

Mortality
There were no mortalities.

Clinical observations
There were no significant signs of toxicity at any dose level of glyphosate acid. Generally the clinical findings observed were consistent with those commonly seen in dermal studies as a consequence of bandaging and were considered not to be related to treatment with glyphosate acid.

Body weight and weight gain
There were no effects due to treatment with glyphosate acid on body weight at any dose level.

Food consumption
There were no effects due to treatment with glyphosate acid on body weight at any dose level.

Haematology
A minimal statistically significant increase in haemoglobin levels was observed in females dosed at 1000 mg glyphosate acid/kg bw/day. A statistically significant decrease compared with control was seen in red cell distribution width in females dosed at 250 and 1000 mg glyphosate acid/kg bw/day. In the absence of any adverse effects on the red cell parameters, these minor changes are considered not to be of toxicological significance.

Table 5.3.3-5: Glyphosate Acid: 21 Day Dermal Toxicity Study in Rats ([redacted], 1996): Intergroup comparison of selected haematology parameters

Parameter	Dose level of glyphosate acid [mg/kg bw/day]							
	Males				Females			
	0	250	500	1000	0	250	500	1000
Haemoglobin [g/dL]	15.2 ± 0.4	15.3 ± 0.6	15.3 ± 0.3	15.0 ± 0.4	13.9 ± 0.6	13.7 ± 0.8	14.1 ± 0.6	**14.6* ± 0.3**
Red cell distribution width [%]	13.1 ± 0.9	12.9 ± 0.9	12.6 ± 0.3	13.4 ± 0.6	13.8 ± 1.2	**12.4** ± 0.8**	13.0 ± 0.4	**12.6* ± 0.7**

* Statistically significant difference from control group mean ($p < 0.05$; Student's t-test, 2-sided);
** Statistically significant difference from control group mean ($p < 0.01$; Student's t-test, 2-sided)

Blood clinical chemistry

Females dosed at 1000 mg glyphosate acid/kg bw/day showed a minimal, but statistically significant increase in plasma urea levels, but there were no differences seen in the plasma creatinine levels. This minimal change in urea was considered not to be of toxicological significance. A minimal but statistically significant decrease in plasma triglycerides was observed in males dosed at 500 mg glyphosate acid/kg bw/day and as this did not form part of a dose response relationship was considered not to be treatment related.

Table 5.3.3-6: Glyphosate Acid: 21 Day Dermal Toxicity Study in Rats ([redacted], 1996): Intergroup comparison of selected clinical chemistry parameters (mean values)

Parameter	Dose level of glyphosate acid [mg/kg bw/day]							
	Males				Females			
	0	250	500	1000	0	250	500	1000
Plasma urea [mmol/L]	8.4 ± 0.5	8.2 ± 0.2	8.5 ± 0.2	8.1 ± 0.8	7.6 ± 0.5	7.7 ± 1.0	6.9 ± 0.5	**8.6* ± 1.1**
Plasma creatinine [µmol/L]	56.8 ± 2.2	57.2 ± 4.4	57.8 ± 4.1	54.4 ± 4.7	58.2 ± 2.3	58.6 ± 3.4	58.0 ± 6.6	58.2 ± 2.4
Plasma trigycerides [mmol/L]	1.27 ± 0.28	1.01 ± 0.17	**0.87* ± 0.22**	1.27 ± 0.34	0.70 ± 0.11	0.66 ± 0.21	0.69 ± 0.19	0.76 ± 0.35

* Statistically significant difference from control group mean ($p < 0.05$; Student's t-test, 2-sided)

Sacrifice and pathology

Organ weights

Testes weights were slightly, but statistically significantly decreased at 500 mg glyphosate acid/kg bw/day, due to one animal having a very low weight recorded. There were no effects due to treatment with glyphosate acid in the other organs weighed.

Macroscopic findings

A small number of lesions were observed in a few animals in the 0 and 500 mg/kg bw/day groups, none of which were related to treatment.

Microscopic findings

A small number of common spontaneous lesions were observed, none of which were related to treatment.

III. CONCLUSIONS

There were no clinical signs of systemic toxicity at any dose level and no adverse compound related effects on body weight, food consumption, haematology, clinical chemistry or organ weights. There was no evidence of toxicity at histopathological examination.

There was no evidence of systemic toxicity or dermal irritation following 15 dermal applications over a 21 day period of up to 1000 mg glyphosate acid/kg bw/day.

The no-effect level (NOEL) for systemic toxicity and dermal irritation was considered to be 1000 mg glyphosate acid/kg bw/day in both sexes.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this dermal toxicity study, groups of five male and five female Alpk:AP$_f$SD (Wistar-derived) rats received 6 hour dermal applications of 0 (control), 250, 500 or 1000 mg glyphosate acid/kg bw/day. The study was conducted according to OECD 410 (1981) and in compliance with GLP.
There was no evidence of systemic effects of toxicological significance or dermal irritation following 15 dermal applications over a 21 day period of up to 1000 mg glyphosate acid/kg bw/day.
The NOAEL for systemic toxicity and dermal irritation was considered to be 1000 mg glyphosate acid/kg bw/day in both sexes.

Assessment and conclusion by RMS:
.

1. Information on the study

Data point:	CA 5.3.3/003
Report author	[redacted] *et al.*
Report year	1993
Report title	Glyphosate: 3 Week Toxicity Study in Rats with Dermal Administration
Report No	7839
Document No	Not reported
Guidelines followed in study	US EPA 82-2 (Pesticide Assessment Guidelines, Subdivision F); in general compliance with OECD 410 (1981)
Deviations from current test guideline (OECD 410, 1981)	Mean weight of the female rats were slightly lighter than requested (195 g instead of 200 – 300 g), organ weights of the adrenals were not determined.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

A group of 5 male and 5 female Sprague-Dawley rats were dosed daily with glyphosate via the dermal route of application, for a period of ca 6 h per day for 3 weeks. The group was dosed at a constant volume of 3 mL/kg body weight at a dose level of 1000 mg glyphosate/kg bw/day. A further group of 5 males and 5 females received vehicle only (diethylphthalate) dermally at the same dose volume to act as a control. Blood samples were collected for haematology and clinical chemistry screens during week 3. After 3 weeks of dosing all rats were killed and necropsied and selected organs weighed. All control and high dose rats underwent a limited histological examination.

No effect on mortality or clinical signs could be observed. Findings in body weight changes or food/water consumption were not consistent and considered to be not treatment-related. The skin assessment showed a minor reaction to the treatment of glyphosate. Haematology, clinical chemistry or organ weights revealed no notable intergroup differences in either sex. Histopathological examination did not reveal any finding that could be attributed to dosing with glyphosate.

In conclusion, following dermal administration of glyphosate to Sprague-Dawley rats for 3 weeks at a dose level of 1000 mg/kg bw/day, there was no evidence of systemic toxicity. A mild transitory irritant effect was noted at the dosing site.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate
Description:	White crystalline solid
Lot/Batch #:	229-Jak-142-6
Purity:	101.5 %
Stability of test compound:	The article is stable at least 2 years from date of analysis when stored at ambient temperature in the dark

2. Vehicle and/or positive control: Diethylphthalate / none

3. Test animals:

Species:	Rat
Strain:	Sprague-Dawley
Source:	[redacted]
Age:	Ca. 8 weeks
Sex:	Male and female
Weight at dosing:	♂ 295 g; ♀ 195 g
Acclimation period:	25 days
Diet/Food:	SDS Rat and Mouse (modified) No. 1 Diet SQC (supplied by Special Diets Services Limited, Witham, Essex, CM8 3AD), *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	Individually in polypropylene cages (over all dimensions ca 420 × 270 × 200 mm) with stainless steel wire grid tops and bottoms.

Environmental conditions: Temperature: 20 ± 2 °C
Humidity: 50 ± 15 %
Air changes: 15 air changes per hour
12 hours light/dark cycle

B: Study design and methods

In life dates: 1992-04-06 to 1992-04-27

Animal assignment and treatment:
A group of 5 male and 5 female Sprague-Dawley rats were dosed daily with glyphosate via the dermal route of application, for a period of ca 6 h per day for 3 weeks. The group was dosed at a constant volume of 3 mL/kg body weight at a dose level of 1000 mg/kg bw/day (high limit dose). A further group of 5 males and 5 females received vehicle only (diethylphthalate) dermally at the same dose volume to act as a Control.

Table 5.3.3-7: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted] 1993): Study design

Test group	Treatment [mg/kg bw/day]	Males	Females
Control (1)	0	5	5
High (2)	1000	5	5

The hair on the animals' backs was clipped as necessary (once during Week 1, twice during Week 3 and not clipped at all during Week 2) and the test material applied daily at the constant volume of 3 mL/kg bw, over an area of approximately 10 % of the total body surface area. After application of the test material the dosing site was covered by a piece of gauze with a silver foil back (approximately 4 cm diameter). The treated area was protected by a semi-occlusive dressing (Micropore, 3M) held in place by means of a non-irritating tape (Blenderm, 3M). Dermal exposure was ca 6 h per day, the site of exposure being cleaned of test material with a soft cloth soaked in diethylphthalate immediately after removal of the dressing. If the animals managed to remove the dressing during the dosing period it was re-applied for the remainder of the 6 h period. A record of animals which managed to remove the dressing was maintained and is shown below.

Table 5.3.3-8: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Dress removal of tested animals

Timepoint	Group/dose level [mg/kg bw/day]							
	Animals found without dressing				Dressing chewed			
	1/0 ♂	2/1000 ♂	1/0 ♀	2/1000 ♀	1/0 ♂	2/1000 ♂	1/0 ♀	2/1000 ♀

			occasion				occasion No. 14 on one occasion	

Preparation of Dosing Suspensions
Dosing suspensions were prepared daily, using diethylphthalate (DEP) as vehicle. Water was originally intended as the vehicle for the study. However, this formed a very poor suspension with glyphosate and allowed a constant dose volume of only 2 mL/kg bw. Therefore, after experimentation at IRI, the vehicle was changed to diethylphthalate. This has been used successfully at IRI as a vehicle in previous dermal studies; it formed a far more homogeneous suspension with glyphosate, and allowed a constant dose volume of 3 mL/kg bw.

Analysis of the dosing suspensions
Analysis of the dosing suspension was conducted in another study and not reported.

Mortality
Animals were checked twice daily for mortality.

Clinical observations
All animals were examined for reaction to treatment during the day. The onset, intensity and duration of all signs were recorded.
In addition, all animals received a detailed clinical examination once each week.

Skin Assessment
Once each week all animals received a detailed examination of skin for erythema, eschar formation and oedema formation.

Table 5.3.3-9: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Grading system for the skin assessment

Erythema and eschar formation	No erythema	0
	Very slight erythema (barely perceptible)	1
	Well defined erythema	2
	Moderate to severe erythema	3
	Severe erythema (beet redness) to slight eschar formation (injuries in depth)	4
Oedema formation	No oedema	0
	Very slight oedema (barely perceptible)	1
	Slight oedema (edges of area well defined by definite raising)	2
	Moderate oedema (edges raised approximately 1 mm)	3
	Severe oedema (raised by more than 1 mm and extending beyond the area of exposure)	4
Skin thickening	Normal	0
	Thicker than normal	1
Desquamation	No desquamation	0
	Mild desquamation (dry skin)	1
	Moderate desquamation (flaky skin)	2
	Severe desquamation (skin cracking)	3

Body weight
The weight of each animal was recorded twice during the week before the start of treatment, on five occasions during Week 1 and twice each week thereafter.

Food and water consumption
The quantity of food consumed by each animal was recorded twice each week starting 1 week pre-trial up until the end of the study.
Water consumption was monitored by visual inspection throughout the treatment period.

Haematology and clinical chemistry
Samples were taken from all animals during Week 3. Blood samples were collected from the orbital sinus under light ether anaesthesia (except Hepato Quick which was taken by tail snip) with overnight food deprivation.

Haematology:
The following parameters were determined: Haematocrit, haemoglobin, total red blood cell count, mean cell volume, mean cell haemoglobin, mean cell haemoglobin concentration, Hepato Quick (clotting time), total white blood cell count and differential white blood cell count.

Clinical chemistry
The following parameters were determined: Aspartate amino transferase (AST), alanine aminotransferase (ALT), creatinine (Crea), total protein (TP), albumin (Alb), AG ratio (AG-R), blood urea nitrogen (BUN), glucose (Glu), total bilirubin (T Bi), sodium (Na), potassium (K), chloride (Cl), calcium (Ca), inorganic phosphorus (P).

Sacrifice and pathology
All animals were killed and necropsied after 3 weeks dosing. Method of killing was by carbon dioxide asphyxiation followed by exsanguination. The gross dissection and necropsy were performed under the supervision of a pathologist.

Organ weights
The following organs were weighed: Kidneys, liver and testes (with epididymides).

Histopathology
Histopathological examinations of the following organs were performed: Abnormal tissue, dosing site, kidneys, liver, lungs, normal skin, ovaries, spleen and testes (with epididymides).

Statistics
Body weight, haematology and clinical chemistry data were statistically analysed for homogeneity of variance using the 'F-max' test. If the group variances appeared homogeneous a parametric ANOVA was used and pairwise comparisons made via Student's t-test using Fisher's F-protected LSD. If the variances were heterogeneous, log or square root transformations were used in an attempt to stabilise the variances. If the variances remained heterogeneous, then a non-parametric test such as Kruskal-Wallis ANOVA was used. Individual between group comparisons were made using Fisher's F-protected LSD method.

Organ weights were analysed as above and conditional on body weight (i.e. analysis of covariance).
Histology data were analysed using Fisher's Exact Probability test.

II. RESULTS AND DISCUSSION

A. ANALYSIS OF THE FORMULATED DOSING SUSPENSIONS

Analysis of the formulated dosing suspension was conducted in another study and not reported.

B. MORTALITY
There were no premature deaths.

C. CLINICAL OBSERVATIONS
There were no clinical signs observed which were considered to be related to treatment with glyphosate.

D. SKIN ASSESSMENT
During Week 2, 2/5 male animals of the high dose group and 3/5 female animals of the high dose group showed very slight erythema, however, during Week 3, this finding was only apparent in 1/5 of the high dose females.

Also during Week 2, desquamation was apparent in 3/5 male animals of the high dose group (ranging from moderate to severe) and in all female high dose animals (ranging from mild to severe), however, during Week 3, only mild desquamation was apparent in 1/5 high dose males and thickening and severe desquamation were apparent in only 1/5 high dose females.

No findings were noted in Control males or females at any time during the study.

Table 5.3.3-10: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Skin assessment

Group / Dose level [mg/kg bw/day]							
Group 1/0 ♂		Group 1/0 ♀		Group 2/1000 ♂		Group 2/1000 ♀	
Animal #	Assessment	Animal #	Assessment	Animal #	Assessment	Animal #	Assessment
1	No reaction	11	No reaction	6	No reaction	16	Week 2: severe desquamation
2	No reaction	12	No reaction	7	Week 2: slight erythema and moderate desquamation	17	Week 2: slight erythema and moderate desquamation

4	No reaction	14	No reaction	9	No reaction	19	Week 2: slight erythema and moderate desquamation
5	No reaction	15	No reaction	10	Week 2: moderate desquamation Week 3: mild desquamation	20	Week 2: mild desquamation

E. BODY WEIGHT
The high dose males showed a moderate reduction in body weight gain (17 %) and the high dose females

showed a large increase in body weight gain (58 %) when compared to their respective controls.

In absolute terms, these changes did not reach statistical significance at all in males, and only once in females (during week 3, $p \leq 0.05$). This lack of statistical difference along with the fact that there was such a wide variation between the sexes and that similar changes have not been observed in previous studies using glyphosate led to the suggestion by the study authors that these changes are not related to treatment with glyphosate.

There were no other notable intergroup differences.

Table 5.3.3-11: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Group Mean Body weight data [g]

Treatment period [days]	Group/Dose level [mg/kg bw/day]			
	1/0 ♂	2/1000 ♂	1/0 ♀	2/1000 ♀
-7	241	↑249	172	172
-4	258	↑265	181	↑185

Body weight gain from day 0 – 21 [g]	70	↓58	38	↑60
% of control	-	83	-	158

* Significantly different from control, $p \leq 0.05$

F. FOOD AND WATER CONSUMPTION

There were no notable intergroup differences for food consumption in males. In females, there was a slight increase in food consumption in the high dose females (14 %) when compared to controls. With the lack of a similar effect in males, and as this finding has not been seen in previous studies using glyphosate, this increase was considered by the study authors a chance effect and not of toxicological importance.

There were no other notable intergroup differences.

Table 5.3.3-12: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Summary of food consumption data [g/rat/time period]

Treatment period [days]	Group/Dose level [mg/kg bw/day]			
	1/0 ♂	2/1000 ♂	1/0 ♀	2/1000 ♀
-7 to -4	28.9	↑31.2	23.1	↑25.2
-4 to 0	32.1	↓31.8	22.3	↑25.5
0-3	33.5	↓31.1	21.9	↑25.1
3-7	35.5	↓33.2	23.5	↑26.8
7-10	33.3	↓32.9	24.5	↑28.0
10-14	34.8	↓33.7	25.9	↑30.5
14-17	34.7	↓34.0	26.5	↑29.5
17-21	38.3	↑39.2	31.1	↑34.7
Total food consumed from day 0 – 21 [g]	701	↓679	510	↑581
% of control	-	97	-	114

There were no visual intergroup differences in either sex noted for water consumption.

G. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

Males: There was a decrease in monocytes (44 %, $p \leq 0.05$) and large unstained cells (62 %, $p \leq 0.05$) in the high dose males compared to Controls.

The study authors stated that these findings have not been seen in previous studies using glyphosate and the decrease in monocytes may partly be due to higher than normal values in Control animals (IRI historical data show a mean of 0.226 ± 0.126, number of samples being 74).

There were no other notable intergroup differences.

Females: There was an increase in MCH (4 %, $p \leq 0.05$) and MCV (4 %, $p \leq 0.01$) in the high dose females compared to Controls.

There was a reduction in neutrophils (31 %, $p \leq 0.05$) in the high dose females compared to Controls.

Again according to the study authors, these findings have not been seen in previous studies using glyphosate.

There were no other notable intergroup differences.

Table 5.3.3-13: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Summary of selected group mean haematology data

Parameter	Group/Dose level [mg/kg bw/day]			
	1/0 ♂	2/1000 ♂	1/0 ♀	2/1000 ♀
Monocytes [$\times 10^9$/L]	0.57 ±0.17	**↓0.32* ± 0.07**	0.23 ± 0.09	↓0.22 ± 0.11
Large unstained cells [$\times 10^9$/L]	0.29 ± 0.14	**↓0.11* ± 0.02**	0.06 ± 0.01	↑0.08 ± 0.04
Mean cell haemoglobin [pg]	19.6 ± 1.0	↓19.4 ± 0.4	19.9 ± 0.2	**↑20.7* ± 0.6**
Mean cell volume [fL]	54.6 ± 1.9	↓54.0 ± 1.3	53.5 ± 0.9	**↑55.8** ± 1.3**
Neutrophils [$\times 10^9$/L]	3.34 ± 1.65	↓1.99 ± 0.62	1.68 ± 0.30	**↓1.16* ± 0.41**

* Significantly different from Control, $p \leq 0.05$;
** Significantly different from Control, $p \leq 0.01$

Blood clinical chemistry

There were no notable intergroup differences in either sex.

H. NECROPSY

Organ weights

There were no notable intergroup differences in either sex.

Gross pathology

Unilateral dilatation of the kidneys was seen in 2/5 high dose males compared to 0/5 Controls. This is a common finding in rats of this age and not considered related to treatment with glyphosate.

There were no notable intergroup differences for females.

Histopathology

Unilateral papillary necrosis was seen in the kidney in 1/5 high dose males and urothelial hyperplasia was seen in the kidney in 2/5 high dose males, both compared to 0/5 in Controls. These lesions are relatively common in rats of this age and strain and are not considered to be related to treatment with glyphosate.

Pelvic dilation was seen in 3/5 high dose males compared to 0/5 in Controls.

There were no other notable intergroup differences for males or females.

Table 5.3.3-14: Glyphosate – 3 Week Toxicity Study in Rats with Dermal Administration ([redacted], 1993): Summary of selected haematology data

Parameter		Group/Dose level [mg/kg bw/day]			
		1/0 ♂	2/1000 ♂	1/0 ♀	2/1000 ♀
Kidneys	No abnormality detected	3	1	4	5
	Localised urothelial hyperplasia (Grade +/-)	0	2	0	0
	Total incidence for score expanded finding	0	2	0	0
	Basophilic tubules (Grade +/-)	0	1	0	0
	Total incidence for score expanded finding	0	1	0	0
	Pelvic dilatation (Grade +/-) (Grade ++) (Grade ++1-)	0 0 0	1 1 1	1 0 0	0 0 0
	Total incidence for score expanded finding	0	3	1	0
	Localised papillary necrosis	0	1	0	0
	Nephropathy (Grade +/-) (Grade +)	1 1	1 0	0 0	0 0
	Total incidence for score expanded finding	2	1	0	0

III. CONCLUSIONS

No effect on mortality or clinical signs could be observed. Findings in body weight changes or food/water consumption were not consistent and considered to be not treatment-related. The skin assessment showed a minor reaction to the treatment of glyphosate. Haematology, clinical chemistry or organ weights revealed no notable intergroup differences in either sex. Histopathological examination did not reveal any finding that could be attributed to dosing with glyphosate.

In conclusion, following dermal administration of glyphosate to Sprague-Dawley rats for 3 weeks at a dose level of 1000 mg/kg bw/day, there was no evidence of systemic toxicity. A mild transitory irritant effect was noted at the dosing site.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study, a group of 5 male and 5 female Sprague-Dawley rats were dosed daily with glyphosate via the dermal route of application, for a period of ca 6 h per day for 3 weeks. The study was in general compliance with OECD 410 (1981) and GLP.

In conclusion, following dermal administration of glyphosate to Sprague-Dawley rats for 3 weeks at a limit dose level of 1000 mg/kg bw/day, there was no evidence of systemic toxicity. A mild irritant effect was noted at the dosing site.

Therefore, the NOAEL for dermal administration in rats under the conditions of this study can be set at 1000 mg/kg bw/day.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The toxicity potential of glyphosate technical was assessed after repeated dermal application to groups of male and female New Zealand white rabbits. Doses of 0, 500, 1000 or 2000 mg/kg bw/day were applied for a 6-hour period on five consecutive days per week over 4 weeks. For application the solid test substance was mixed with water resulting in a 50 % (w/v) solution, and spread evenly over the application site.

There were no mortalities and no treatment-related signs of systemic toxicity. Very slight erythema was noted in one high-dose male and one low-dose female. However, this effect is not considered biologically significant and was not seen in the histopathological examination.
There were no treatment-related effects on body weight, food consumption, haematological and clinical chemistry parameters observed in any of the dose groups. The macroscopic and histopathological findings observed at necropsy were considered incidental and unrelated to the test substance.

Repeated dermal administration of glyphosate technical to rabbits for a period of 28 consecutive days at doses of up to 2000 mg/kg bw/day resulted only in slight dermal irritation in one high-dose male and one low-dose female. There were no treatment-related systemic signs of toxicity.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	White powder
Lot/Batch #:	39730494
Purity:	99.6 %
Stability of test compound:	Not reported

2. Vehicle and/or positive control: Water

3. Test animals:

Species: Rabbit

Strain:	New Zealand
Source:	[redacted]
Age:	Young, adult
Sex:	Male and female
Weight at dosing:	♂ 2200 – 2800 g; ♀ 2100 – 2500 g
Acclimation period:	7 days
Diet/Food:	Altromin Rabbit Chow, *ad libitum*
Water:	Water, *ad libitum*
Housing:	Individually in wire mesh cages
Environmental conditions:	Temperature: 18 ± 2 °C Humidity: Not reported Air changes: 10 / hour 12 hours light / dark cycle

B: Study design and methods

In life dates: 1994-05-23 to 1994-06-20

Animal assignment and treatment:
The potential dermal toxicity of glyphosate technical after repeated exposure was assessed using young adult New Zealand albino rabbits (males and females). Five rabbits per sex per dose received daily dermal applications of 0, 500, 1000 or 2000 mg/kg bw/day, five days per week for a total of 20 applications.

Two days prior to the first application about 15 % of the skin of the dorsal back of the animals was clipped free of hair. The clipping was repeated weekly thereafter.

For each application the test substance was mixed with water to give a final concentration of 50 % (w/v) of glyphosate. Each dose was spread evenly over about 10 % of the body surface area and covered with a occlusive dressing made of polyethylene material that was secured by hypoallergenic Leucoplast tape. After an exposure period of six hours the dressings were removed and the application site was cleaned with hand soap, water and clean, absorbent paper pads. Applications were performed once daily, five days per week for a total of 28 days.

Clinical observations
A check for mortality, clinical signs of toxicity, and general appearance and behaviour, as well as a quantitative assessment of food and water intake was made twice daily. The applications sites were assessed for signs of irritation once daily.

Body weight
Individual body weights were recorded at weekly intervals during the pre-test and study periods and before sacrifice.

Food consumption
Food consumption was assessed at weekly intervals during the pre-test and study periods and before sacrifice.

Haematology and clinical chemistry
Haematological and blood chemical investigations were performed on all rabbits at termination.

The following parameters were measured: Haematocrit, haemoglobin, erythrocyte count, platelet count, total leukocyte count, differential leukocyte count, mean cell volume (MCV), mean cell haemoglobin

(MCH), mean cell haemoglobin concentration (MCHC), coefficient of variation of erythrocyte volume (RDW), platetelet volume distribution (PDW), mean platelet volume (MPV), thrombocrit (volume % of platelets), aspartate amino transferase (AST), alanine aminotransferase (ALT), blood urea nitrogen, total protein, glucose, albumin, total bilirubin, creatinine, inorganic phosphorus, calcium, sodium, potassium and chloride.

Sacrifice and pathology
All animals sacrificed at scheduled termination were subjected to a gross pathological examination. Any macroscopic findings were recorded.

The following organ weights were determined: Adrenals, brain, heart, kidneys, liver, lung, spleen, stomach, thymus, and testes. The organ-to-brain weight ratios were calculated.

Tissue samples were taken from the following organs and preserved in buffered formalin: Treated and untreated skin, adrenals, brain, heart, kidneys, liver, lungs, ovaries, spleen, stomach gl., testes, and thyroid. Histopathological examinations were performed on all collected tissues from the control and high-dose animals, as well as from abnormal tissues of animals from the low- and mid-dose groups.

Statistics
Body weights, haematological and clinical chemistry parameters, absolute and relative organ weights and histopathology data of treated animals were compared with control animals. Body weight, food consumption and haematology and clinical chemistry parameters were analysed by t-test. Histopathology data were analysed by Fisher´s exact test.

II. RESULTS AND DISCUSSION

A. MORTALITY
No deaths occurred during the study.

B. CLINICAL OBSERVATIONS
There were no signs of systemic toxicity noted in any animal of any dose group.

Signs of dermal irritation consistent of very slight erythema without oedema were observed in one high-dose male and one low dose female. The erythema lasted from day 7 to 20 for the male, and for 5 days for the female.

C. BODY WEIGHT
There were no statistically significant differences observed in body weights or body weight gains between the control and treated groups.

D. FOOD CONSUMPTION
There were statistically significant differences in food consumption between the control and the treated groups. Observed differences were unrelated to treatment. See Table below:

Table 5.3.3-15: Glyphosate technical (Alkaloida, Tiszavasvári): Repeated Dose Twenty-eight-Day Dermal Toxicity Study in Rabbits ([redacted], 1994): Group mean food consumption values [g] and standard deviations (SD)

Dose level [mg/kg bw/day]	Week 1	Week 2	Week 3	Week 4
Males

* Significantly different from control group ($p < 0.05$);
** Significantly different from control group ($p < 0.01$)

E. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

No treatment-related effects were detected in the haematological parameters measured.

In females of the mid-and high-dose group Mean Corpuscular Volume of Platelets (MPV) and Coefficient of Variation of Platelets Volume (PDW) values were significantly lower when compared to controls. However, the values were within the historical control range for female NZW rabbits of this age. Thus, these changes were not considered treatment-related (see **Error! Reference source not found.** below).

Blood chemistry

There were no treatment-related effects. The incidental significant changes observed with regard to urea level in high dose males were within the historical control range (not shown in this study report) of the testing facility (see table below, Table 5.3.3-16).

Table 5.3.3-16: Glyphosate technical (Alkaloida, Tiszavasvári): Repeated Dose Twenty-eight-Day Dermal Toxicity Study in Rabbits ([redacted], 1994): Group mean haematological and blood chemical values and standard deviations (SD)

Dose level [mg/kg bw/day]	MPV [fL]	PDW [fL]	Urea [mmol/L]
Males			
0	7.48 ± 0.28	5.80 ± 1.10	7.80 ± 0.66
500	↑7.94 ± 0.62	↑6.80 ± 1.57	↑8.72 ± 1.68
1000	7.64 ± 0.42	↑6.20 ± 1.04	7.64 ± 0.50
2000	7.48 ± 0.04	5.60 ± 0.42	**↑9.82** ± 1.02**

Table 5.3.3-16: Glyphosate technical (Alkaloida, Tiszavasvári): Repeated Dose Twenty-eight-Day Dermal Toxicity Study in Rabbits ([redacted], 1994): Group mean haematological and blood chemical values and standard deviations (SD)

Females			
0	8.96 ± 0.85	9.70 ± 1.86	10.24 ± 1.09
500	↓8.15 ± 0.99	↓7.50 ± 2.71	↓9.70 ± 0.53
1000	**↓7.62* ± 0.13**	**↓6.20* ± 0.57**	10.58 ± 0.39
2000	**↓7.46* ± 0.27**	**↓5.10*** ± 0.65**	↓9.96 ± 1.31

MPV: Mean platelet volume; PDW: Platelet volume distribution (coefficient of variance of platelets volume);
* Significantly different from control group ($p < 0.05$);
** Significantly different from control group ($p < 0.01$);
*** Significantly different from control group ($p < 0.001$)

I. NECROPSY

Organ weights

Absolute but not relative testes to brain weights were statistically increased in high dose males but this was not considered treatment-related.

Table 5.3.3-17: Glyphosate technical (Alkaloida, Tiszavasvári): Repeated Dose Twenty-eight-Day Dermal Toxicity Study in Rabbits ([redacted] 1994): Group mean absolute and relative to brain testes weight values and standard deviations (SD)

Dose level [mg/kg bw/day]	Absolute weight [g]	Relative weight [g/1g brain wt.]
0	3.88 ± 0.327	0.4310 ± 0.0215
500	3.70 ± 1.255	0.3744 ± 0.1211
1000	↑4.36 ± 0.658	0.4692 ± 0.0730
2000	**↑4.52* ± 0.497**	0.4618 ± 0.0773

* Significantly different from control group ($p < 0.05$)

Gross pathology

There were no treatment-related macroscopic abnormalities observed in the treated skin or any other tissues in any group.

Histopathology

There was an increased incidence in high dose males versus control animals of erosions in the stomach (4/5 high dose versus 1/5 control) and interstitial nephritis (3/5 high dose versus 1/5 control) but these findings were not considered treatment-related lesions.

III. CONCLUSIONS

There were no treatment-related effects on body weight, food consumption, haematological and clinical chemistry parameters observed in any of the dose groups. The macroscopic and histopathological findings observed at necropsy were considered incidental and unrelated to the test substance.

Repeated dermal administration of glyphosate technical to rabbits for a period of 28 consecutive days at doses of up to 2000 mg/kg bw/day resulted only in slight dermal irritation in one high-dose male and one

low-dose female. There were no compound-related gross and microscopic findings noted.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study, the toxicity potential of glyphosate technical was assessed after repeated dermal application to groups of male and female New Zealand white rabbits. Doses of 0, 500, 1000 or 2000 mg/kg bw/day were applied for a period of 6 hours a day, five days per week for 4 weeks. The study was conducted according to OECD 410 (1981) and in compliance with GLP.
Repeated dermal administration of glyphosate technical to rabbits for a period of 28 consecutive days at doses of up to 2000 mg/kg bw/day resulted only in slight dermal irritation in one of five high-dose males and one low-dose female. There were no treatment-related systemic signs of toxicity. Thus, the NOAEL is considered to be 2000 mg/kg bw/day.

Assessment and conclusion by RMS:
.

1. Information on the study

Data point:	CA 5.3.3/007
Report author	[redacted]
Report year	1985
Report title	Subacute dermal toxicity (for 21 days in rabbits) of glyphosate (technical)
Report No	Not reported
Document No	Not reported
Guidelines followed in study	Not reported, comparable to OECD 410 (1981)
GLP	No
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	In a 21-day dermal toxicity study, glyphosate (purity not reported) was dermally applied to the intact skin of New Zealand White rabbits for 6 hours per day. The dose levels were 0, 500, 1000, and 2000 mg/kg bw/day and the groups consisted of 3 male and 3 female rabbits per group. Treatment was performed 5 days per week for 3 consecutive weeks. Treatment was followed by a 14-day recovery period prior to sacrifice. Animals were observed daily for clinical signs of toxicity and irritation. Food consumption was calculated daily and body weights were determined weekly. Laboratory investigations (haematology, clinical chemistry, and urinalysis) were performed on days 0, 21, and 35. At study termination, all animals were subjected to a gross and histopathological examination.
Short description of results:	There were no mortalities and no treatment-related signs of clinical toxicity. There were no signs of dermal irritation. Body weight and food consumption were not affected by treatment. Laboratory investigations and gross and histopathological examinations did not reveal any treatment-related effects. The No Observed Adverse Effect Level (NOAEL) was established at 2000 mg/kg bw/day based on the lack of effects.

Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered supportive due to serious reporting deficiencies in the Monograph (2000) and not accepted in the RAR (2015). Test substance purity and batch number or study details like study number were not reported. Additionally, a statistical analysis of the results was not reported. Therefore and since the study report is not available, this study is not considered to be reliable.
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL.

Report author	[redacted]
Report year	1982
Report title	21-Day Dermal Toxicity Study in Rabbits
Report No	[redacted]-81-195
Document No	Not reported
Guidelines followed in study	No guideline followed; in general compliance with OECD 410 (1981)
Deviations from current test guideline (OECD 410, 1981)	The application area in the high-dose group was about 1.5 – 2 times higher than the recommended 10 % of the body surface area.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The toxicity potential of glyphosate technical was assessed after repeated dermal application to groups of 5 male and 5 female New Zealand white rabbits on intact and on abraded skin. Doses of 0, 100, 1000 or 5000 mg/kg bw/day were applied five days per week for three consecutive weeks. The abrading was accomplished by producing shallow incisions (not deep enough to cause bleeding) with the blunt end of a scalpel. For application the solid test substance was moistened with an appropriate amount of water, and spread evenly over the application site. It has to be noted that the surface areas covered (i.e. 1 – 2 %, 5 – 10 % and 15 – 20 % body surface area for the low, mid- and high-dose group, respectively) were below and above the area of 10 % recommended by actual guidelines. Due to the higher exposed surface area in the high dose group, it has to be considered that more test substance can be absorbed through the skin and could be therefore systemically available.

There were no mortalities and no treatment-related signs of systemic toxicity. There were also no signs of dermal irritation observed in the control, low- and mid-dose group. At 5000 mg/kg bw/day slight dermal

irritation consisting of barely perceptible to slight erythema and oedema was noted. However, this effect is considered not to be of biological significance and no signs of irritation were seen in the histopathological examination.

There were no treatment-related effects on body weight, food consumption, haematological and clinical chemistry parameters observed in any of the dose groups. The macroscopic and histopathological findings observed at necropsy were considered incidental and unrelated to the test substance.

Repeated dermal administration of glyphosate technical to rabbits for a period of 21 consecutive days at doses of up to 5000 mg/kg bw/day resulted only in slight dermal irritation at 5000 mg/kg bw/day. No such effects were observed in the 0, 100 and 1000 mg/kg bw/day treatment groups. There were no treatment-related systemic signs of toxicity.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	White powder
Lot/Batch #:	NBP 1992026
Purity:	Not reported
Stability of test compound:	Not reported

2. Vehicle and/or positive control: None

3. Test animals:

Species:	Rabbit
Strain:	New Zealand
Source:	[redacted]
Age:	Young, adult
Sex:	Male and female
Weight at dosing:	♂ 2359 – 2883 g; ♀ 2344 – 2955 g
Acclimation period:	14 – 16 days
Diet/Food:	Purina Certified Rabbit Chow #5322 (Ralston Purina Company, Missouri, USA), *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	Individually in wire mesh cages
Environmental conditions:	Temperature: Not reported Humidity: Not reported Air changes: Not reported 12 hours light / dark cycle

B: Study design and methods

In life dates: 1981-07-28 to 1981-08-19

Animal assignment and treatment:
The potential dermal toxicity of glyphosate technical after repeated exposure was assessed using young

adult New Zealand albino rabbits (males and females). Ten rabbits per sex per dose received daily dermal applications of 0, 100, 1000 or 5000 mg/kg bw. The dose groups were further divided in halves. One half received the treatment on intact skin, the other half on abraded skin. Abrasion was done twice per week immediately prior to test substance application by producing shallow incisions (not deep enough to cause bleeding) with the blunt end of a scalpel blade.

The day prior to the first application about 30 % of the skin of the back of the animals was clipped free of hair. During the study rabbits were shaved as needed.

For each application the test substance was moistened with an appropriate amount of physiological saline. Each dose was spread evenly over the maximum body surface area possible (see **Error! Reference source not found.** table below) covered with a semi-occlusive dressing. After an exposure period of six hours the dressings were removed and the application site was cleaned with tepid tap water and dried with paper towels. Applications were performed once daily, five days per week for three consecutive weeks. Individual doses were adjusted weekly based on the body weight determined at the beginning of each study week.

Table 5.3.3-18: 21-Day Dermal Toxicity Study in Rabbits ([redacted], 1982): Application details for repeated dermal applications

Dose group [mg/kg bw/day]	Number of animals				Volume of physiological saline used for moistening [mL]	Total percent of the body surface covered by test substance [%]
	Intact skin		Abraded skin			
	♂	♀	♂	♀		
0	5	5	5	5		-
100	5	5	5	5	0.2	1 – 2
1000	5	5	5	5	1.5 – 2.0	5 – 10
5000	5	5	5	5	8.0 – 9.0	15 – 20

It has to be noted that the application area according to current guidelines (OECD and EC) should be about 10 % of the body surface. Thus, the body surface covered with test material in the 100 mg/kg bw/day dose group is lower than recommended, whereas the treatment-area in the high dose group is about 1.5 – 2 times higher than recommended. Due to the higher exposed surface area in the high-dose group a higher amount of test substance can be absorbed and therefore potentially be systemically available.

Clinical observations
A check for mortality was made twice daily. Observations for clinical signs of toxicity and behavioural changes were made once daily on all animals. The applications sites were assessed for signs of irritation.

Body weight
Individual body weights were recorded at weekly intervals during the pre-test and study periods and before sacrifice.

Food consumption
Food consumption was assessed daily for each individual animal by visual inspection.

Haematology and clinical chemistry
Haematological and blood chemical investigations were performed on 5 rabbits per sex and dose group with intact and abraded skin on day 21 after an overnight fast.

The following parameters were measured: Haematocrit, haemoglobin, erythrocyte count, reticulocyte count, platelet count, total leukocyte count, differential leukocyte count, mean corpuscular volume (MCV), mean corpuscular haemoglobin (MCH), mean corpuscular haemoglobin concentration (MCHC), alkaline phosphatase, aspartate amino transferase (AST), alanine aminotransferase (ALT), γ-glutamyl-transferase,

creatine kinase, creatinine, blood urea nitrogen, total protein, glucose, albumin, globulin (calculated), total bilirubin, creatinine, lactate dehydrogenase, total cholesterol, inorganic phosphorus, calcium, sodium, potassium and chloride.

Sacrifice and pathology
All animals sacrificed at scheduled termination were subjected to a gross pathological examination. Any macroscopic findings were recorded.

The following organ weights were determined: Adrenals, gonads, heart, kidneys, liver, pituitary and thyroid (with parathyroid).

Tissue samples were taken from the following organs and preserved in buffered formalin: Treated and untreated skin (3 samples/each), adrenals, bone & bone marrow (sternum), brain (at three levels), colon, duodenum, eyes with Harderian gland, gross lesions, heart, ileum, jejunum, kidneys, liver, lungs with main stem bronchi, mammary gland, lymph nodes (mediastinal, mesenteric and regional when applicable), muscle (skeletal), oesophagus, ovaries, pancreas, pituitary, prostrate, salivary glands, sciatic nerve, seminal vesicles, spinal cord (cervical), spinal cord and vertebrae (lumbar), spleen, stomach, testes with epididymis, thymus, thyroid/parathyroid, trachea, urinary bladder, uterus and vagina.

Histopathological examinations were performed on the following tissues: Treated and untreated skin, liver, kidney, gonads and any gross lesions.

Statistics
Terminal body weights, haematological and clinical chemistry parameters, absolute and relative organ weights were analysed by one-way analysis of variance, Bartlett´s test for homogeneity of variance and appropriate t-test.

II. RESULTS AND DISCUSSION

A. MORTALITY
No deaths occurred during the study.

B. CLINICAL OBSERVATIONS
A number of incidental findings were observed in some animals in all dose groups. The most frequent signs were soft stool, diarrhoea, mucoid diarrhoea and ocular and nasal discharge.

No signs of dermal irritation were observed in the control, low- and mid-dose group. In the high-dose group at 5000 mg/kg bw/day doubtful or barely perceptible to very slight erythema and doubtful or barely perceptible oedema were noted. Dermal effects were observed as early day 2 with increasing number of animals showing the effects after additional exposures. There were no differences between the animals with intact and abraded skin.

C. BODY WEIGHT
There were no statistical significant differences observed in body weights or body weight gains between the control and treated groups (with abraded and intact skin).

D. FOOD CONSUMPTION
There were no major differences in food consumption between the control and the treated groups.

E. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology
No treatment-related effects were detected in the haematological parameters measured.
There were some statistical significance differences in some parameters. However, these were incidental and considered to be biologically insignificant (see table below**Error! Reference source not found.** Table 5.3.3-19).

Blood chemistry
There were no treatment-related effects. The incidental significant changes observed were considered not to be biologically significant (see Table 5.3.3-19).

I. NECROPSY

Organ weights
Except for the statistically increased relative kidney weight observed in females at 5000 mg/kg bw/day (see table below), there were no treatment-related effects on absolute and relative organ weights noted. Since no histopathological changes were observed in the kidneys of high-dose females, the increase in relative kidney weights is considered to be of no toxicological relevance.

Table 5.3.3-20: 21-Day Dermal Toxicity Study in Rabbits ([redacted], 1982): Group mean absolute and relative kidney weights and standard variations (± SD)

* Significantly different from control group ($p < 0.05$)

Gross pathology
There were no treatment-related macroscopic abnormalities observed in the treated skin or any other tissues in any group.

Histopathology
There were no treatment-related lesions observed in any dose group.

Microscopic evaluation of treated skin samples demonstrated only mild inflammatory cell infiltration and trace necrosis in the 1000 mg/kg bw/day group. However, in untreated skin samples of three rabbits from the 1000 mg/kg bw/day group from one rabbit of the high-dose group there was also mild necrosis, indicating that this lesion was incidental and unrelated to treatment. The lesions in treated and untreated skins of the control and test substance groups were similar indicating that the effects were not related to glyphosate treatment.

Trace/mild seminiferous tubule degeneration observed in the testis was not dose related in either incidence or severity and was considered unrelated to treatment. Other lesions observed in kidney, liver, lung, ovary, lymph node, salivary gland and skin (non-application site) were considered incidental or spontaneous (see tables below). In general there were no major differences between the treatment groups of intact and abraded skin.

III. CONCLUSIONS

There were no mortalities and no treatment-related signs of systemic toxicity. There were also no signs of dermal irritation observed in the control, low- and mid-dose group. At 5000 mg/kg bw/day slight dermal irritation consisting of barely perceptible to slight erythema and oedema was noted. However, this effect is considered not to be of biological significance and no signs of irritation were seen in the histopathological examination.

There were no treatment-related effects on body weight, food consumption, haematological and clinical chemistry parameters observed in any of the dose groups. The macroscopic and histopathological findings observed at necropsy were considered incidental and unrelated to the test substance.

Repeated dermal administration of glyphosate technical to rabbits for a period of 21 consecutive days at doses of up to 5000 mg/kg bw/day resulted only in slight dermal irritation at 5000 mg/kg bw/day. No such effects were observed in the 0, 100 and 1000 mg/kg bw/day treatment groups. There were no treatment-related systemic signs of toxicity. No test article-related macroscopic or microscopic lesions were observed.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study, the toxicity potential of glyphosate technical was assessed after repeated dermal application to groups of male and female New Zealand white rabbits on intact and on abraded skin. Doses of 0, 100, 1000 or 5000 mg/kg bw/day were applied five days per week for three consecutive weeks. The study was conducted following a testing regime in general compliance with OECD 410 (1981) and with GLP.

Repeated dermal administration of glyphosate technical to rabbits for a period of 21 consecutive days at doses of up to 5000 mg/kg bw/day resulted only in slight dermal irritation at 5000 mg/kg bw/day. No such effects were observed in the 0, 100 and 1000 mg/kg bw/day treatment groups. There were no treatment-related systemic signs of toxicity of biological significance. Thus, the NOAEL is considered to be 5000 mg/kg bw/day.

In light of an *in vitro* dermal absorption of glyphosate with rabbit skin following OECD 428 (Hadfield 2012; CA 5.8.2/014), demonstrating 2.66 % bioavailability via the skin exposure, the systemic NOAEL in this study is 133 mg/kg bw/day, de

1. Information on the study

Data point:	CA 5.3.3/009
Report author	[redacted]
Report year	1985
Report title	Report on subacute inhalation toxicity in rats (14 days) of glyphosate (technical)
Report No	Not reported
Document No	Not reported
Guidelines followed in study	Not applicable
GLP	No, pre-GLP
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Four groups of 5 male and 5 females Wister rats (bred at [redacted]) were exposed to an atmosphere containing glyphosate (purity not stated) in propylene glycol for 6 hours per day, 5 days per week for two weeks. There were one low and one high dose group and two intermediate dose groups. One of the latter groups was sacrificed 14 days after the treatment period had been finished (reversal group). Two control groups of the same size were also included, one of them being exposed to filtered air only and the other to an atmosphere containing the vehicle propylene glycol. Glyphosate was mixed with the vehicle and nebulised by using compressed air. The animals were exposed in a dynamic inhalation chamber by mouth and nose route by restraining them in polypropylene tubes. The target, the nominal and the actually measured mean concentrations for the various groups are given in the table below.

Table 5.3.3-23: Report on subacute inhalation toxicity in rats (14 days) of glyphosate (technical) [redacted] 1985): Mean concentrations [mg/L air] of the test material or the vehicle

Dose group	Target concentration	Nominal concentration	Measured concentration
Control (filtered air)	0	0	0
Vehicle control	5.0	16.5	5.6
Low dose	0.25	0.90	0.28
Intermediate	1.0	3.01	0.93

	dose: —; —; — Intermediate dose (reversal): 1.0; 3.10; 0.90 High dose: 4.0; 11.7; 3.8 With the exception of the exposure periods, animals were housed five per cage and had free access to food and drinking water. The rats were examined individually before, during and after exposure for any signs of toxicity. Food consumption was recorded daily and body weight was determined at pretest and then on every 4th day during the study and on the day of termination. Blood samples for haematological (red and white blood cell parameters, thrombocyte count and prothrombin time) and clinical chemistry (total serum protein, blood urea nitrogen, glucose, alanine aminotransferase (ALAT) and alkaline phosphatase (AP)) investigations were taken before first exposure and after one week from some animals of each group and from all animals (except the recovery group) after the last exposure. From reversal group rats, blood was obtained at termination. Urinalysis was also performed. All rats were necropsied and the following organs were removed and weighed: adrenals, gonads, heart, kidneys, liver, and spleen. These organs as well as aorta, brain, eyes, intestines, larynx, lungs, lymph nodes (axillary and mesenteric), nose, oesophagus, pancreas, pituitary, seminal vesicle, stomach, thyroid, trachea, urinary bladder and uterus were examined microscopically.
Short description of results:	Mass median aerodynamic diameters of all atmospheres were within the respirable range of 0 - 7 µm on all occasions. The temperature, humidity, oxygen concentration and air flow were similar for all groups. There was no mortality during the treatment or the recovery periods. Neither treatment-related clinical signs nor effects on body weight or food consumption were observed. In the vehicle control group and in all groups exposed to glyphosate, salivation, lacrimation, redness to nose and urination were observed during exposure. No change in the rate of respiration was seen. No adverse effects of treatment on haematology, clinical chemistry and urinalysis were noted in any of the groups. No significant changes in organ weights or upon gross examination were seen. Histopathology did not reveal evidence of adverse effects. Up to the highest concentration tested of approx. 3.8 mg/L air (mean measured concentration) repeated inhalative exposure of Wistar rats to an aerosol containing glyphosate did not lead to any local (respiratory) or systemic toxicity. Therefore, the NOAEC for rats under the conditions of this study was 3.8 mg/L.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	Monograph (2000): The study was considered supportive since an effect dose was lacking. In addition, there were some reporting deficiencies. Furthermore, statistical analysis of the results obtained was either not performed or not reported. RAR (2015): The study was considered unacceptable due to serious reporting deficiencies, e.g., absence of information on batch and purity of the test material. Therefore and since the study report is not available, this study is

	considered invalid.
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL.

2. Full summary of the study according to OECD format

Together with three other herbicide active substances (quizalofop-p-ethyl, isoxaflutole and mesotrione) the effect of glyphosate on the transcriptome and metabolome profile of differentiated HepaRG cells was investigated.

Materials and methods
Chemicals - Glyphosate (purity ≥ 96 %) was purchased from Sigma-Aldrich, Gillingham, Dorset, UK.

HepaRG cell culture - Differentiated HepaRG™ cells (HPR 116) were purchased from Biopredic International (Rennes, France). Cells were thawed, suspended and plated in general purpose medium (Williams' E medium + GlutaMAX™) containing the ADD670 supplement. Cells were kept in general purpose medium until day 8, when the culture becomes well organized and includes well-delineated trabeculae and many canaliculi-like structures. At this time, the culture is composed of primitive biliary epithelial cells and mature hepatocytes with basal metabolic activities similar to freshly isolated primary cells. From day 8 to day 14, cells were switched to the test medium composed of Williams' E medium + GlutaMAX™ supplemented with 2 % foetal bovine serum and 1 % DMSO, as well as different concentrations of glyphosate or solvent as a control. Glyphosate was tested at 0.06 µM (concentration representative of low environmental exposure), 6 µM, and 600 µM.

Library generation and RNA-sequencing - A 100 ng aliquot of total RNA from each sample was used to prepare total RNA libraries using the KAPA Stranded RNA-Seq Kit with RiboErase, and samples were randomised before preparation. Polymerase chain reaction (PCR) was performed for 14 cycles for final

library amplification. Resulting libraries were quantified using the Qubit 2.0 spectrophotometer and average fragment size assessed using the Agilent 2200 Tapestation. The transcriptome of HepaRG cells exposed to glyphosate was sequenced employing this strategy, except that the libraries were prepared as previously described. A total of 3 separate sequencing pools were created using equimolar quantities of each sample with compatible indexes: 2 with 17 samples each, and one with 16 samples. Paired-end reads of 75bp were generated for each library using the Illumina NextSeq®500 in con-junction with the NextSeq®500 v2 high-output 150-cycle kit.

Mass spectrometry-based metabolomics - Approximately 5,000,000 hepaRG cells per sample were harvested from the 6 well-plates to obtain a sufficient quantity of material to perform the metabolomics experiment. Cells were detached using 0.05 % trypsin EDTA, and centrifuged to eliminate trypsin residues. Finally, cell pellets were frozen at -80 °C pending analysis. Metabolomics analysis of the frozen cell pellets was conducted by Metabolon Inc. The sample extracts were stored overnight under nitrogen before preparation for analysis. The resulting extract was analysed on four independent instrument platforms: two different separate RP/UPLC-MS/MS with positive ion mode electrospray ionisation (ESI), a RP/UPLC-MS/MS with negative ion mode ESI, as well as by hydrophilic-interaction chromatography(HILIC)/UPLC-MS/MS with negative ion mode ESI as previously described. Compounds were identified by comparison to library entries of purified standards or recurrent unknown entities. Biochemical identifications are based on 3 criteria: retention index within a narrow retention time/index (RI) window of the proposed identification, accurate mass match to the library +/- 10 ppm, and the MS/MS forward and reverse scores between the experimental data and authentic standards. The use of all three data points can be utilised to distinguish and differentiate biochemicals. Peaks were quantified using the area-under-the-curve method.

Statistics - Metabolome data analysis was performed using in-house services of Metabolon Inc. Biochemical data were normalized with respect to protein concentration as determined by the Bradford assay. The Welch's two-sample t-test was used to test whether control and treatment group means are different from two independent populations. This version of the two-sample t-test allows for unequal variances. FDR methods and estimated q-values were used to account for the highest number of false positive results caused by the high number of statistical tests. The RNA-seq data analysis was performed using the new version of the Tuxedo protocol with HISAT2, StringTie and Ballgown. A standard linear model-based comparison of transcript abundance was performed without adjusting for other covariates to identify differentially expressed transcripts for each group. Although 3 concentrations were tested for glyphosate, no multigroup comparisons were used because dose spacing was too large to allow reliable conclusions to be drawn from these methods. Instead, pairwise comparisons were used.

Results

Control, untreated cell cultures presented no visible signs of aging after a 6-day exposure. Transcriptome profiles of HepaRG cells were then determined using the Illumina-based RNA sequencing platform. The highest concentration of glyphosate tested caused significant changes in transcriptome profiles. Alterations in gene expression caused by the 2 lowest concentrations (0.06 and 6 µM) failed to pass the statistical threshold that took into account the high number of tests performed. A total of 7 transcripts had their levels altered ($p < 0.05$) with glyphosate at 600 µM. The number of genes disturbed by the exposure to glyphosate was insufficient to use a functional annotation tool for pathway enrichment analysis. It is not clear if glyphosate lacks hepatic toxic effects at these concentrations or if this experimental design lacks sensitivity to detect hepatic effects of weak toxicants. To further explore changes in liver metabolism caused by glyphosate in greater detail, a global metabolome profiling of HepaRG cells exposed to three concentrations of glyphosate was explored. The Metabolon HD4 platform detected 802 named biochemicals in the HepaRG samples. Overall, glyphosate did not cause significant alterations in metabolome composition. However, exposure did cause a significant decrease in long chain fatty acids (LCFAs) and polyunsaturated fatty acids (PUFAs). HepaRG cells exposed to the lowest concentration of glyphosate tested (0.06 µM) showed the most dramatic effects in the levels of these fatty acids as either significant or trends towards significant lower levels. At the higher glyphosate concentrations of 6 µM and 600 µM, lower lipid levels were also observed but these did not reach statistical significance.

Discussion and conclusion

An in-depth investigation was conducted of transcriptome profile alterations in HepaRG human liver cells caused by exposure to pesticide active substances. Glyphosate was found to be only weakly toxic inducing little change in transcriptome profiles. Interestingly, a follow-up metabolomics analysis of HepaRG cells treated with the lowest (0.06 µM) concentration of glyphosate revealed a significant decrease in the levels of LCFAs and PUFAs. Although these findings from an *in vitro* tissue culture model system cannot be readily translated to effects *in vivo*, they are nevertheless indicative of differences in toxicity potency between pesticide ingredients. The exact nature of this low dose effect of glyphosate cannot be determined from this single experiment, but it is possible that at higher concentrations, more overtly toxic mechanisms are masking the effects on lipids. Another possibility is that a saturation effect is occurring once the low dose is exceeded bearing in mind that glyphosate levels found in the HepaRG cells during the metabolomics analysis increased by 3.7-and 336.35-fold at the intermediate and highest concentrations tested compared to the negative controls. Glyphosate was the least toxic of the compounds tested in this study.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Together with three other herbicide active substances (quizalofop-p-ethyl, isoxaflutole and mesotrione) the effect of glyphosate on the transcriptome and metabolome profile of differentiated HepaRG cells was investigated at 0.06, 6 and 600 µM. Glyphosate was found to be only weakly toxic inducing little change in transcriptome profiles when compared with the other herbicides tested. A follow-up metabolomics analysis of HepaRG cells exposed to glyphosate at 0.06 µM revealed a significant decrease in the levels of long chain fatty acids (LCFAs) and polyunsaturated fatty acids (PUFAs). At the higher glyphosate concentrations of 6 and 600 µM, lower lipid levels were also observed but these did not reach statistical significance. It is not clear, however, how these findings from an *in vitro* tissue culture model can be translated to effects *in vivo*.N

Reliability criteria for *in vitro* toxicology studies

Publication: Mesnage *et al*., 2018.	Criteria met? Y/N/?	Comments
Guideline-specific		
Study in accordance to valid internationally accepted testing guidelines	N	
Study performed according to GLP	N	
Study completely described and conducted following scientifically acceptable standards	Y	
Test substance		
Test material (Glyphosate) is sufficiently documented and reported (i.e. purity, source, content, storage conditions)	Y	Glyphosate (purity ≥ 96 %). Source: Sigma-Aldrich, Gillingham, Dorset, UK.
Only glyphosate acid or one of its salts is the tested substance	N	Also three other pesticide active substances were tested (quizalofop-p-ethyl, isoxaflutole and mesotrione).
AMPA is the tested substance	N	
Test system clearly and completely described	Y

2. Full summary of the study according to OECD format

The aim of this study was to explore the mechanisms of glyphosate-induced pulmonary pathology by utilizing murine models and real environmental samples. C57BL/6, TLR4–/–, and IL-13–/– mice inhaled extracts of glyphosate-rich air samples collected on farms during spraying of herbicides or inhaled different doses of glyphosate and ovalbumin. The cellular response, humoral response, and lung function of exposed mice were evaluated. Exposure to glyphosate-rich air samples as well as glyphosate alone to the lungs increased: eosinophil and neutrophil counts, mast cell degranulation, and production of IL-33, TSLP, IL-13, and IL-5. In contrast, in vivo systemic IL-4 production was not increased. Co-administration of ovalbumin with glyphosate did not substantially change the inflammatory immune response. However, IL-13-deficiency resulted in diminished inflammatory response but did not have a significant effect on airway resistance upon methacholine challenge after 7 or 21 days of glyphosate exposure. Glyphosate-rich farm air samples as well as glyphosate alone were found to induce pulmonary IL-13-dependent inflammation and promote Th2 type cytokines, but not IL-4 for glyphosate alone.

Materials and methods

Mice

C57BL/6 female (6–9 weeks) mice were purchased from Jackson Laboratory (Sacramento, CA). TLR4–/– mice (backcrossed 10 generations) were received from Cincinnati Children's Hospital Medical Center (CCHMC). Both strains were subsequently bred in house. Female mice of wild type and IL-13–/– BALB/c background were received from the laboratory of Dr. Fred Finkelman, CCHMC. Mice were housed in individually ventilated cages in a pathogen free facility at the Department of Environmental Health, University of Cincinnati (UC) following the UC Institutional Animal Care and Use Committee (IACUC) guidelines and all experiments were conducted following a UC IACUC – approved protocol.

Antibodies and reagents

The following antibodies for flow cytometry were purchased: Ly-6G (Gr-1) eFluor1 450 (RB6-8C5; Isotype Rat IgG2b) from eBioscience (San Diego, CA). CD16/CD32 (2.4G2; Isotype Rat IgG2b) and SiglecF-PE (E50-2440; Isotype Rat IgG2a) were purchased from BD PharMingen (San Jose, CA). A kit for measuring serum levels of MMCP1 was purchased from eBioscience.

Collection of farm air samples during summer pesticide spray seasons

Air samples were collected by three sets of total inhalable aerosol samplers (Button Inhalable Aerosol Sampler, SKC Inc., Eighty Four, PA) operated in parallel on three farms in Butler County, Ohio during summer glyphosate spray seasons. Samplers were installed at 1.5 m height at the edge of the field downwind from the spraying locations (sizes: approx. 5000 - 10,000 m^2). The sampling period was approximately 24 h starting from glyphosate spraying and air samples were collected at a flow rate of approximately 4 l/min on glass fiber filters. The filters from one set of samplers containing aerosolized glyphosate were eluted using PBS and the suspensions were filtered. A stock solution was prepared by pooling the samples collected from three farms (from now on referred as 'Real Env.') and used for intranasal treatment of mice. The filters from the other two sets of samplers were analysed for glyphosate and endotoxin to estimate the levels of glyphosate and endotoxin in 'Real Env.' samples.

Analysis of glyphosate in filter extracts

Glyphosate residues from filters were extracted using KH2PO4 buffer/1 M NaOH in an automatic shaker followed by freeze-drying. The freeze-dried samples were dissolved with deionised water and filtered through 0.45 mM Millipore filter. Glyphosate levels in the suspensions were determined by Abraxis ELISA Kit at 450 nm. The average amount of glyphosate per filter was 17.33 µg, which correspond to average airborne concentration of 22.59 ng/m^3.

Analysis of endotoxin in filter extracts

Endotoxin in filter extracts were analysed using the Limulus amebocyte lysate assay (Pyrochrome LAL; Associates of Cape Cod Inc., Falmouth, MA), as described previously. The samples were spiked with endotoxin standard of 0.50 EU/mL to assure that there was no inhibition or enhancement between the filter extracts and the reagents. The average amount of endotoxin per filter was 24.49 EU, which correspond to average airborne concentration of 4.87 EU/m^3.

Treatment of mice with farm-derived air samples, glyphosate and sensitization with OVA

PBS suspended farm air sample ('Real Env.'; estimated amount of glyphosate: 8.66 µg/mL) and reagent grade glyphosate (Sigma – Aldrich, St. Louis, MO) (100 ng, 1 µg or 100 µg) were delivered (in 30 µL) to the nose of anesthetised mice which were witnessed to aspirate the solution. Treatments were administered either: daily for 7 days or 3 times a week for 3 weeks. Same exposure schedule was followed for OVA alone (100 µg) and for OVA (100 µg) plus different dose of farm air sample and glyphosate. Mice were sacrificed 24 h after final airway treatment with sodium pentobarbital.

Histological analysis of lung

Formalin-fixed paraffin embedded lung sections (5 µm thick) were prepared for H&E and chloroacetate esterase (CAE) staining. The entire histological slide from each mouse was examined in blinded fashion and given a global categorical severity score based on infiltration of cells into parenchymal, peribronchial,

and perivascular regions of lungs.

Immunohistochemical staining
To analyse IL-33 and TSLP expression in the lungs section, the following antibodies were used for immunostaining: mouse IL-33 (0.2 mg/mL, AF3626, R&D Systems, Minneapolis, MN); mouse TSLP biotinylated (0.2 mg/ml, BAF555, R&D Systems) and respective isotype controls (R&D Systems). IL-33 and TSLP antibody–antigen complex were detected using Cy3 donkey anti-goat IgG (1:10,000) (Invitrogen/Molecular probes, Grand Island, NY). Slides were counterstained with DAPI (Vector Labs, Burlingame, CA). Images were obtained using a Nikon A1R Si microscope.

Isolation of lung inflammatory cells
Lungs were perfused with PBS, removed, manually minced into 1–2 mm fragments and then placed in Hank's Balanced Salt Solution (Sigma–Aldrich) containing Liberase TL (50 µg/mL; Roche Diagnostics, Indianapolis, IN) and DNase I (0.5 mg/mL; Sigma – Aldrich). Tissue was digested at 37 °C in a CO_2 incubator for 30 min. The tissue suspension was then passed through a 40 µm cell strainer. ACK lysis buffer (invitrogen) was used to clear red blood cells.

Flow cytometric analysis
Single cell suspensions from lungs (10^6 per mL) were blocked with anti-mouse CD16/CD32 antibodies before cell-surface staining. Cells were stained with fluorescently-labeled antibodies against SiglecF, Ly-6G/C (Gr-1), in different combinations according to the experiment. Analysis was performed using a FACSCanto II cytometer and FACSDIVA software (BD Biosciences). Eosinophils were defined as being $SiglecF^+Gr\text{-}1^+$ and neutrophils as $SiglecF^-$ $Gr\text{-}1^+$.

Cytokine measurement
IL-4, IL-10, IL-13, and IFN-γ production were measured by the in vivo cytokine capture assay (IVCCA). Briefly, biotinylated cytokine-specific mAbs were injected via tail vein immediately before the last airway treatment, and blood was collected 24 h later; sera or plasma were analysed with microtiter plates wells coated with corresponding anti-cytokine mAbs. Cytokine levels were also assessed in Bronchoalveolar lavage fluid (BALF) that was obtained 24 h after the last airway treatment. A kit for measuring in vivo IL-4 production by IVCCA, R46A2 and XMG1.2 anti-IFN-γ mAbs was purchased from Becton–Dickinson (Franklin Lakes, NJ); eBio1316H and eBio13A anti-IL-13 mAbs JES5-2A5 and JES5-16E3 anti-IL-10 mAbs ELISA Ready-SET-Go analysis kits for measurement IL-33 and IL-5 were purchased from eBioscience. Assays were performed according to the kit's manufacturer protocols.

Statistical analyses
Data were analysed with Sigma Plot 12.0 (Systat Software, Inc., San Jose, CA). Statistically significant differences in means were determined by one-way ANOVA followed by Bonferroni multiple comparison tests. Kruskal–Wallis tests were conducted if the data did not have a normal distribution. All the data are presented as mean ± SD for each group. Probability values of <0.05 were considered significant.

Results
Exposure of air samples collected during glyphosate spray on farms stimulates airway inflammation
Wild type C57BL/6 (WT) and TLR4–/– mice were intranasally exposed to 'Real Env.' samples (PBS suspended farm air samples) daily for 7 days. 'Real Env.' exposure was found to substantially increase the cell count in both the lungs and BAL fluid of WT and TLR4–/– mice. Additionally, the increase in pulmonary infiltrate in lungs was found to be higher in TLR4–/– than in WT mice (Fig. 1A and B). Similarly, an increase in eosinophil and neutrophil levels in 'Real Env.' treated mice (Fig. 1C–F) were observed. This inflammation was also confirmed by histological examinations (Fig. 1G) and elevated IgG1 and IgG2a levels. Additional experiments were conducted using reagent grade glyphosate of different doses. Administration of reagent grade glyphosate to the airway of mice produced substantial pulmonary inflammation whether the daily dose given was 100 ng, 1 µg or 100 µg for 7 days.

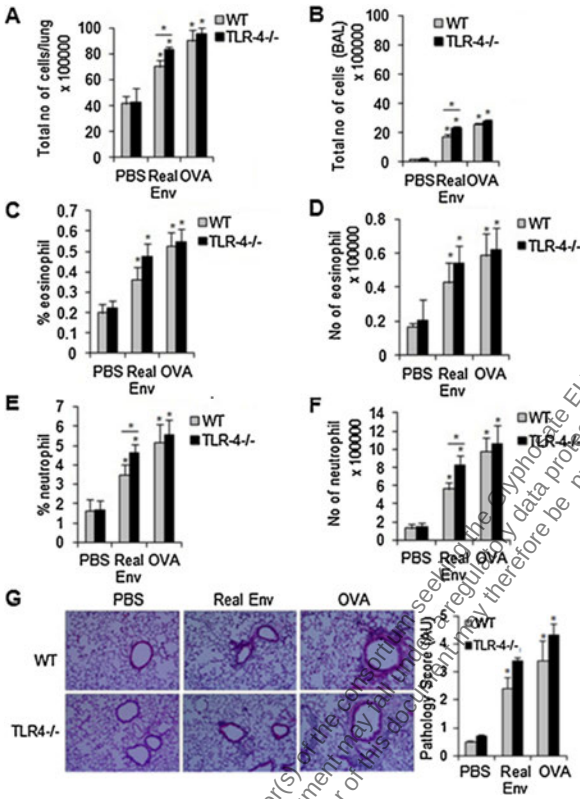

Figure 1: Increase in total number of cells, eosinophils, and neutrophils in lung and BAL fluids upon airway exposure to farm air samples ('Real Env.') and OVA for seven consecutive days (mean ± SD; *n* = 8). Increase in total number of cells in (A) lung and (B) BAL fluids. Increase in percentage (C) and total number (D) of eosinophils and neutrophils (E, F) per lung upon exposure to farm air samples ('Real Env.'). (G) Representative lung sections (H&E staining) and its pathology score from mice treated with PBS, farm air samples ('Real Env.') and OVA intranasally for 7 consecutive days (mean ± SD; *n* = 8); magnification 200x. * Indicates statistically significant differences (p <0.05) with respect to PBS treated control and in between WT and TLR4–/– mice group.

In the BALF and lung digests, a significant increase in the total cell count when treated with glyphosate at 1 µg or 100 µg (Fig. 2A and D) was found. Eosinophils (Fig. 2B and C), neutrophils, (Fig. 2E and F), and IgG1 and IgG2a levels) were also increased in glyphosate-treated mice compared to controls. However, No significant changes in the total cell count, eosinophils and neutrophils, IgG1 and IgG2a at glyphosate dose of 100 ng were found. Inflammation was confirmed by histological examination (Fig. 2M). Mice treated with both reagent grade glyphosate and OVA demonstrated significantly higher cell count (Fig. 2G and J), eosinophils (Fig. 2H and K), neutrophils (Fig. 2I and L), IgG1, and IgG2a compared to PBS treated mice.

Because pulmonary mastocytosis is typically observed in protein-allergen-induced experimental asthma, the pulmonary mast cell burden in the mice were assessed.

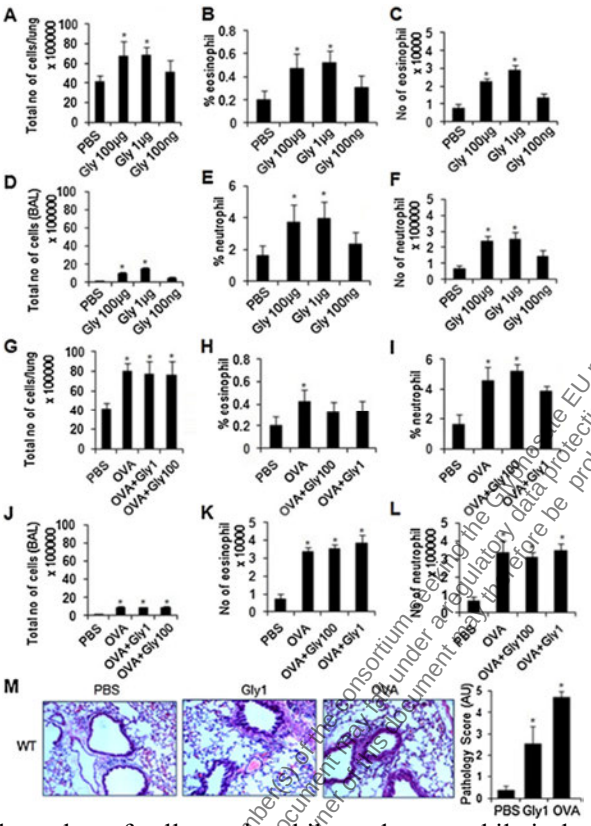

Figure 2: Increase in total number of cells, eosinophils, and neutrophils in lung and BAL fluids of WT mice upon airway exposure to glyphosate and combinations of glyphosate and OVA for seven consecutive days (mean ± SD; $n = 8$). Increase in total number of cells in (A) lungs and (D) BAL fluids upon exposure to different doses of glyphosate (100 ng, 1 µg or 100 µg). Increase in percentage (B) and total number (C) of eosinophils and neutrophils (E and F) per lung upon exposure to two doses of glyphosate. Increase in total number of cells in (G) lungs and (J) BAL fluids upon exposure to combination of glyphosate (1 µg or 100 µg) with OVA (100 µg). Increase in percentage and total number of (H and K) eosinophils and (I and L) neutrophils per lung upon exposure to OVA and combination of glyphosate, respectively. (M) Representative lung sections (H&E staining) and its pathology score from WT mice treated with PBS, glyphosate (1 µg) and OVA (100 µg) intranasally for 7 consecutive days (mean ± SD; $n = 8$); magnification 200 x. * Indicates statistically significant differences ($p < 0.05$) with respect to PBS and treated WT mice group

A significant increase in mast cell number in lungs treated with the substances isolated from the air on active farms ('Real Env.') and reagent grade glyphosate (Fig. 3A and C) was not observed. However, the MCPT-1 levels were found to be substantially higher in both groups indicating increased mast cell degranulation in the treated mice (Fig. 3B and D).

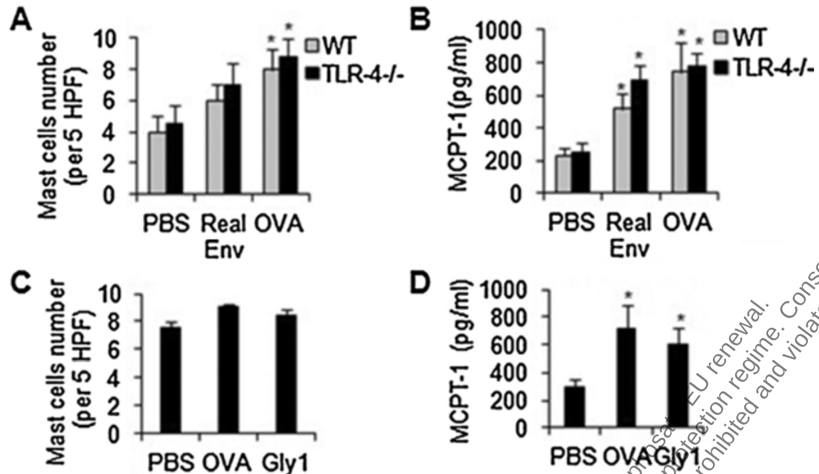

Figure 3: Farm air samples containing glyphosate as well as pure glyphosate alone induce increased mast cell degranulation but no increase in lung mast cell numbers upon airway exposure. (A) Mast cells number in CAE stained lung section and (B) serum MCPT-1 concentration in blood 4 h after last exposure of PBS, farm air samples ('Real Env.'), and ovalbumin (OVA). (C) Mast cells number in CAE stained lung section and (D) serum MCPT-1 concentration from mice treated with PBS, ovalbumin and 1 µg of glyphosate delivered to intranasally for 7 consecutive days (mean ± SD; n = 8). * Indicates statistically significant differences ($p < 0.05$) with respect to PBS and treated mice group.

Glyphosate-rich farm air samples induced airway inflammation and higher production of IL-10, IL-13, IL-5, IFN-γ and IL-4 but glyphosate alone failed to produce IL-4

To evaluate the glyphosate-induced inflammation, the systemic cytokine profile (Fig. 4A–E) of 'Real Env.' and glyphosate exposed mice were measured using IVCCA (Finkelman and Morris, 1999). Significantly higher levels of IL-5, IL-10, IL-13, and IL-4 were found upon treatment with 'Real Env.' alone in WT and TLR4–/– mice (Fig. 4A–D) approaching the levels induced by treating with OVA alone. The production of IL-5, IL-13 and IL-10 following 'Real Env.' exposures was higher in TLR4–/– than in WT mice. No significant difference in IL-4 production between TLR4–/– and WT mice were found (Fig. 4D). Production of these cytokines in mice given two different doses of glyphosate were then tested and found significantly higher levels of IL-5, IL-10, IL-13 and IFN-γ (Fig. 4F) that approached those levels induced by treating with OVA alone. Notably, there was no additional or synergistic effect when OVA was co-administered with glyphosate (Fig. 4G). Another interesting finding is that glyphosate alone was unable to induce significant levels of IL-4 while airway treatment with glyphosate with OVA did so.

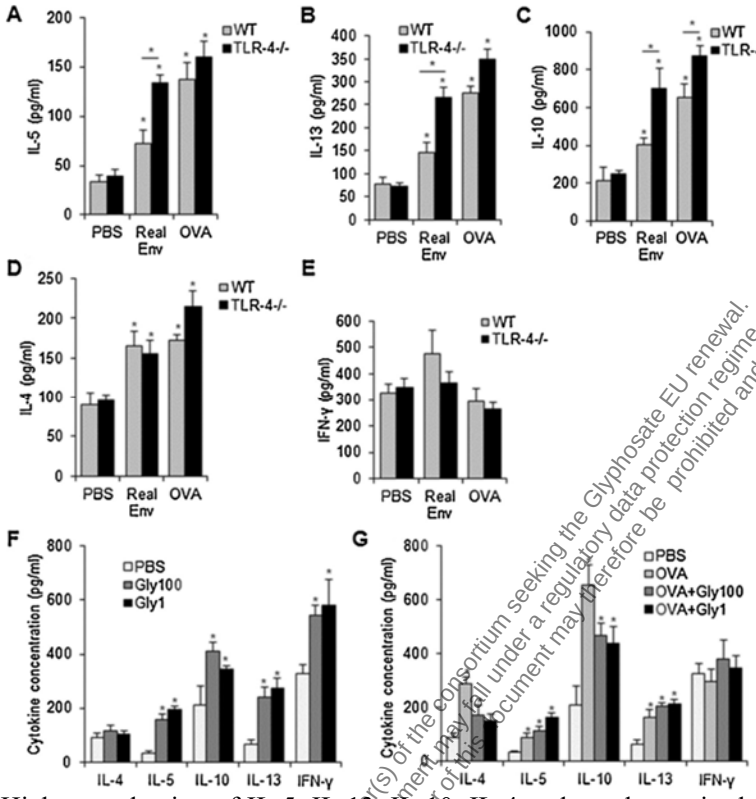

Figure 4: (A–E) Higher production of IL-5, IL-13, IL-10, IL-4 and no change in the IFN-γ levels upon exposure to farm air samples in WT and TLR4–/– mice. (F) The increased level of IL-5, IL-10, IL-13, IFN-γ and no change in the IL-4 levels upon glyphosate (1 or 100 µg) exposure to WT mice. (G) The increased level of IL-4, IL-5, IL-10, IL-13, and no change in IFN-γ levels upon combination of glyphosate (1 or 100 µg) and ovalbumin (100 µg) exposure to WT mice (mean ± SD; $n = 8$). Levels of cytokines were evaluated by IVCCA in serum of mice upon 7 consecutive days of intranasal treatment with farm air samples ('Real Env.') and glyphosate. Blood samples were collected 24 h after the last exposure. IL-5 was measured in the BAL fluids. * Indicates statistically significant differences ($p < 0.05$) with respect to PBS treated control and in between WT and TLR4–/– mice group.

IL-33 and TSLP in lungs are increased upon exposure to glyphosate-rich air samples as well as reagent grade glyphosate alone

As the cytokine profile of mice treated with 'Real Env.' and glyphosate approximated those treated with OVA, mediators known to promote type 2 pathology were examined. IL-33 and TSLP appeared to be logical choices because of their well-recognized effector functions, and due to their source – the respiratory epithelium cells which would be the first cells to encounter inhaled glyphosate. The IL-33 and TSLP content of BALF were measured directly and found an abundance of both cytokines in 'Real Env.' – treated WT and TLR4–/– mice (Fig. 5A and B). IL-33 production was observed to be significantly higher in TLR4–/– mice compared to WT mice. An abundance of both cytokines in glyphosate-treated mice were observed (Fig. 5C and D). This finding was confirmed by immunohistochemical staining of IL-33 and TSLP in lung sections of glyphosate-treated mice (Fig. 5E) and 'Real Env.' – treated WT and TLR4–/– mice, which demonstrated substantial production of both cytokines, which was limited to the respiratory epithelium after glyphosate exposure.

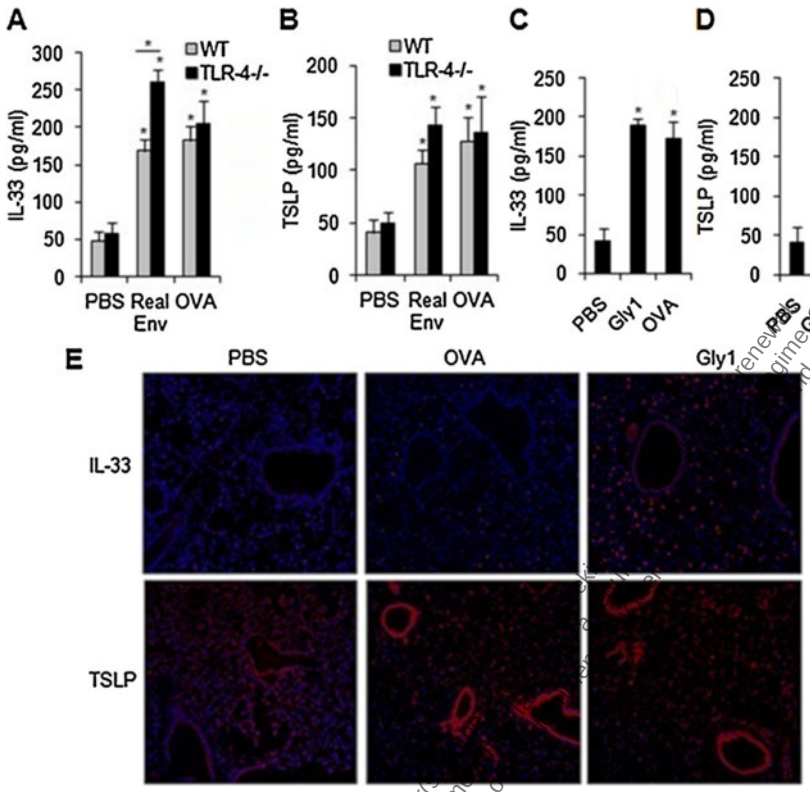

Figure 5: IL-33 and TSLP productions increased in the lung upon exposure to farm air samples and glyphosate. (A and B) ELISA based measurement of IL-33 and TSLP in BAL fluids of PBS, farm air samples and ovalbumin (100 µg) treated WT and TLR4–/– mice, respectively (mean ± SD; $n = 8$). (C and D) ELISA based measurement of IL-33 and TSLP in BAL fluids of PBS, OVA and pure glyphosate (1 µg) treated WT mice, respectively (mean ± SD; $n = 8$). (E) Immunofluorescence staining of IL-33 and TSLP in the lung sections of the glyphosate treated WT mice, magnification 200x. * Indicates statistically significant differences ($p < 0.05$) with respect to PBS treated control and in between WT and TLR4–/– mice group.

Glyphosate-induced pulmonary inflammation is attenuated in IL-13 –/– mice

Glyphosate as a small molecule may not be efficiently presented to conventional T cells by antigen-presenting cells. The involvement of innate pathways upon glyphosate exposure, as hypothesized, was supported by the absence of an increased production of IL-4. This absence would have been expected if type 2 innate lymphoid cells (ILC2s) were the primary source of the IL-5 and IL-13 detected. IL-33 and TSLP have been well described to induce ILC2s, which in turn causes lung pathology particularly via IL-13-dependent mechanism. To test this hypothesis, IL-13 deficient mice were exposed to glyphosate for 7 and 21 days and assessed lung inflammation. While there was no change in IL-4 levels, the inability to produce IL-13 prevented the rise in IL-5 production, but not the rise in IL-10 production, at both time points during glyphosate treatment. Deficiency in IL-13 also prevented a significant rise in IL-33 and TSLP levels at the early time point but not the latter one (Fig. 6A–D). Lack of IL-13 production was also associated with significantly less ($p < 0.05$) severe cellular infiltration noted on histology (Fig. 6E). Despite significant inflammation, no airway hyper responsiveness was found in glyphosate-treated wild type and IL-13–/– mice.

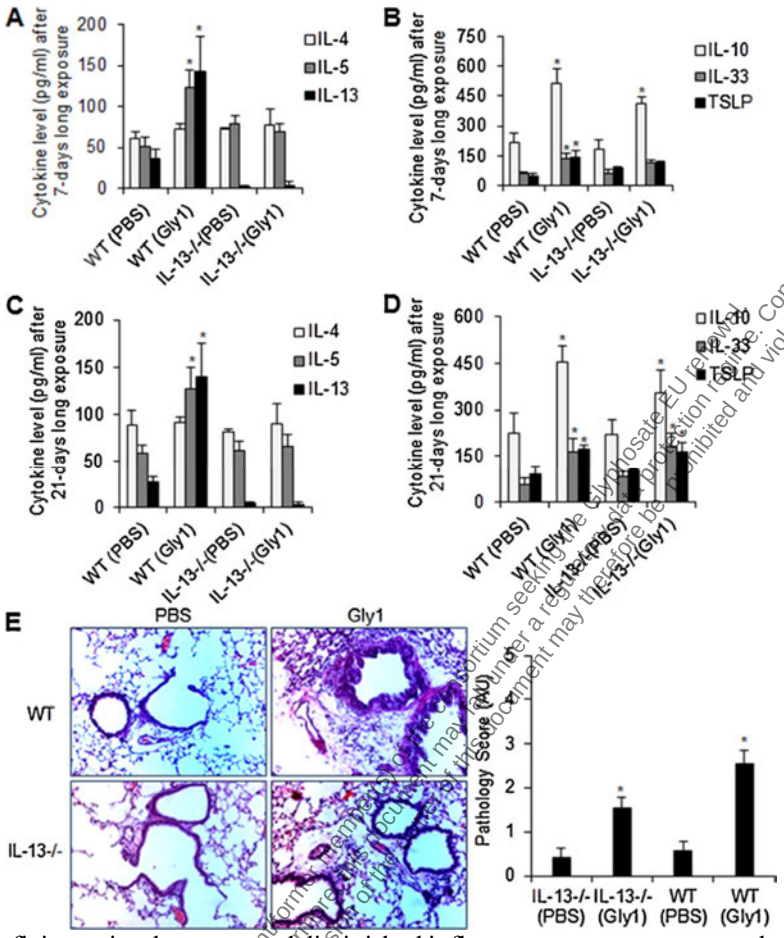

Figure 6: IL-13-deficient mice demonstrated diminished inflammatory response upon glyphosate exposure. (A, C) Diminished production of IL-5 but no change in IL-4 level, and (B, D) diminished production of TSLP, IL-33, IL-10 levels, between IL-13-deficient mice and WT mice upon glyphosate exposure (1 µg) for 7 or 21 days, respectively (mean ± SD; *n*=8). (E) Representative lung sections (H&E staining) from mice treated with PBS and glyphosate (1 µg) intranasally 3 times a week for 21 days; magnification 200 x (left panel). Arbitrary scores were based on inflammatory cells infiltration in lungs parenchyma, peribronchial, and perivascular regions. Analysis was performed in a double-blinded manner (right panel). * Indicates statistically significant differences (p <0.05) with respect to PBS treated control group.

Conclusion

The results demonstrate the capacity of glyphosate-rich air samples from farms as well as pure glyphosate to induce type 2 airway inflammation, over both short and longer time courses. Furthermore, glyphosate induced inflammation was found to be associated with induction of IL-33 and TSLP. This work also highlights the production of IL-13 as well as modulation of innate immune system by glyphosate, which may play an important role in exacerbation of airway inflammation by this low molecular weight chemical.

3. Assessment and conclusion

Assessment and conclusion by applicant:

This study evaluated nose-only exposure to glyphosate and collected farm air samples containing glyphosate and evaluated the immune response in the lungs. This is not a guideline study nor an endpoint used in risk assessment. This study in not usable for risk assessment in terms of hazard assessment. In terms of exposure, the study determined that average amount of glyphosate per filter from environmental samples after spray application to fields was 17.33 µg, which correspond to average airborne concentration of 22.59 ng/m^3. The method for the collection and analysis of the air samples was not

validated and the assumptions and calculations used in the determination of the average airborne concentration were not provided, therefore the results cannot be verified. While the study itself is acceptable, it is unreliable in terms of usable endpoints for risk assessment.

Assessment and conclusion by RMS:

Reliability criteria for *in vivo* toxicology studies

Publication: Kumar et al., 2014.	Criteria met? Y/N/?	Comments
Guideline-specific		
Study in accordance to valid internationally accepted testing guidelines	N	
Study performed according to GLP	N	
Study completely described and conducted following scientifically acceptable standards	Y	
Test substance		
Test material (Glyphosate) is sufficiently documented and reported (i.e. purity, source, content, storage conditions)	Y	Purity is reagent grade. Source: Sigma - Aldrich, St. Louis, USA.
Only glyphosate acid or one of its salts is the tested substance	N	Sampling of aerosols from field spraying also contain co-formulants of the GBH applied.
AMPA is the tested substance	N	
Study		
Test species clearly and completely described	Y	Female mice of wild type and IL-13-/- BALB/c background.
Test conditions clearly and completely described	Y	
Route and mode of administration described	Y	Intranasal application of air samples taken during glyphosate field application (24 hours) and glyphosate.
Dose levels reported	Y	Field air sample and 100 ng, 1 µg or 100 µg of glyphosate delivered intranasally.
Number of animals used per dose level reported	Y	
Method of analysis described for analysis test media	Y	Glyphosate measured in air sample with ELISA kit.
Positive control	Y	Ovalbumin.
Validation of the analytical method	N	
Analytical verifications of test media	N	
Complete reporting of effects observed	Y	
Statistical methods described	Y	
Historical control data of the laboratory reported	N	
Dose-effect relationship reported	Y	For glyphosate.
Overall assessment		
Reliable without restrictions		

Reliable with restrictions	Y	
Reliability not assignable		
Not reliable		
This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the method for the collection and analysis of the air samples was not validated.		

Assessment and conclusion by RMS:

CA 5.4 Genotoxicity

In the 2001 EU evaluation glyphosate was examined for genotoxicity in a wide range of test systems covering all relevant endpoints *in vitro* (see CA 5.4.1) and *in vivo*, in both somatic (see CA 5.4.2) and germ cells (see CA 5.4.3). Additional studies have been conducted on glyphosate since the last EU review, however, all these studies were negative and are considered confirmatory data.

In addition to studies commissioned by representatives of the Glyphosate Renewal Group, several publications identified from the open literature have been submitted. The majority of these publications report *in vitro* comet assay data, although there are also data from two mouse bone marrow micronucleus tests and *in vitro* chromosome aberration, cytotoxicity and cytokinesis block micronucleus tests. It is noted that a common deficieny for many of these publications is a lack of adequate information concerning the characterisation of the glyphosate source used.

The two *in vivo* publications report negative results for six out of a total of seven different batches of glyphosate tested, thus confirming the findings of the Glyphosate Renewal Group studies. The one batch reported as positive is likely to have been compromised by the presence of 0.13 % formaldehyde.

Although a small number of publications reported negative *in vitro* findings (CA 5.4/003 and CA 5.4/007), the majority of studies are indicated to be positive for DNA damage. Due to inconsistencies in methodology (e.g. cell lines used, exposure conditions, toxicity meansurements, concentrations investigated etc) the genotoxicological relevance of the reported data is unclear. However, the majority of the publications indicate the observed DNA damage was frequently concomitant with high, confounding toxicity and markers of oxidative damage. When considered alongside the consistently negative findings in the regulatory mutagenicity studies (see Sections CA 5.4.1, CA 5.4.2 and CA 5.4.3), it is concluded that the results of these indicator tests (i.e. assays that do not measure an apical mutagenicity endpoint) confirm the lack of an ability for glyphosate to react directly with cellular DNA. Instead the findings are indicative of DNA damage occurring secondary to other toxic cellular events. Furthermore, as demonstrated by the consistent negative findings in *in vivo* models, provided that normal homeostasis mechanisms are not overwhelmed, glyphosate-induced secondary DNA damage does not occur *in vivo*.

The overwhelming weight of evidence gathered from all the submitted studies, is that glyphosate does not exhibit a genotoxic risk to humans.

Nota bene: In autumn of 2019 NGOs and media published accusations against the German based contract research organization "[redacted]" on animal welfare and GLP. In the frame of this glyphosate renewal dossier GRG is submitting 24 studies performed during the years 1995 – 2010 at [redacted]. All these studies were conducted during the validity periods of GLP certificates routinely renewed and re-confirming the GLP-standard every three years. Studies performed at this laboratory are clearly indicated in the overview table (Table 5.4.1-1, 5.4.2.-1) as well as in the respective study header. Due to the large number of corroborative studies available within the Glyphosate Renewal

Group, the overall endpoint conclusion of glyphosate is not reliant on the results of the studies performed at [redacted]

CA 5.4.1 *In vitro* studies

Gene mutation in bacteria

Twenty-four bacterial reverse mutation ("Ames") studies are available for glyphosate (Table 5.4.1-1). Although several of these have some deficiencies compared to OECD 471 (1997), and thus are considered as supportive or invalid, there are 12 valid studies (reliable with restrictions) that are either fully compliant with OECD 471 (1997) or have only minor deviations that do not affect the validity or integrity of the data. Overall, there are sufficient, reliable data to allow thorough evaluation of this data requirement. There is no evidence that glyphosate is able to cause gene mutations in bacterial systems.

Table 5.4.1-1: Summary of *in vitro* genotoxicity testing with glyphosate acid: Gene mutation in bacteria

Annex Point	Study (Data owner)	Study type Test system	Substance, Purity Dose levels Metabolic activation	Reference list-related category[2]	Result

SPT: Standard plate test (plate-incorporation method); PIT: Pre-incubation test
[1] Testing was performed at the Laboratory of Pharmacology and Toxicology (LPT), Hamburg, Germany.
[2] The category describes the acceptability/reliability of the study within the AIR 5 submission. This category does not describe hazard classification. (for details please refer to the Doc ID: 110054-B-GRG_Jun_2020)

1. Information on the study

Data point	CA 5.4.1/001
Report author	[redacted]
Report year	2014
Report title	Glyphosate: Reverse Mutation Assay 'Ames Test' using *Salmonella typhimurium* and *Escherichia coli*
Report No	41401854
Document No	Not reported
Guidelines followed in study	OECD 471 (1997), Commission Regulation (EC) no. 440/2008 Method B13/14 (2008), U.S. EPA OCSPP 870.5100, Japanese MAFF
Deviations from current test guideline OECD 471 (1997)	None
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate (batch: 04062014, purity: 85.79 %) was assessed for it's potential to induce gene mutations in bacteria in an Ames test conducted with *S. typhimurium* strains TA 98, TA 100, TA 1535 and TA 1537 and *E. coli* strain WP2uvrA in the presence and absence of metabolic activation (phenobarbitone / β-naphthoflavone-induced rat liver S9 fraction). Two independent experiments were performed, using the plate-incorporation method (standard plate test, first experiment) and the pre-incubation method (second experiment). Triplicate cultures each were exposed to test item concentrations in the range of 1.5 – 5000 µg/plate (first experiment) and 5 – 5000 µg/plate (second experiment). Negative (untreated), vehicle (DMSO) and positive controls were included in each experiment. After an incubation period of 48 hours, the plates were inspected for a possible reduction in the bacterial background lawn and the number of revertant colonies were counted for each plate.

There was no precipitation observed in any tester strain up to the highest tested concentration, neither in the presence nor absence of S9 mix. Cytotoxicity, evident as a reduction in the bacterial background lawn, was evident in both experiments at 5000 µg/plate for all strains in the absence of metabolic activation. There was no reduction in bacterial growth observed in the presence of S9 mix, however, a reduced frequency in the number of revertant colonies was noted in tester strain TA100 in the first experiment at 5000 µg/plate and in tester strain WP2 uvrA in the second experiment at 5000 µg/plate.

There was no statistically significant increase in the frequency of revertant colonies noted for any of the bacterial strains at any dose level, either with or without S9 mix. The number of revertant colonies for the vehicle control and for negative (untreated) controls were considered acceptable. All of the positive controls induced marked increases in the frequency of revertant colonies, thus confirming the activity of the metabolic activation system and the sensitivity of the test itself.
Based on the experimental findings, the test item is not mutagenic in bacteria with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate

Identification:	Not specified
Description:	White crystalline solid
Lot/Batch #:	04062014
Purity:	85.79 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature in the dark) and in solvent (vehicle) was not specified. All formulations were used within 4 h of preparation and were assumed to be stable for this period.
Solvent (vehicle) used:	Dimethylsulfoxide (DMSO)

2. Control materials:

Negative control:	Untreated controls were included in each experiment.
Solvent (vehicle) control:	Dimethylsulfoxide (DMSO)
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to table below.

Strain	Metabolic activation	Mutagen	Conc. [µg/plate]
S. typhimurium strains			
TA 100	-S9	N-ethyl-N'-nitro-N-nitrosoguanidine (ENNG)	3.0
	+S9	2-Aminoanthracene (2-AA)	1.0
TA 1535	-S9	N-ethyl-N'-nitro-N-nitrosoguanidine (ENNG)	5.0
	+S9	2-Aminoanthracene (2-AA)	2.0
TA 98	-S9	4-Nitroquinoline-1-oxide (4-NQO)	0.2
	+S9	Benzo[a]pyrene (BP)	5.0
TA 1537	-S9	9-Aminoacrinidine (9AA)	80.0
	+S9	2-Aminoanthracene (2-AA)	2.0
E. coli strain(s)			
WP2 uvrA	-S9	N-ethyl-N'-nitro-N-nitrosoguanidine (ENNG)	2.0
	+S9	2-Aminoanthracene (2-AA)	10.0

3. Metabolic activation:

S9 mix was produced from the livers of male rats, which were treated orally with 80 mg/kg bw/day phenobarbitone and 100 mg/kg bw/day β-naphthoflavone for three days. On Day 4, the livers were prepared and S9 homogenate was generated. The S9 mix was thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
0.2 M Sodium phosphate buffer (pH 7.4)	25.0	mL
1.65 M KCl/0.4 M $MgCl_2$	1.0	mL
NADPH-generating system		
0.1 M Glucose 6-phosphate	2.5	mL
0.1 M NADP	2.0	mL
Sterile distilled water	14.5	mL
S9	5.0	mL

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA	✓	Deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		Ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 1538				Histidine auxotrophy (automatically *via* the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Plate incorporation test ± S9 mix:	
Concentrations:	*1.5, 5, 15, 50, 150, 500, 1500 and 5000 µg/plate*
Tester strains:	TA 98, TA 100, TA 1535, TA 1537 and WP2 uvrA

Replicates:	*Triplicates*
Pre-incubation test ± S9 mix:	
Concentrations:	*5, 15, 50, 150, 500, 1500 and 5000 µg/plate*
Tester strains:	TA 98, TA 100, TA 1535, TA 1537 and WP2 uvrA
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 16 Jul – 31 Aug 2014
Finalisation date: 02 Sep 2014

2. **Standard plate test (plate-incorporation test, SPT):**
An aliquot of 0.1 mL test solution, vehicle or positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL phosphate buffer (in tests without metabolic activation) were added to 2 mL of molten trace amino acid supplemented medium (1.0 mM histidine + 1.0 mM biotin or 1.0 mM tryptophan). After mixing, the mixture was then overlayed onto a Vogel-Bonner agar plate. Negative (untreated) controls were included in each experiment. The plates were incubated at 37 ± 3 °C for approximately 48 hours and scored for the presence of revertant colonies and thinning of the bacterial background lawn.

3. **Pre-incubation test (PIT):**
0.1 mL of test solution, vehicle or positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL phosphate buffer (in tests without metabolic activation) were mixed and pre-incubated for 20 minutes at 37 ± 3 °C while shaking. After pre-incubation, 2.0 mL of molten amino acid supplemented medium (1.0 mM histidine + 1.0 mM biotin or 1.0 mM tryptophan), the mixture was plated onto Vogel-Bonner agar plates. Negative (untreated) controls were included in each experiment. The plates were incubated at 37 ± 3 °C for approximately 48 hours and scored for the presence of revertant colonies and thinning of the bacterial background lawn.

4. **Cytotoxicity**
Toxicity was detected by a
   - reduction in the number of spontaneous revertants
   - clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. **Statistics**
Statistical analysis was performed according to the UKEMS sub-committee on guidelines for mutagenicity testing[10].

6. **Acceptance criteria**
The test was considered valid if the following criteria were met:
   - All bacterial strains must have demonstrated the required characteristics as determined by their respective strain checks.

[10] Mahon G.A.T. (1989) Analysis of data from microbial colony assays. In: KIRKLAND D.J. (eds). Statistical Evaluation of Mutagenicity Test Data. Cambridge University Press Report, pp. 26-65

- All tester strains cultures should exhibit a characteristic number of spontaneous revertants per plate, which is in the range of historical control data.
- All tester strain cultures should be in the range of 0.9 – 9 x 10^9 bacteria per mL.
- Positive control chemicals should induce marked increases in the frequency of revertant colonies, both with or without metabolic activation, which are in the range of historical control data.
- There should be a minimum of 4 non-toxic test item concentrations.
- There should be no evidence of excessive contamination.

7. Evaluation criteria

A test item was considered positive for mutagenicity if the following criteria were met:

- There was a dose-related increase in mutant frequency over the dose range tested.
- There was a reproducible, statistically significant increase at one or more concentrations.
- There was a biological relevance against the laboratories historical control ranges.
- The increase fold was greater than two times the concurrent solvent control for any tester strain.

A test item was considered non-mutagenic (negative) in the test system if the above-mentioned criteria were not met.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline

B. CYTOTOXICITY

Cytotoxicity, evident as a visible reduction in the growth of the bacterial background lawn was observed in the first experiment (plate incorporation test) for all tester strains at 5000 µg/plate in the absence of metabolic activation.

There was no reduction in the bacterial background lawn observed in the presence of S9 mix, however, when compared to solvent controls, strain TA 100 exhibited a lower number of revertant colonies at 5000 µg/plate.

In the second experiment (pre-incubation test), cytotoxicity results in the absence of S9 mix were identical to those of the first experiment, showing a reduced bacterial background lawn at 5000 µg/plate for all strains. In the presence of S9 mix, the bacterial growth was not impaired, but a lower frequency of revertant colonies was noted for tester strain WP2 uvrA at 5000 µg/plate.

C. SOLUBILITY

Precipitation of the test item was not observed on the plates at any of the dose levels tested, neither in the presence nor absence of S9 mix.

D. MUTATION ASSAY

There was no statistically significant increase in the frequency of revertant colonies recorded for any of the bacterial strains at any dose of the test item, either with or without metabolic activation. The number of revertant colonies for the vehicle control and for negative (untreated) controls were considered acceptable. In the first experiment, one value of the strain TA1535 was slightly outside of the historical control range, but as the count was only two colonies out of range and all other counts were within the range of historical controls, the value was considered acceptable. All of the positive controls induced marked increases in the frequency of revertant colonies, thus confirming the activity of the metabolic activation system and the sensitivity of the test itself.

III. CONCLUSION

Under the conditions of the present study, the test item is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA100, TA98, TA1535 and TA1537 and *E. coli* WP2uvrA) in the presence and absence of metabolic activation.

The study was performed according to OECD guideline 471 (1997) and compliant with GLP. It is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/002
Report author	[redacted]
Report year	2012
Report title	Reverse Mutation Assay using Bacteria (*Salmonella typhimurium*) with Glyphosate tech.
Report No	126159
Document No	Not reported
Guidelines followed in study	OECD 471 (1997), Commission Regulation (EC) No. 440/2008 B.13/14 (2008), US EPA OPPTS 870.5100 (1998)
Deviations from current test guideline OECD 471 (1997)	None
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: 20110107-2, purity: 97 %) was assessed for its potential to induce gene mutations in bacteria in an Ames test conducted in *S. typhimurium* strains TA 98, TA 100, TA 102, TA 1535 and TA 1537. All strains were exposed, to the test item, solvent (DMSO), negative (water) and appropriate positive controls in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction) for at least 48 h.

Concentrations were selected based on the results of a preliminary cytotoxicity test, in which the test item induced cytotoxicity in strain TA 100 at ≥ 2500 µg/plate in the presence of metabolic activation. Test item concentrations for the main mutagenicity study ranged from 10 to 5000 µg/plate. Two independent experiments were performed, using the plate incorporation method (standard plate test, experiment 1) and the pre-incubation method (experiment 2).

There was no precipitation observed up to the highest concentration tested, neither in the presence, nor in the absence of metabolic activation. Cytotoxicity was observed in the first experiment for strain TA98 at 5000 µg/plate in the presence of S9 mix, for strain TA 100 at ≥ 2500 µg/plate in the presence and absence of S9 mix and in strains TA 1535 and TA 102 at 5000 µg/plate in the absence of S9 mix.

In the second experiment, cytotoxicity was observed in strains TA 98 and TA 100 at 5000 µg/plate in the absence of S9 mix, in strain TA 1537 at ≥ 2500 µg/plate in the absence of S9 mix and in strain TA102 at 5000 µg/plate in the presence and absence of S9 mix.

Upon treatment with glyphosate technical, there was no statistically significant or biologically relevant increase in the number of revertant colonies in any of the five tester strains in any experiment up to the highest tested concentration, neither in the presence, nor in the absence of S9 mix.
The number of revertant colonies in the solvent, negative and positive control was within the range of the laboratories historical control data, demonstrating the functionality of the S9 mix and the validity of the test system.

Under the experimental conditions, glyphosate technical was considered negative for gene mutation in bacteria with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate Tech. (N-phosphonomethyl)glycine

Identification:	Not specified
Description:	Not specified
Lot/Batch #:	20110107-2
Purity:	97 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature, protected from light) was guaranteed until 01 Feb 2013. The stability of the test item in solvent (vehicle) was not specified.
Solvent (vehicle) used:	Dimethylsulfoxide (DMSO)

2. Control materials:

Negative control:	Distilled water
Solvent (vehicle) control:	Dimethylsulfoxide (DMSO)

Solvent (vehicle)/final concentration: 0.1 mL per plate.

Positive controls: Please refer to table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)[1]	DMSO	2.5
TA 1535	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)[1]	DMSO	2.5
TA 98	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	10
	+S9	2-Aminoanthracene (2-AA)[1]	DMSO	2.5
TA 1537	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	40.0
	+S9	2-Aminoanthracene (2-AA)[1]	DMSO	2.5
TA 102	-S9	Methylmethanesulfonate (MMS)	Water	1.0 µL/plate
	+S9	2-Aminoanthracene (2-AA)[1]	DMSO	10.0

[1] The functionality of the S9 mix batch used was checked with benzo(a)pyrene and showed the expected results

3. Metabolic activation:

S9 mix was prepared by [redacted] ([redacted], Experiment 1) and purchased from [redacted] ([redacted], Experiment 2). S9 mix from [redacted] was obtained from the livers of male Wistar rats, that received phenobarbital (80 mg/kg bw) and β-naphthoflavone (100 mg/kg bw) by oral treatment for three consecutive days. S9 mix from [redacted] was produced from male Sprague-Dawley rats, which were induced with phenobarbital / β-naphthoflavone.

Prior to each experiment, co-factor was added to the S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	5	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102	✓				
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Plate incorporation test ± S9 mix:	
Concentrations:	*3.16, 10, 31.6, 100, 316, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 98 and TA 100
Replicates:	*Triplicates*

(b) Mutation assays:

Plate incorporation test ± S9 mix:	
Concentrations:	*10, 31.6, 100, 316, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and TA 102
Replicates:	*Triplicates*
Pre-incubation test ± S9 mix:	
Concentrations:	*10, 31.6, 100, 316, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and TA 102
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 13 Nov - 10 Dec 2012
   Finalisation date: 17 Dec 2012

2. **Standard plate test (plate-incorporation test, SPT):**
An aliquot of 0.1 mL test solution, negative control (water), solvent control (DMSO) or positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten overlay agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin). All components were mixed in a test tube and poured onto minimal agar plates. Each concentration and the controls were tested in triplicates. After incubation at 37 °C upside down for at least 48 h in the dark, the background bacterial lawn was examined and the bacterial colonies (his^+ revertants) were counted.

3. **Pre-incubation test (PIT):**
0.1 mL of test solution, negative control (water), solvent control (DMSO) or positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were pre-incubated at 37 °C for 60 minutes, followed by addition of 2 mL molten overlay agar. Each concentration and the controls was tested in triplicates. The mixture was poured onto the surface of a minimal agar plate and after solidification, the plates were incubated upside down for at least 48 h at 37°C in the dark. Subsequently, the number of bacterial colonies (his^+ revertants) was counted.

4. Cytotoxicity

Toxicity was detected by a

- reduction in the number of spontaneous revertants (approx. 50 % reduced in relation to the solvent control).
- clearing or diminution of the background lawn (= reduced background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics

Results were judged without statistical analysis.

6. Acceptance criteria

The test was valid if the following criteria were met:

- The bacteria demonstrated their typical responses to ampicillin (TA 98, TA 100 and TA 102).
- The control plates with and without S9 mix were within the ranges of the laboratory's historical data.
- Corresponding background growth on negative control, solvent control and test plates was observed.
- The positive controls showed a distinct enhancement of revertant rates over the control plate.

7. Evaluation criteria

A test item was considered as mutagenic if the following criteria were met:

- A clear and dose-related increase in the number of revertants occurred and/or
- A biologically relevant positive response for at least one of the dose groups occurred in at least one tester strain with or without metabolic activation. A biologically relevant increase was obtained when the number of revertants was at least two-fold when compared to solvent controls for testers strains TA 98, TA 100 and TA 102 and at least three-fold when compared to solvent controls for tester strains TA 1535 and TA 1537.

A test item was considered non-mutagenic if it produced neither a dose-related increase in the number of revertants nor a reproducible biologically relevant positive response at any of the dose levels.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study as not required by the test guideline.

B. CYTOTOXICITY

In the preliminary toxicity test, cytotoxicity was observed in strain TA 100 at ≥ 2500 µg/plate in the presence of metabolic activation.

In the main mutagenicity assay, cytotoxicity was observed in the first experiment (standard plate test = plate-incorporation method) for strain TA98 at 5000 µg/plate in the presence of S9 mix, for strain TA 100 at ≥ 2500 µg/plate in the presence and absence of S9 mix and in strains TA 1535 and TA 102 at 5000 µg/plate in the absence of S9 mix.

In the second experiment (pre-incubation test), cytotoxicity was observed in strains TA 98 and TA 100 at 5000 µg/plate in the absence of S9 mix, in strain TA 1537 at ≥ 2500 µg/plate in the absence of S9 mix and in strain TA 102 at 5000 µg/plate in the presence and absence of S9 mix.

The reduction in the number of revertant colonies in strain TA 1537 at 100 µg/plate in the absence of S9 mix was regarded as not biologically relevant, due to a lack of a dose-response relationship.

C. SOLUBILITY

There was no precipitation of the test substance observed up to the highest dose tested in any of the experiments, neither in the presence nor absence of S9 mix.

D. MUTATION ASSAY

There was no statistically significant or biologically relevant increase in the number of his$^+$ revertant colonies in any of the five tester strains in any of the two experiments up to the highest tested concentration, neither in the presence, nor in the absence of S9 mix.
The number of revertant colonies in the solvent, negative and positive control was within the range of the laboratories historical control data. The positive controls induced a marked increase in the number of revertant colonies, demonstrating the functionality of the S9 mix and the validity of the test system.

III. CONCLUSION

In conclusion, based on the experimental findings, glyphosate tech. did not induce gene mutations by base pair exchanges or frameshifts in the genome of the five tested *S. typhimurium* strains. Therefore, the test item was considered non-mutagenic in the bacterial reverse mutation test (Ames test).

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 98, TA 100, TA 102, TA 1535 and TA 1537) with and without metabolic activation.

The study was performed according to OECD guideline 471 (1997) and under GLP conditions. There were no deviations when compared to the guideline. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/003
Report author	[redacted]
Report year	2010
Report title	Mutagenicity study of Glyphosate TC in the *Salmonella typhimurium* Reverse Mutation Assay (*in vitro*)
Report No	24880
Document No	Not reported

Guidelines followed in study	OECD 471 (1997), Commission Regulation (EC) No. 440/2008 B.13/14 (2008), US EPA OPPTS 870.5100 (1998)
Deviations from current test guideline OECD 471 (1997)	Historical control data for the positive controls were not included in the study report.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid[1]
Category study in AIR 5 dossier (L docs)	Category 2a

[1]: Following the feedback from the Assessment Group Glyphosate in March 2020, the Notifier is aware of concerns regarding work conducted at this specific contract laboratory (LPT). For the sake of completeness, this study is included in the dossier submission since it was part of the data package of previous EU evaluation processes.

2. Full summary

Glyphosate technical (batch: 2009051501, purity 95.23 %) was investigated for its potential to induce gene mutation in bacteria in an Ames test. In the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction), *S. typhimurium* strains TA 98, TA 100, TA 102, TA 1535 and TA 1537 were exposed to the test item, vehicle (aqua ad iniectabilia) and positive controls for 48 – 72 hours at 37 °C.

Based on the results of a preliminary cytotoxicity test conducted in strain TA 100 in the absence of metabolic activation, test item concentrations in the main mutagenicity test ranged from 31.6 to 3160 µg/plate. Two independent experiments were performed, using the standard plate test (plate-incorporation method) and the pre-incubation test. After 48 to 72 hours of incubation, the number of revertant colonies was counted and the bacterial background lawn was examined.

Precipitation of the test item was observed in the preliminary toxicity study at 5000 µg/plate, but at no concentration used in the main mutagenicity test. For all tester strains in the presence and absence of metabolic activation, cytotoxicity was observed at 3160 µg/plate.

There was no increase in the number of revertant colonies when compared to control counts observed in any of the five tester strains following treatment with glyphosate technical tested up to 3160 µg/plate, neither in the presence nor in the absence of metabolic activation.

In both experiments, the number of revertants induced by the vehicle control was within the range of the historical control data for each strain. A distinct increase in the number of revertant colonies was observed for the positive controls, demonstrating the functionality of the S9 mix and the sensitivity of the test system.

Based on the result of the present study and under the experimental conditions of the test, glyphosate technical is negative for mutagenicity in bacteria in the Ames standard plate and pre-incubation test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate TC

Identification: 37/206/09

Description:	White powder
Lot/Batch #:	2009051501
Purity:	95.23 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until the mentioned expiry date 15 May 2011. The stability of the test item in vehicle was not specified in the study report.
Solvent (vehicle) used:	Aqua ad iniectabilia

2. Control materials:

Negative control:	Sterility controls were not included in the present study
Solvent (vehicle) control:	Aqua ad iniectabilia
Solvent (vehicle) /final concentration:	1 mL per plate
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide	Water	10.0
	+S9	Cyclophosphamide	Water	1500.0
TA 1535	-S9	Sodium azide	Water	10.0
	+S9	Cyclophosphamide	Water	1500.0
TA 98	-S9	2-Nitrofluorene	DMSO	10
	+S9	2-Aminoanthracene	DMSO	2.0
TA 1537	-S9	9-Aminoacridine	Ethanol	100.0
	+S9	2-Aminoanthracene	DMSO	2.0
TA 102	-S9	Methylmethane sulfonate	DMSO	1300.0
	+S9	2-Aminoanthracene	DMSO	2.0

3. Metabolic activation:

S9 mix was obtained from the livers of 20 – 30 rats treated with Aroclor 1254. The pooled fraction exhibited a protein content of 26.6 mg/mL and a cytochrome P450 level of 0.21 nmol/protein. Aliquots of the S9 mix were thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100.0	mM
KCl	33.0	mM
NADPH-generating system		
Glucose 6-phosphate	5.4	mM
NADP	4.1	mM
$MgCl_2$	8.0	mM
S9	5.0	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		*E. coli*			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB genes)	✓
TA 1537	✓				
TA 102	✓				
TA 1538				Histidine auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay

Plate incorporation test - S9 mix:	
Concentrations:	*0.316, 1.0, 3.16, 10.0, 31.6, 100, 316, 1000, 3160 and 5000 µg/plate*
Tester strain:	TA 100
Replicates:	*Duplicates*

(b) Main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*31.6, 100, 316, 1000 and 3160 µg/plate*
Tester strains:	TA 98, TA 100, TA 102, TA 1535 and TA 1537
Replicates:	*Triplicates*
Pre-incubation test ± S9 mix:	
Concentrations:	*31.6, 100, 316, 1000 and 3160 µg/plate*
Tester strains:	TA 98, TA 100, TA 102, TA 1535 and TA 1537
Replicates:	*Triplicates*

B. STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 15 Oct – 23 Nov 2009
   Finalisation date: 25 Jan 2010

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 1 mL test solution or vehicle or 0.1 mL positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 phosphate buffer (in tests without metabolic activation) were added to 2.0 mL of molten top agar (supplemented with 0.5 mM L-histidine + 0.5 mM biotin). The test components were mixed by vortexing at low speed, poured onto coded minimal glucose agar plates and the plates were quickly tilted and rotated for homogenous distribution. Each concentration and the controls were tested in triplicates. After solidification, the plates were incubated upside down for 48 to 72 hours at 37 °C in the dark. After incubation, the number of revertant colonies was counted and the presence of bacterial background lawn was confirmed.

3. Pre-incubation test (PIT):
1 mL of test solution or vehicle or 0.1 mL of positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix phosphate buffer (in tests without metabolic activation) were pre-incubated for 20 minutes at 37 °C using a shaker.
Afterwards, 2.0 mL of molten top agar was added to each test tube and the mixture was poured on coded minimal glucose agar plates. Each concentration and the controls were tested in triplicates. After solidification, the plates were incubated upside down for 48 to 72 hours at 37 °C in the dark. After incubation, the number of revertant colonies was counted and the presence of bacterial background lawn was examined.

4. Cytotoxicity
Toxicity was detected by

- a reduction in the number of spontaneous revertants (below 50 % when compared to solvent controls)
- a clearing or diminution of the background lawn (= reduced his^- background growth)
- the degree of survival of the treated cultures

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics
Statistical significance for an increased number of revertants compared to the solvent control was determined using the Mann-Whitney U-test. A concentration-related effect was identified using the Spearman's rank correlation coefficient.

6. Acceptance criteria
Acceptance criteria were not defined in the study report.

7. Evaluation criteria
A test item was considered to show a positive response if the following criteria were met:

- The number of revertant colonies was statistically significantly increased compared to the solvent control to at least 2-fold of the solvent control for TA 98, TA 100 and TA 102 and 3-fold of the solvent control for TA 1535 and TA 1537 in both experiments.
- There was a statistically significant concentration-related effect.
- Positive results were reproducible and the histidine independence of the revertants was confirmed by streaking random samples on histidine-free agar plates

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
In the preliminary toxicity test, cytotoxicity was observed in tester strain TA100 at concentrations of 3160

µg/plate and above in the absence of metabolic activation. Hence, 3160 µg/plate was chosen as top concentration for the main mutagenicity study.

In the main mutation assay, cytotoxicity, indicated by scarce background lawn and a reduction in the number of revertants, was noted at the top concentration of 3160 µg/plate for all tester strains in both experiments (plate-incorporation and pre-incubation test), both in the presence and absence of metabolic activation.

C. SOLUBILITY

Precipitation of the tests item was observed in the preliminary toxicity test in tester strain TA100 at the top concentration of 5000 µg/plate without metabolic activation. There was no precipitation in the main mutagenicity study.

D. MUTATION ASSAY

There was no increase in the number of revertant colonies when compared to control counts observed in any of the five tester strains following treatment with glyphosate technical tested up to 3160 µg/plate, neither in the presence nor in the absence of metabolic activation.

In both experiments, the number of revertants induced by the vehicle control was within the range of the historical control data for each strain. A distinct increase in the number of revertant colonies was observed for the positive controls, demonstrating the functionality of the S9 mix and the sensitivity of the test system.

III. CONCLUSION

According to the results and under the conditions of the present study, glyphosate technical is not mutagenic in the Ames standard plate and pre-incubation test with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 98, TA 100, TA 102, TA 1535 and TA 1537) with and without metabolic activation.
The study was performed according to OECD guideline 471 (1997) and under GLP conditions. Deviations from the guideline were considered to be of minor degree that do not hinder data evaluation. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/004
Report author	[redacted]
Report year	2010
Report title	*Salmonella typhimurium* and *Escherichia coli* Reverse Mutation Assay with Solution of Glyphosate TC spiked with Glyphosine
Report No	1332300
Document No	Not reported
Guidelines followed in study	OECD 471 (1997), Commission Regulation (EC) No. 440/2008 B13/14 (2008)
Deviations from current test guideline OECD 471 (1997)	None
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: 2009051501, purity 97.16 %) spiked with glyphosine was investigated with regard to its potential to induce gene mutation in bacteria in an Ames test. *S. typhimurium* strains TA 98, TA 100, TA 1535 and TA 1537, and *E. coli* strain WP2 uvrA were exposed to the test item in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction) for at least 48 hours at 37 °C. Vehicle (deionized water), untreated and positive controls were included in each experiment.

A pre-experiment was conducted to identify cytotoxic concentrations of the test item. In a standard plate test (plate incorporation method), test item concentrations in the range of 3 to 5000 µg/plate did not show

any cytotoxic effects in the presence and absence of metabolic activation. The pre-experiment was designated experiment I of the main mutation assay and analysed for the number of revertant colonies. A second main mutation assay was performed using the preincubation method and concentrations in the same concentration range. In both experiments, all conditions were tested in triplicates. After at least 48 hours of incubation, the mean number of revertant colonies was counted for each plate.

Precipitation of the test substance was observed for all tester strains in the second experiment only (preincubation method) at ≥ 2500 µg/mL in the presence of metabolic activation. In none of the experiments, cytotoxicity was observed.

There was no substantial increase in the number of his^+ or trp^+ revertant colonies observed in any of the five tester strains at any dose level, neither in the presence nor in the absence of metabolic activation.
The number of revertants induced by the vehicle control was within the range of the historical control data for each strain, thus demonstrating an acceptable experimental performance. Appropriate positive control compounds showed a distinct increase in the number of revertant colonies, confirming the activity of the S9 mix and the validity of the test system.

Based on the results of the present study and under the experimental conditions of the test, glyphosate technical spiked with glyphosine did not cause any genotoxic effect in the Ames standard plate and pre-incubation test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical (5000 mg/L), containing glyphosine (32 mg/L)

Identification:	S1111311
Description:	An aqueous solution of glyphosate technical grade active ingredient (purity 97.16 % w/w), containing 0.63 % (w/w) glyphosine in the technical grade active ingredient.
Lot/Batch #:	2009051501
Purity:	97.16 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature, light protected) was guaranteed for two weeks from the date of preparation. The stability of the test item in vehicle was not specified in the study report.
Solvent (vehicle) used:	Deionised water

2. Control materials:

Negative control:	Controls which remained untreated were included in each experiment.
Solvent (vehicle) control:	Deionised water
Solvent (vehicle)/final concentration:	0.1 mL per plate
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1535	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 98	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	10
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1537	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	50.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
E. coli strain				
WP2 uvrA	-S9	Methylmethane sulfonate (MMS)	Water	3.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	10.0

* The functionality of the S9 mix batch used was additionally checked with benzo(a)pyrene and showed the expected results.

3. Metabolic activation:

S9 mix was obtained from the livers of 8 – 12 weeks old male Wistar rats, weighing approx. 220 - 320 g. The animals received intraperitoneal injections of phenobarbital (80 mg/kg bw) and oral administration of β-naphthoflavone (80 mg/kg bw) each on three consecutive days. The livers were prepared 24 h after the last treatment. Aliquots of the S9 mix were thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E. coli***			
TA 98	✓	WP2 *uvr*A	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 *uvr*A (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓	WP2 pKM101		UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay/Experiment 1 of the main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA

Replicates:		*Triplicates*	

(b) Experiment 2 of the main mutation assay

Pre-incubation test ± S9 mix:		
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*	
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA	
Replicates:	*Triplicates*	

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 17 – 22 Mar 2010
   Finalisation date: 07 Apr 2010

2. **Standard plate test (plate-incorporation test, SPT):**
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 1.0 mL of molten overlay agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin or 2.5 mg/L tryptophan). The mixture was mixed in a test tube and poured onto selective agar plates. Each concentration and the controls were tested in triplicates. After solidification, the plates were incubated upside down for at least 48 hours at 37 °C in the dark. After incubation, the background bacterial lawn was examined and the number of bacterial colonies (his^+ or trp^+ revertants) was counted.

3. **Pre-incubation test (PIT):**
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were mixed in a test tube and shaken at 37 °C for 60 minutes. After pre-incubation, 1.0 mL of molten overlay agar was added to each test tube. Each concentration and the controls were tested in triplicates. The mixture was poured on selective agar plates. After solidification the plates were incubated upside down for at least 48 h at 37°C in the dark. Subsequently, the number of bacterial colonies (his^+ or trp^+ revertants) was counted.

4. **Cytotoxicity**
Toxicity was detected by a
- reduction in the number of spontaneous revertants (below the indication factor of 0.5 when compared to solvent controls)
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. **Statistics**
Results were judged without statistical analysis.

6. **Acceptance criteria**
The test was valid if
- There was a regular background growth in the negative and solvent control.

- The spontaneous reversion rates in the negative and solvent control were in the range of the laboratory's historical data.
- The positive control substances produced a significant increase in mutant colony frequencies.

7. Evaluation criteria

A test item was considered as a mutagen if a biologically relevant increase in the number of revertants exceeding the threshold of twice the colony count of the corresponding solvent control was observed.

A dose dependent increase was considered biologically relevant if the threshold was exceeded at more than one concentration.

An increase exceeding the threshold at only one concentration was judged as biologically relevant if reproduced in an independent second experiment. A dose dependent increase in the number of revertant colonies below the threshold was regarded as an indication of a mutagenic potential if reproduced in an independent second experiment. However, whenever the colony counts remained within the historical range of negative and solvent controls such an increase was not considered biologically relevant.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study as not required by the test guideline.

B. CYTOTOXICITY

In the preliminary toxicity test, there were no cytotoxic effects observed in any tester strain up to the highest tested concentration of 5000 µg/mL, neither in the presence nor the absence of metabolic activation. Since the second experiment was performed before the results of the preliminary experiment/experiment I were available, both experiments were performed with concentrations from 3 to 5000 µg/plate.

C. SOLUBILITY

Precipitation was observed only in the second experiment at 2500 and 5000 µg/mL in all strains in the presence of metabolic activation. There was no precipitation in the first experiment and no precipitation in the absence of metabolic activation.

D. MUTATION ASSAY

There was no substantial increase in the number of his^+ or trp^+ revertant colonies observed in any of the five tester strains following treatment with glyphosate technical spiked with glyphosine at any dose level, neither in the presence nor in the absence of metabolic activation.

The number of revertants induced by the vehicle control was within the range of the historical control data for each strain, thus demonstrating an acceptable experimental performance.

Appropriate positive control compounds showed a distinct increase in the number of revertant colonies, confirming the activity of the S9 mix and the validity of the test system.

III. CONCLUSION

According to the results and under the experimental conditions of the present study, glyphosate technical spiked with glyphosine is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2 *uvr*A) with and without metabolic activation.
The study was conducted under GLP conditions and according to OECD guideline 471 (1997) with no deviations. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/005
Report author	[redacted]
Report year	2010
Report title	Reverse Mutation Assay using bacteria (*Salmonella typhimurium*) with

	Glyphosate TC
Report No	101268
Document No	Not reported
Guidelines followed in study	OECD 471 (1997), Commission Regulation (EC) No. 440/2008 B.13/14 (2008), US EPA OPPTS 870.5100 (1998)
Deviations from current test guideline OECD 471 (1997)	2-Aminoanthracene was used as sole positive control in the presence of metabolic activation.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535, TA 97a, and TA102 were exposed to glyphosate technical (batch: 200903051, purity: 98.2 %) in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction). Test item concentrations in the range of 31.6 to 5000 µg/plate were applied in two independent experiments using the plate-incorporation method (first experiment) and the pre-incubation method (second experiment). Sterility controls (untreated), vehicle (deionised water) and positive controls were included in each experiment. All conditions were tested in triplicates. After an exposure period of at least 48 h the bacterial background lawn was examined and the number of revertant colonies was counted.

There was no biologically relevant increase in the number of revertant colonies observed in any experiment at any tested concentration either in the presence or absence of metabolic activation. The spontaneous mutation rates of negative controls remained within the range of historical control data. Appropriate positive controls induced a distinct response in the number of revertant colonies, thus demonstrating the functionality and validity of the test system. Based on the results and under the conditions of the present study, glyphosate is not mutagenic in the Ames test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

	Glyphosate technical
Identification:	/
Description:	Solid
Lot/Batch #:	200903051
Purity:	98.2 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until 26 Mar 2011.
Solvent (vehicle) used:	DMSO. Due to the low solubility of the test item stock solutions at 50 and 25 mg/mL were prepared and processed by ultrasound for 30 minutes at 37 °C.

2. Control materials:

Negative control:	Sterility controls were performed in accordance with the experimental design, but without addition of bacterial suspension.
Solvent (vehicle) control:	Deionised water and DMSO
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)	DMSO	2.5
TA 1535	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)	DMSO	2.5
TA 98	-S9	4-Nitro-o-phenylene-diamine (4-NOPD)	DMSO	10
	+S9	2-Aminoanthracene (2-AA)	DMSO	2.5
TA 1537	-S9	4-Nitro-o-phenylene-diamine (4-NOPD)	DMSO	40.0
	+S9	2-Aminoanthracene (2-AA)	DMSO	2.5
TA 102	-S9	Methyl methane sulfonate (MMS)	Water	1.0
	+S9	2-Aminoanthracene (2-AA)	DMSO	10.0

3. Metabolic activation:

S9 mix was obtained from the livers of male Wistar rats that were induced (oral treatment) with 80 mg/kg bw phenobarbital and 100 mg/kg bw β-naphthoflavone for three consecutive days. Aliquots of the S9 mix were thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium ortho phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	5	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes)	✓
TA 1537	✓				
TA 102	✓				
TA 1538				Histidine auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

Plate-incorporation test ± S9 mix:	
Concentrations:	31.6, 100, 316, 1000, 2500 and 5000 µg/plate
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 TA 102
Replicates:	Triplicates

Pre-incubation test ± S9 mix:	
Concentrations:	31.6, 100, 316, 1000, 2500 and 5000 µg/plate
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 TA 102
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 25 Mar – 06 Apr 2010
   Finalisation date: 08 Apr 2010

2. **Standard plate test (plate-incorporation test, SPT):**
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten overlay agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin). All components were mixed and poured onto minimal agar plates. Each concentration and the controls were tested in triplicates. After incubation at 37 °C for at least 48 h in the dark, the background bacterial lawn was examined and the number of bacterial colonies (his^+ revertants) was counted.

3. **Pre-incubation test (PIT):**
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were pre-incubated at 37 °C for 60 minutes. Afterwards, 2 mL of overlay agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin) were added and poured onto minimal agar plates. Each concentration and the controls were tested in triplicates. After solidification the plates were inverted and incubated for at least 48 h at 37°C in the dark. Subsequently, the background bacterial lawn was examined and the number of bacterial colonies (his^+ revertants) was counted.

4. **Cytotoxicity**
Toxicity was detected by a
- reduction in the number of spontaneous revertants down to a mutation factor of approximately ≤ 0.5 in relation to the solvent control
- clearing or diminution of the background lawn (= reduced his^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. **Statistics**
Statistical evaluation of the results was not regarded as necessary.

6. **Acceptance criteria**
The test was considered valid for each strain if
- The bacteria demonstrated their typical responses to ampicillin (TA 98, TA 100 and TA 102)
- The control plates with and without S9 mix (mean values of spontaneous reversion rates) were in the range of the laboratory's historical data
- Corresponding background growth on negative control, solvent control and test plates was observed
- The positive controls showed a distinct enhancement of revertant rates over the control plate.

7. **Evaluation criteria**
A test item was considered as a mutagen if the following criteria were met:
- There was a clear and dose-related increase in the number of revertants observed and/or
- There was a biologically relevant positive response for at least one of the dose groups observed in at least one

tester strain with or without metabolic activation.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

Cytotoxicity was observed in the first experiment in strain TA100 at 5000 µg/plate and in strain TA1535 at ≥ 2500 µg/plate both in the presence and absence of metabolic activation. In the second experiment cytotoxicity was evident at 5000 µg/plate in tester strain TA100 without metabolic activation and in strain TA1535 with and without metabolic activation.

C. SOLUBILITY

There was no precipitation of the test substance in any tester strain observed up to the highest tested concentration, neither in the presence, not in the absence of metabolic activation.

D. MUTATION ASSAY

There was no biologically relevant increase in the number of revertant colonies observed in any experiment at any tested concentration either in the presence or absence of metabolic activation. The spontaneous mutation rates of negative controls remained within the range of historical control data and appropriate positive controls induced a distinct increase in the number of revertant colonies, thus demonstrating the functionality and validity of the test system.

§ Information on respective positive control is reported in Material and Method section I.A.2

Historical control data generated in 2007 - 2009

N Negative control historical control data combine solvent or vehicle as well as untreated controls

III. CONCLUSION

Based on the results of the present study and under the experimental conditions of the test, the test item is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535, TA 1537 and TA102) with and without metabolic activation.

The study was performed according to OECD guideline 471 (1997) and under GLP conditions. There were only minor deviations, which were considered to not compromise the validity of the study. The study is therefore considered valid and acceptable.

<u>Assessment and conclusion by RMS</u>:

1. Information on the study

Data point	CA 5.4.1/006
Report author	[redacted]
Report year	2009
Report title	Mutagenicity study of Glyphosate TC in the *Salmonella typhimurium* Reverse Mutation Assay (*in vitro*)
Report No	23916
Document No	Not reported
Guidelines followed in study	OECD 471 (1997), Commission Regulation (EC) No. 440/2008 B.13/14 (2008), US EPA OPPTS 870.5100 (1998), ICH S2A (CPMP/ICH/141/95) and ICH S2B (CPMP/ICH/174/95)
Deviations from current test guideline OECD 471 (1997)	Historical control data for the positive controls were not included in the study report.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid[#]
Category study in AIR 5 dossier (L docs)	Category 2a

Following the feedback from the Assessment Group Glyphosate in March 2020, the Notifier is aware of concerns regarding work conducted at this specific contract laboratory (LPT). For the sake of completeness, this study is included in the dossier submission since it was part of the data package of previous EU evaluation processes.

2. Full summary

Glyphosate technical (batch: 20080801, purity 98.8 %) was investigated for its potential to induce gene mutations in bacteria in an Ames test. *S. typhimurium* strains TA98, TA100, TA102, TA1535 and TA1537 were exposed to the test item in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction) for 48 to 72 hours at 37 °C. Vehicle (aqua ad iniectabilia) and positive controls were included in each experiment.

Based on the results of a preliminary cytotoxicity test conducted in strain TA100 in the absence of metabolic activation, test item concentrations in the main mutagenicity test ranged from 31.6 to 3160 µg/plate. Two independent experiments were performed, using the standard plate test (plate-incorporation method) and the pre-incubation test. After 48 to 72 hours of incubation, the number of revertant colonies was counted and the bacterial background lawn was examined.

Precipitation of the test item was not reported. Cytotoxicity was observed for all tester strains at 3160 µg/plate in the presence and absence of metabolic activation.

There was no increase in the number of revertant his^+ colonies as compared to vehicle controls observed in any of the five tester strains following treatment with glyphosate technical tested up to concentrations of 3160 µg/plate, neither in the presence, nor in the absence of metabolic activation.

The number of revertants induced by the vehicle control was within the range of the laboratory's historical control data. The positive controls markedly induced the number of revertant colonies in each strain, demonstrating the functionality of the S9 mix and the sensitivity of the test system.

Based on the experimental results, glyphosate technical does not cause gene mutations in bacteria in the Ames standard plate and pre-incubation test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate TC

Identification:	37/064/08
Description:	Solid, white
Lot/Batch #:	20080801
Purity:	98.8 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until the mentioned expiry date 01 Aug 2010. The stability of the test item in vehicle was not specified in the study report.
Solvent (vehicle) used:	Aqua ad iniectabilia

2. Control materials:

Negative control:	Sterility controls were not included in the present study
Solvent (vehicle) control:	Aqua ad iniectabilia
Solvent (vehicle)/final concentration:	0.1 mL per plate
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide	Water	10.0
	+S9	Cyclophosphamide	Water	1500.0
TA 1535	-S9	Sodium azide	Water	10.0
	+S9	Cyclophosphamide	Water	1500.0
TA 98	-S9	2-Nitrofluorene	DMSO	10
	+S9	2-Aminoanthracene	DMSO	2.0
TA 1537	-S9	9-Aminoacridine	Ethanol	100.0
	+S9	2-Aminoanthracene	DMSO	2.0
TA 102	-S9	Methylmethane sulfonate	DMSO	1300.0
	+S9	2-Aminoanthracene	DMSO	2.0

3. Metabolic activation:

S9 mix was obtained from the livers of 20 – 30 rats treated with Aroclor 1254. The pooled fraction exhibited a protein content of 31.55 mg/mL and a cytochrome P450 level of 0.41 nmol/protein. Aliquots of the S9 mix were thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100.0	mM
KCl	33.0	mM
NADPH-generating system		
Glucose 6-phosphate	5.4	mM
NADP	4.1	mM
$MgCl_2$	8.0	mM
S9	5.0	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB genes)	✓
TA 1537	✓				
TA 102	✓				
TA 1538				Histidine auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay

Plate incorporation test - S9 mix:	
Concentrations:	*0.316, 1.0, 3.16, 10.0, 31.6, 100, 316, 1000, 3160 and 5000 µg/plate*
Tester strain:	TA100
Replicates:	*Duplicates*

(b) Main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*31.6, 100, 316, 1000 and 3160 µg/plate*
Tester strains:	TA 98, TA 100, TA 102, TA 1535 and TA 1537
Replicates:	*Triplicates*
Pre-incubation test ± S9 mix:	
Concentrations:	*31.6, 100, 316, 1000 and 3160 µg/plate*
Tester strains:	TA 98, TA 100, TA 102, TA 1535 and TA 1537
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 04 – 27 Feb 2009
   Finalisation date: 30 Apr 2009

2. **Standard plate test (plate-incorporation test, SPT):**

An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 phosphate buffer (in tests without metabolic activation) were added to 2.0 mL of molten overlay agar (supplemented with 0.5 mM L-histidine + 0.5 mM biotin). The test components were mixed by vortexing at low speed, poured onto coded minimal glucose agar plates and the plates were quickly tilted and rotated for homogenous distribution. Each concentration and the controls were tested in triplicates. After solidification, the plates were incubated upside down for 48 to 72 hours at 37 °C in the dark. After incubation, the number of revertant colonies was counted and the presence of bacterial background lawn was confirmed.

3. Pre-incubation test (PIT):
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix phosphate buffer (in tests without metabolic activation) were pre-incubated for 20 minutes at 37 °C using a shaker.
Afterwards, 2.0 mL of molten overlay agar was added to each test tube and the mixture was poured on coded minimal glucose agar plates. Each concentration and the controls were tested in triplicates. After solidification, the plates were incubated upside down for 48 to 72 hours at 37 °C in the dark. After incubation, the number of revertant colonies was counted and the presence of bacterial background lawn was examined.

4. Cytotoxicity
Toxicity was detected by

- a reduction in the number of spontaneous revertants (below 50 % when compared to solvent controls)
- a clearing or diminution of the background lawn (= reduced his^- background growth)
- the degree of survival of the treated cultures

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics
Statistical significance for an increased number of revertants compared to the solvent control was determined using the Mann-Whitney U-test. A concentration-related effect was identified using the Spearman's rank correlation coefficient.

6. Acceptance criteria
Acceptance criteria were not defined in the study report.

7. Evaluation criteria
A test item was considered to show a positive response if the following criteria were met:

- The number of revertant colonies was statistically significantly increased compared to the solvent control to at least 2-fold of the solvent control for TA 98, TA 100 and TA 102 and 3-fold of the solvent control for TA 1535 and TA 1537 in both experiments.
- There was a statistically significant, concentration-related effect.
- Positive results were reproducible and the histidine independence of the revertants was confirmed by streaking random samples on histidine-free agar plates

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study as not required by the test guideline.

B. CYTOTOXICITY
In the preliminary toxicity test, cytotoxicity was noted in tester strain TA 100 at concentrations of 3160 and 5000 µg/plate in the absence of metabolic activation. Hence, 3160 µg/plate was chosen as top concentration for the main mutagenicity study.

In the main mutation assay, cytotoxicity (scarce background lawn) was noted for all tester strains at 3160 µg/plate in both experiments (plate-incorporation and pre-incubation test), both in the presence and absence of metabolic activation.

C. SOLUBILITY

Precipitation of the tests item was not reported.

D. MUTATION ASSAY

There was no increase in the number of revertant colonies as compared to control counts observed in any of the five tester strains following treatment with glyphosate technical tested up to 3160 µg/plate, neither in the presence nor in the absence of metabolic activation.
The number of revertants induced by the vehicle control was within the range of the historical control data for each strain. A marked increase in the number of revertant colonies was observed for the positive controls, demonstrating the functionality of the S9 mix and the sensitivity of the test system.

III. CONCLUSION:

According to the results and under the conditions of the present study, glyphosate technical is not mutagenic in the Ames standard plate and pre-incubation test with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 98, TA 100, TA 102, TA 1535 and TA 1537) with and without metabolic activation.

The study was conducted according to OECD guideline 471 (1997) and in compliance with GLP. There were only minor deviations when compared to OECD 471 (1997) that do not hinder data evaluation. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/007
Report author	[redacted]
Report year	2009
Report title	Glyphosate technical - *Salmonella typhimurium* and *Escherichia coli* Reverse Mutation Assay
Report No	1264500
Document No	Not reported
Guidelines followed in study	OECD 471 (1997), US EPA OPPTS 870.5100 (1998), Commission Regulation (EC) 2008/440 B13/B14 (2008)
Deviations from current test guideline OECD 471 (1997)	None
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535 and TA 1537, and *E. coli* strains WP2 uvrA (pKM101) and WP2 pKM101 were exposed to glyphosate technical (batch: 569753, purity: 96.3 %) in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction) for 48 hours at 37 °C. Vehicle (deionized water), sterility (untreated) and positive controls were included in each experiment.

A pre-experiment was conducted to identify cytotoxic concentrations of the test item. In a standard plate test (plate incorporation method), test item concentrations in the range of 3 to 5000 µg/plate did not show any cytotoxic effects in the presence and absence of metabolic activation. The pre-experiment was designated experiment I of the main mutation assay and analysed for the number of revertant colonies. A second main mutation assay was performed using the preincubation method and concentrations in the range of 33 to 5000 µg/plate. Both experiments were performed with triplicates. Following 48 hours of incubation, the mean number of revertant colonies was counted for each plate.

Precipitation of the test substance was not reported and there were no indications of cytotoxicity in any of the six tester strains up to the highest tested concentration of 5000 µg/plate.

There was no substantial increase in the number of his^+ or trp^+ revertants observed in any experiment at any dose level, neither in the presence nor absence of metabolic activation. In addition, there was no dose-dependent increase in mutation rates in the range below the generally acknowledged border of biological relevance.

The laboratory's historical control range was exceeded for tester strain WP2 uvrA pKM101 in the untreated and solvent control plates with and without S9 mix in the preliminary toxicity experiment/experiment I, and for tester strain WP2 uvrA pKM101 in the untreated control with S9 mix and the solvent control with

and without S9 mix in experiment II. In strain WP2 pKM101 with and without metabolic activation in experiment I, the number of spontaneous revertants was below the lower limit of the laboratory historical control range. As discussed in the study report, the observations were considered to be the result of biologically irrelevant fluctuations in the number of colonies and were judged to have no detrimental impact on the outcome of the study. Since the number of revertants is consistent in all concentrations for these strains without major variability, and no increase of the number of revertant colonies was observed at all, the overall conclusion of an absence of a mutagenic effect is considered to be valid also for these tester strains.

Appropriate positive controls induced a marked increase in the number of revertants, confirming the activity of the S9 mix and the validity of the test system.

Based on the results of the present study and under the experimental conditions chosen, glyphosate technical is considered not mutagenic in the Ames standard plate and pre-incubation test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	S1008322
Description:	Not specified
Lot/Batch #:	569753
Purity:	96.3 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) and in vehicle were not specified in the study report.
Solvent (vehicle) used:	Deionised water

2. Control materials:

Negative control:	Controls which remained untreated were included in each experiment.
Solvent (vehicle) control:	Deionised water
Solvent (vehicle) final concentration:	0.1 mL per plate
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1535	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 98	-S9	4-Nitro-o-phenylene-diamine (4-NOPD)	DMSO	10
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1537	-S9	4-Nitro-o-phenylene-diamine (4-NOPD)	DMSO	50.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
E. coli strains				
WP2 uvrA (pKM101)	-S9	Methylmethane sulfonate (MMS)	Water	3.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	10.0
WP2 pKM101	-S9	Methylmethane sulfonate (MMS)	Water	3.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	10.0

* The functionality of the S9 mix batch used was checked with benzo(a)pyrene and showed the expected results.

3. Metabolic activation:

S9 mix was obtained from the livers of 8 – 12 weeks old male Wistar rats, weighing approx. 220 - 320 g. The animals received intraperitoneal injections of phenobarbital (80 mg/kg bw) and oral administration of β-naphthoflavone (80 mg/kg bw) on three consecutive days. The livers were prepared 24 h after the last treatment. Aliquots of the S9 mix were thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for

5. Test concentrations:

(a) Preliminary cytotoxicity assay/Experiment 1 of the main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*

Tester strains:	TA 1535, TA 1537, TA 98, TA 100, WP2 uvrA (pKM101) and WP2 pKM101
Replicates:	*Triplicates*

(b) Experiment 2 of the main mutation assay

Pre-incubation test ± S9 mix:	
Concentrations:	*33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100, WP2 uvrA (pKM101) and WP2 pKM101
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 23 Sep – 13 Oct 2009
Finalisation date: 18 Dec 2009

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten overlay agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin or 2.5 mg/L tryptophan). The mixture was mixed in a test tube and poured onto selective agar plates. Each concentration and the controls were tested in triplicates. After solidification, the plates were incubated upside down for at least 48 hours at 37 °C in the dark. After incubation, the background bacterial lawn was examined and the number of the bacterial colonies (his^+ or trp^+ revertants) was counted.

3. Pre-incubation test (PIT):
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were mixed in a test tube and shaken at 37 °C for 60 minutes. After pre-incubation, 2 mL of molten overlay agar was added to each test tube. Each concentration and the controls were tested in triplicates. The mixture was poured on selective agar plates. After solidification the plates were incubated upside down for at least 48 h at 37°C in the dark. Subsequently, the number of bacterial colonies (his^+ or trp^+ revertants) was counted.

4. Cytotoxicity
Toxicity was detected by a

- reduction in the number of spontaneous revertants
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics
Results were judged without statistical analysis.

6. Acceptance criteria
The test was valid if

- There was a regular background growth in the negative and solvent control.

- The spontaneous reversion rates in the negative and solvent control were in the range of the laboratory's historical data.
- The positive control substances produced a significant increase in mutant colony frequencies.

7. Evaluation criteria

A test item was considered as a mutagen if a biologically relevant increased in the number of revertants exceeding the threshold of twice the colony count of the corresponding solvent control is observed.

A dose dependent increase was considered biologically relevant if the threshold is exceeded at more than one concentration.

An increase exceeding the threshold at only one concentration was judged as biologically relevant if reproduced in an independent second experiment. A dose dependent increase in the number of revertant colonies below the threshold was regarded as an indication of a mutagenic potential if reproduced in an independent second experiment. However, whenever the colony counts remained within the historical range of negative and solvent controls such an increase was not considered biologically relevant.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

In the preliminary toxicity experiment, there were no indications of cytotoxicity up to the highest tested concentration of 5000 µg/plate. The preliminary experiment was designated as experiment I. Since no cytotoxic effects were observed, 5000 µg/plate were chosen as top concentration for experiment II. The plates incubated with the test item showed normal background growth up to 5000 µg/plate with and without metabolic activation in both independent experiments. No toxic effects, evident as a reduction in the number of revertants (below the indication factor of 0.5), occurred in the test groups with and without metabolic activation

C. SOLUBILITY

There was no precipitation of the test substance observed up to the highest concentration tested.

D. MUTATION ASSAY

There was no substantial increase in the number of his^+ or trp^+ revertants observed in any of the six tester strains at any dose level, neither in the presence nor absence of metabolic activation. In addition, there was no dose-dependent increase in mutation rates in the range below the generally acknowledged border of biological relevance.

For tester strain WP2 uvrA pKM101 the laboratory's historical control range was exceeded in the untreated and solvent control plates with and without S9 mix in the preliminary toxicity experiment/experiment I, and in the untreated control with S9 mix and the solvent control with and without S9 mix in experiment II. In strain WP2 pKM101 the lower limit of the laboratory historical control range was not quite reached in the untreated control with and without metabolic activation in experiment I. As discussed in the study reports, these elevated colony counts were considered to be the result of biologically irrelevant fluctuations in the number of colonies and were judged to have no detrimental impact on the outcome of the study.

Appropriate positive controls induced a marked increase in the number of revertants, confirming the activity of the S9 mix and the validity of the test system.

§ Information on respective positive control is reported in Material and Method section I.A.2

Historical control data generated from January - October 2008, representing approx. 600 experiments (approx. 150 experiments for WP2 uvrA pKM101; approx. 80 experiments for WP2 pKM101)

III. CONCLUSION:

Based on the results of the present study and under the experimental conditions of the test, the test item is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2 uvrA (pKM101) and WP2 pKM101) with and without metabolic activation.

The study was performed under GLP conditions and compliant with OECD guideline 471 (1997), without any deviations. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/008
Report author	[redacted]
Report year	2008
Report title	Evaluation of the mutagenic potential of the test substance Glyphosate Technical by reverse mutation assay in *Salmonella typhimurium* (Ames Test)
Report No	RF-3996.401.392.07
Document No	Not reported
Guidelines followed in study	OECD 471 (1997)
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	*S. typhimurium* strains TA 98, TA 100, TA 1535, TA 97a, and TA102 were exposed to glyphosate (batch: 20070606, purity: 98.05 %) in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Based on the results of a preliminary cytotoxicity test in tester strain TA100, in which cytotoxicity was observed at 2500 µg/plate in the absence of metabolic activation, concentrations in the range of 1 - 1000 µg/plate were selected for the main mutation assay. Triplicates of all tester strains were exposed via the plate-incorporation method to the test item for 72 hours. Sterility controls (untreated), vehicle (sterile water) and positive controls were included. Following incubation, the number of revertant colonies was counted for each strain.
Short description of results:	There was no clear evidence for cytotoxicity in any tester strain up to the highest concentration (1000 µg/plate) in the presence or absence of S9 mix, based on the number of revertant colonies. In addition, the test substance did not promote an increase in the number of revertant colonies in any strain either in the presence or absence of S9 mix. A statistically significant increase in the number of revertant colonies was observed with TA98 at 1 and 10 µg/plate and with TA100 at 500 µg/plate, both with S9 mix. However, the values were not increased by a factor of at least 2 compared to the values of the solvent controls and there was no dose-response relationship evident, therefore the findings were considered to be without relevance. The spontaneous mutation rates of negative controls remained within the range of historical control data and appropriate positive controls induced a marked increase in the number of revertants, thus demonstrating the functionality and validity of the test system. Based on the results of the present study and under the conditions of the test, glyphosate is not mutagenic in the Ames pre-incubation test with and without metabolic activation.
Reasons for why the study is not considered relevant/reliable or not	No evidence of mutagenicity was obtained in the plate-incorporation assay up to 1000 µg/plate (highest concentration tested). As much lower concentrations were tested than in most

considered as key study:	other studies, the study was not considered as key study (and not accepted in RAR 2015).

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535 and TA 1537, and *E. coli* strain WP2 uvrA were exposed to glyphosate technical (NUP-05068, batch: 200609062, purity: 95.1 %) in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction) for 48 h. Untreated, vehicle (deionised water) and positive controls were included in each experiment. A pre-experiment was conducted to identify cytotoxic concentrations of the test item. Test item concentrations in the range of 3 to 5000 µg/plate did not show any cytotoxic effects in the presence and absence of metabolic activation. In the main mutation assay two independent experiments were performed, using the plate incorporation method (first experiment) with concentrations in the range of 3 to 5000 µg/plate and the preincubation method (second experiment) with concentrations in the range of 33 to 5000 µg/plate.

There was no substantial increase in the number of his^+ and trp^+ revertant colony numbers in any of the experiments in any of the five tester strains at any dose level, neither in the presence nor absence of metabolic activation. The spontaneous reversion rate with and without metabolic activation was demonstrated with vehicle controls. Appropriate positive controls validated the sensitivity of the test system and the functionality of the metabolic activity of the S9 mix. Based on the results of the present study, glyphosate is not mutagenic in the Ames test with and without metabolic activation under the experimental conditions of the test.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	NUP-05068
Description:	Crystalline powder
Lot/Batch #:	200609062
Purity:	95.1 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until 14 Sep 2008. The stability of the test item in solvent (vehicle) was not indicated by the sponsor.
Solvent (vehicle) used:	Deionised water

2. Control materials:

Negative control:	Controls which remained untreated were included in each experiment.
Solvent (vehicle) control:	Deionised water
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1535	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 98	-S9	4-Nitro-o-phenylene-diamine (4-NOPD)	DMSO	10
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1537	-S9	4-Nitro-o-phenylene-diamine (4-NOPD)	DMSO	50.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
E. coli strain				
WP2 uvrA	-S9	Methylmethane sulfonate (MMS)	Water	3.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	10.0

* The functionality of the S9 mix batch used was additionally checked with benzo(a)pyrene and showed the expected results

3. Metabolic activation:

S9 mix was obtained from livers of 8 – 12 weeks old male Wistar HanIbm rats, weighing approx. 220 - 320 g. The animals received intraperitoneal injections of phenobarbital (80 mg/kg bw) and oral administration of β-naphthoflavone (80 mg/kg bw) on three consecutive days. The livers were prepared 24 h after the last treatment. The S9 mix was thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	5	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Plate incorporation test ± S9 mix:	
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*

(b) Mutation assays:

Plate incorporation test ± S9 mix:	
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*
Pre-incubation test ± S9 mix:	
Concentrations:	*33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 15 – 25 Jan 2007
Finalisation date: 16 Mar 2007

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten agar (supplemented with 10.5 mg/L L-histidine + 12.2

mg/L biotin or 2.5 mg/L tryptophan). The mixture was thoroughly shaken and poured onto minimal agar plates. Each concentration and the controls were tested in triplicates. After incubation at 37 °C for at least 48 h in the dark, the background bacterial lawn was examined and the bacterial colonies (his^+ or trp^+ revertants) were counted.

3. Pre-incubation test (PIT):
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were mixed in a test tube and shaken at 37 °C for 60 minutes. After pre-incubation 2 mL of molten overlay agar was added to each test tube. Each concentration and the controls were tested in triplicates. The mixture was poured on selective agar plates. After solidification the plates were incubated upside down for at least 48 h at 37°C in the dark. Subsequently, the number of bacterial colonies (his^+ or trp^+ revertants) were counted.

4. Cytotoxicity
Toxicity was detected by a

- reduction in the number of spontaneous revertants
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics
Results were judged without statistical analysis.

6. Acceptance criteria
The test was valid if

- There was a regular background growth in the negative and solvent control.
- The spontaneous reversion rates in the negative and solvent control were in the range of the laboratory's historical data.
- The positive control substances produced a significant increase in mutant colony frequencies.

7. Evaluation criteria
A test item was considered as a mutagen if a biologically relevant increase in the number of revertants exceeding the threshold of twice (strains TA 98, TA 100, and WP2 uvrA) or thrice (strains TA 1535 and TA 1537) the colony count of the corresponding solvent control was observed.
A dose dependent increase was considered biologically relevant if the threshold was exceeded at more than one concentration.
An increase exceeding the threshold at only one concentration was judged as biologically relevant if reproduced in an independent second experiment. A dose dependent increase in the number of revertant colonies below the threshold was regarded as an indication of a mutagenic potential if reproduced in an independent second experiment. However, whenever the colony counts remained within the historical range of negative and solvent controls such an increase was not considered biologically relevant.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
In the preliminary toxicity test, the test substance did not show any cytotoxicity to any strain up to the highest dose of 5000 µg/plate with and without metabolic activation.
In the second experiment of the main mutation assay toxicity, a reduction in the number of revertant colonies, was observed in tester strain TA 1537 at 5000 µg/plate in the absence of metabolic activation.

C. SOLUBILITY

There was no precipitation of the test substance observed up to the highest dose tested.

D. MUTATION ASSAY

There was no relevant increase in the number of his^+ or trp^+ revertants observed in any experiment at any tested concentration, neither in the presence nor in the absence of metabolic activation. In addition, there was no dose-dependent increase in mutation rates in the range below the generally acknowledged border of biological relevance.

The number of revertants induced by the vehicle control was slightly above the range of historical control data (except for strain TA 98). The finding was judged to be based on biologically irrelevant fluctuations and was considered to have no impact on the outcome of the study. The absence of impact was confirmed by the negative results obtained with the test solution at all tested concentrations in all strains.

Appropriate positive control compounds induced a marked increase in the number of revertants, demonstrating the validity of the test system and the functionality of the S9 mix.

III. CONCLUSION

In conclusion, under the experimental conditions reported, the test item (NUP-05068) did not induce gene mutations by base pair changes or frameshifts in the genome of the strains used. There is no indication for mutagenicity in bacteria (Ames test) with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2 uvrA) with and without metabolic activation.

The study was performed according to OECD guideline 471 (1997) and under GLP conditions. There were only minor deviations when compared to the guideline, which were considered to not compromise the validity of the study. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/010
Report author	[redacted]
Report year	2007
Report title	*Salmonella typhimurium* and *Escherichia coli* Reverse mutation assay with Glyphosate technical (NUP-05070)
Report No	1061402
Document No	Not reported
Guidelines followed in study	OECD 471 (1997) referenced as EEC Directive 92/69 Method B13/B14; Japanese MAFF (2005)
Deviations from current test guideline OECD 471 (1997)	No reporting of bacterial cell density.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535 and TA 1537, and *E. coli* strain WP2 uvrA were exposed to glyphosate technical (NUP-05070, batch: 20060901, purity: 97.7 %) in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction) for 48 h. Untreated, vehicle (deionised water) and positive controls were included in each experiment. A pre-experiment was conducted to identify cytotoxic concentrations of the test item. In a standard plate test (plate incorporation method), cytotoxicity was observed as a reduced bacterial background lawn for strain TA 1537 at 333 – 5000 µg/plate in the presence of S9 mix, for strain TA 100 at ≥ 2500 µg/plate in the presence of S9 mix and for strain WP2 uvrA at 5000 µg/plate in the presence and absence of S9 mix.

The pre-experiment was designated experiment 1 of the main mutation assay. A second experiment was performed in the main mutation assay using the preincubation method and concentrations in the range of 33 to 5000 µg/plate. Both experiments were performed with triplicates. There was no reduced bacterial growth in the second experiment. Toxicity, evident as a reduced number of revertant colonies, was observed for strain WP2 uvrA at 5000 µg/plate without S9 mix in the first experiment and for strains TA 98 and WP2 uvrA at 5000 µg/plate in the presence and absence of S9 mix.

There was no substantial increase in the number of his^+ and trp^+ revertant colony numbers in any of the five tester strains at any dose level, neither in the presence nor absence of metabolic activation.

The spontaneous reversion rate with and without metabolic activation of the solvent (vehicle) control was within the range of historical control data. The sensitivity of the test system and the functionality of the S9 mix was demonstrated with appropriate positive controls. Based on the results of the present study and under the experimental conditions of the test, glyphosate is not mutagenic in the Ames test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	NUP-05070
Description:	Crystalline powder
Lot/Batch #:	20060901
Purity:	97.7 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until 01 Sep 2008. The stability of the test item in solvent (vehicle) was guaranteed for 30 days at room temperature.
Solvent (vehicle) used:	Deionised water

2. Control materials:

Negative control:	Controls which remained untreated were included in each experiment.
Solvent (vehicle) control:	Deionised water
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5

	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1537	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	50.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
E. coli strain				
WP2 uvrA	-S9	Methylmethane sulfonate (MMS)	Water	3.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	10.0
* The functionality of the S9 mix batch used was additionally checked with benzo(a)pyrene and showed the expected results				

3. Metabolic activation:

S9 mix was obtained from the livers of 8 – 12 weeks old male Wistar HanIbm rats, weighing approx. 220 - 320 g. The animals received intraperitoneal injections of phenobarbital (80 mg/kg bw) and oral administration of β-naphthoflavone (80 mg/kg bw) on three consecutive days. The livers were prepared 24 h after the last treatment. The S9 mix was thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	5	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E. coli***			
TA 98	✓	WP2 uvrA	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay/Experiment 1 of the main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*

(b) Experiment 2 of the main mutation assay

Pre-incubation test ± S9 mix:	
Concentrations:	*33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 16 – 25 Jan 2007
Finalisation date: 16 Mar 2007

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture

and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin or 2.5 mg/L tryptophan). The mixture was thoroughly shaken and poured onto minimal agar plates. Each concentration and the controls were tested in triplicates. After incubation at 37 °C for at least 48 h in the dark, the background bacterial lawn was examined and the bacterial colonies (his^+ or trp^+ revertants) were counted.

3. Pre-incubation test (PIT):
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were mixed in a test tube and shaken at 37 °C for 60 minutes. After pre-incubation 2 mL of molten overlay agar was added to each test tube. Each concentration and the controls were tested in triplicates. The mixture was poured on selective agar plates. After solidification the plates were incubated upside down for at least 48 h at 37°C in the dark. Subsequently, the number of bacterial colonies (his^+ or trp^+ revertants) were counted.

4. Cytotoxicity
Toxicity was detected by a

- reduction in the number of spontaneous revertants
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics
Results were judged without statistical analysis.

6. Acceptance criteria
The test was valid if

- There was a regular background growth in the negative and solvent control.
- The spontaneous reversion rates in the negative and solvent control were in the range of the laboratory's historical data.
- The positive control substances produced a significant increase in mutant colony frequencies.

7. Evaluation criteria
A test item was considered as a mutagen if a biologically relevant increase in the number of revertants exceeding the threshold of twice (strains TA 98, TA 100, and WP2 uvrA) or thrice (strains TA 1535 and TA 1537) the colony count of the corresponding solvent control was observed.
A dose dependent increase was considered biologically relevant if the threshold is exceeded at more than one concentration.
An increase exceeding the threshold at only one concentration was judged as biologically relevant if reproduced in an independent second experiment. A dose dependent increase in the number of revertant colonies below the threshold was regarded as an indication of a mutagenic potential if reproduced in an independent second experiment. However, whenever the colony counts remained within the historical range of negative and solvent controls such an increase was not considered biologically relevant.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
Cytotoxicity, indicated by a reduced background lawn was evident in the pre-test/first experiment in strain

TA 1537 at concentrations in the range of 333 – 5000 µg/plate in the presence of S9 mix, in strain TA 100 at 2500 – 5000 µg/plate in the presence of S9 mix and in strain WP2 uvrA at 5000 µg/plate both in the presence and absence of S9 mix. There was no reduced bacterial background growth in the second experiment.

Toxic effects evident as a reduction in the number of revertant colonies was observed for strain WP2 uvrA at 5000 µg/plate without S9 mix in the first experiment and for strains TA 98 and WP2 uvrA at 5000 µg/plate with and without S9 mix in the second experiment.

C. SOLUBILITY

There was no precipitation of the test substance observed up to the highest dose tested.

D. MUTATION ASSAY

No relevant increase in the number of his^+ or trp^+ revertants was observed in any experiment at any tested concentration either in the presence or absence of metabolic activation. In addition, there was no dose-dependent increase in mutation rates in the range below the generally acknowledged border of biological relevance.

The number of revertants detected in the vehicle control was within expected range for each strain, thus demonstrating an acceptable experimental performance.

Appropriate positive control compounds induced a marked increase in the number of revertants, demonstrating the validity of the test system and the functionality of the S9 mix.

III. CONCLUSION:

According to the results of the present study and under the conditions of the test, the test item (NUP-05070) is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2 uvrA) with and without metabolic activation.

The study was performed according to OECD guideline 471 (1997) and under GLP conditions. There were only minor deviations when compared to the guideline, which were considered to not compromise the validity of the study. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/011
Report author	[redacted]
Report year	2007
Report title	*Salmonella typhimurium* and *Escherichia coli* Reverse mutation assay with Glyphosate technical (NUP-05067)
Report No	1061403
Document No	Not reported
Guidelines followed in study	OECD 471 (1997) referenced as EEC Directive 92/69 Method B13/B14; Japanese MAFF (2005)
Deviations from current test guideline OECD 471 (1997)	No reporting of bacterial cell density.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

This study was performed to investigate the potential of glyphosate technical (NUP-05070, batch: 0609-1, purity: 95.0 %) to induce gene mutations in *Salmonella typhimurium* strains TA 1535, TA 1537, TA 98, and TA 100, and the *Escherichia coli* strain WP2 uvrA. All strains were exposed, to the test item, vehicle (deionised water), untreated and appropriate positive controls in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction) for at least 48 h.
A pre-experiment was conducted to identify cytotoxic concentrations of the test item. In a standard plate test (plate incorporation method), the highest test item concentration (5000 µg/plate) induced cytotoxicity in strain WP2 uvrA in the absence of metabolic activation. The pre-experiment was designated experiment 1 of the main mutation assay and analysed for the number of revertant colonies. A second main mutation assay was performed using the pre-incubation method and concentrations in the range of 33 to 5000 µg/plate. Both experiments were performed with triplicates.

In the second experiment, cytotoxicity was observed at 5000 µg/plate for strain WP2 uvrA in the presence and absence of S9 mix.

No substantial increase in revertant colony numbers of any of the five tester strains was observed following treatment with the test item at any dose level, in any of the experiments, neither in the presence nor absence

of metabolic activation. The spontaneous reversion rate with and without metabolic activation of the solvent control was within the range of historical control data. A marked increase in the number of revertant colonies was obtained with appropriate positive controls, demonstrating the sensitivity of the test system and the functionality of the S9 mix. Based on the results of the present study and under the experimental conditions of the test, glyphosate is not mutagenic in the Ames test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	NUP-05070
Description:	Crystalline powder
Lot/Batch #:	0609-1
Purity:	95.0 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until 15 Aug 2008. The stability of the test item in solvent (vehicle) was guaranteed for 30 days at room temperature.
Solvent (vehicle)used:	Deionised water

2. Control materials:

Negative control:	Controls which remained untreated were included in each experiment.
Solvent (vehicle) control:	Deionised water
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1535	-S9	Sodium azide (NaN_3)	Water	10.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 98	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	10
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
TA 1537	-S9	4-nitro-o-phenylene-diamine (4-NOPD)	DMSO	50.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	2.5
E. coli strain				
WP2 uvrA	-S9	Methylmethane sulfonate (MMS)	Water	3.0
	+S9	2-Aminoanthracene (2-AA)*	DMSO	10.0
* The functionality of the S9 mix batch used was checked with benzo(a)pyrene and showed the expected results.				

3. Metabolic activation:

S9 mix was obtained from the livers of 8 – 12 weeks old male Wistar HanIbm rats, weighing approx. 220 - 320 g. The animals received intraperitoneal injections of phenobarbital (80 mg/kg bw) and oral administration of β-naphthoflavone (80 mg/kg bw) on three consecutive days. The livers were prepared 24 h after the last treatment. The S9 mix was thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	5	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

TA 98	✓	WP2 uvrA	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay/Experiment 1 of the main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*3, 10, 33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*

(b) Experiment 2 of the main mutation assay

Pre-incubation test ± S9 mix:	
Concentrations:	*33, 100, 333, 1000, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 16 – 25 Jan 2007
Finalisation date: 16 Mar 2007

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten agar (supplemented with 10.5 mg/L L-histidine + 12.2 mg/L biotin or 2.5 mg/L tryptophan). The mixture was thoroughly shaken and poured onto selective agar plates. Each concentration and the controls were tested in triplicates. After incubation at 37 °C for at least 48 h in the dark, the background bacterial lawn was examined and the bacterial colonies (his^+ or trp^+ revertants) were counted.

3. Pre-incubation test (PIT):
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were mixed in a test tube and shaken at 37 °C for 60 minutes. After pre-incubation 2 mL of molten overlay agar was added to each test tube. Each concentration and the controls were tested in triplicates. The mixture was poured on selective agar plates. After solidification the plates were incubated upside down for at least 48 h at 37°C in the dark. Subsequently, the number of bacterial colonies (his^+ or trp^+ revertants) were counted.

4. Cytotoxicity
Toxicity was detected by a

- reduction in the number of spontaneous revertants
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics
Results were judged without statistical analysis.

6. Acceptance criteria
The test was valid if

- There was a regular background growth in the negative and solvent control.
- The spontaneous reversion rates in the negative and solvent control were in the range of the laboratory's historical data.
- The positive control substances produced a significant increase in mutant colony frequencies.

7. Evaluation criteria
A test item was considered as a mutagen if a biologically relevant increase in the number of revertants exceeding the threshold of twice (strains TA 98, TA 100, and WP2 uvrA) or thrice (strains TA 1535 and TA 1537) the colony count of the corresponding solvent control was observed.
A dose dependent increase was considered biologically relevant if the threshold was exceeded at more than one concentration.
An increase exceeding the threshold at only one concentration was judged as biologically relevant if reproduced in an independent second experiment. A dose dependent increase in the number of revertant colonies below the threshold was regarded as an indication of a mutagenic potential if reproduced in an independent second experiment. However, whenever the colony counts remained within the historical range of negative and solvent controls such an increase was not considered biologically relevant.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

Cytotoxicity indicated by a reduced background lawn was observed in the pre-test/first experiment in *E. coli* strain WP2 uvrA at 5000 µg/plate in the absence of metabolic activation. There was no reduced bacterial growth noted in the second experiment. Toxic effects evident as a reduction in the number of revertant colonies was observed at minor degree in both experiments at 5000 µg/plate in strain WP2 uvrA in the absence of metabolic activation.

C. SOLUBILITY

There was no precipitation of the test substance observed up to the highest dose tested.

D. MUTATION ASSAY

There was no substantial increase in the number of his^+ or trp^+ revertants observed in any experiment at any tested concentration either in the presence or absence of metabolic activation. In addition, there was no dose-dependent increase in mutation rates in the range below the generally acknowledged border of biological relevance.

The spontaneous mutation rates of negative controls remained within the range of historical control data and appropriate positive controls induced a marked increase in the number of revertants, thus demonstrating the functionality and validity of the test system.

III. CONCLUSION:

Based on the results of the present study and under the experimental conditions of the test, the test item is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2 uvrA) with and without metabolic activation.

The study was performed according to OECD guideline 471 (1997) and under GLP conditions. There were only minor deviations when compared to the guideline, which were considered to not compromise

the validity of the study. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/012
Report author	[redacted]
Report year	2007
Report title	Bacterial reverse mutation test (Ames Test) for Glifosato Téchnico
Report No	RL3393/2007-2.0AM-B
Document No	Not reported
Guidelines followed in study	OECD 471 (1997)
Deviations from current test guideline OECD 471 (1997)	2-Aminoanthracene was used as sole positive control in the presence of metabolic activation. Only a single experiment was performed, without giving a justification for not conducting a confirmatory experiment. Historical control data were restricted to solvent controls, but not differentiated for exposures in the presence or absence of metabolic activation.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535, TA 1537 and TA 102 were exposed to glyphosate technical (batch: 2007091801, purity: 98.01 %) in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Based on the results of a preliminary cytotoxicity test, in which no toxicity was observed up to 5000 µg/plate, concentrations for the main mutation assay were selected. In the main experiment the tester strains were exposed via the plate-incorporation method to test item concentrations in the range of 648 to 5000 µg/plate for 72 hours. Vehicle (sterile water) and positive controls were included. Following incubation, the bacterial background lawn was examined and the number of revertant colonies was counted for each strain.

Precipitation of the test substance was not reported. Cytotoxicity as indicated by a statistically significant reduction in the number of revertant colonies was observed at 5000 µg/plate in strain TA 1537 in the absence of S9 mix.

There was no substantial increase in the number of his^+ and trp^+ revertants (exceeding a mutation rate by a factor of at least 2 when compared to solvent controls) observed in any experiment either in the presence or absence of metabolic activation and no dose-response relationship in the range below the generally acknowledged border of biological significance. Vehicle controls were within the range of historical control data and positive controls demonstrated the sensitivity and the functionality of the test substance.
Based on the results of the present study, glyphosate is not mutagenic in the Ames pre-incubation test with and without metabolic activation under the experimental conditions of the test.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	Glifosato Téchnico Helm
Description:	Solid
Lot/Batch #:	2007091801
Purity:	98.01 %
Stability of test compound:	The stability of the test item under storage conditions was guaranteed until 17 Sep 2009. In addition, it was confirmed by CIPAC MT 46 at 54 °C for 14 days
Solvent (vehicle) used:	Dimethylsulfoxide (DMSO)

2. Control materials:

Negative control:	Not examined
Solvent (vehicle) control:	Dimethylsulfoxide (DMSO)
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Conc. [µg/plate]
TA 100	-S9	Sodium azide	5.0
	+S9	2-Aminoanthracene	2.5
TA 1535	-S9	Sodium azide	5.0
	+S9	2-Aminoanthracene	2.5
TA 98	-S9	2-Nitrofluorene	0.5
	+S9	2-Aminoanthracene	2.5
TA 1537	-S9	ICR 191-Acridine	10.0
	+S9	2-Aminoanthracene	2.5
TA 102	-S9	Mitomycin C	0.5
	+S9	2-Aminoanthracene	2.5

3. Metabolic activation:

S9 mix was purchased from [redacted] ([redacted]). The homogenate was produced from the livers of rats which were induced with Aroclor 1254. The concentration of protein in S9 fraction employed in the assay was 34.9 mg/mL.

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes)	✓
TA 1537	✓				
TA 102	✓				
TA 1538				Histidine auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Plate incorporation test without S9 mix:	
Concentrations:	*8, 40, 200, 1000 and 5000 µg/plate*
Tester strains:	TA 100
Replicates:	*Triplicates*

(b) Mutation assay:

Plate incorporation test ± S9 mix:	
Concentrations:	*648, 1080, 1800, 3000 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and TA 102
Replicates:	*Triplicates in a single experiment.*

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 06 Nov – 03 Dec 2007
Finalisation date: 13 Dec 2007

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 3 mL of top agar. Each suspension was incubated on selective agar plates for 72 h. After incubation the background bacterial lawn was examined and the bacterial colonies (his^+ or trp^+ revertants) were counted.

3. Cytotoxicity
Cytotoxicity was investigated in a preliminary dose-range finding study, which was performed in tester strain TA100 in the absence of metabolic activation. Toxicity was detected by a

- decrease in the number of revertants
- clearing or diminution of the background lawn (= reduced his^- background growth)

and recorded for all test groups both with and without S9 mix.

4. Statistics
Analysis of variance (ANOVA) was performed on the data to identify statistical significance (p ANOVA < 0.05)

5. Acceptance criteria
The following acceptance criteria were defined:

- Presence of background lawn in the test plates.
- Spontaneous revertant colonies of the negative control were in the range reported in literature and established in the laboratory by historical control values.
- Positive controls showed mutagenicity in all tested strains.

6. Evaluation criteria

Results were judged positive when the following criteria were met:

- The mutation rates after 72 hours of incubation of strains exposed to the test chemical were higher than 2 for strains TA 98, TA 100 and TA 102 or higher than 3 for strains TA 1535 and TA1537.
- The positive result was statistically significant (pANOVA < 0.05) and a clear dose-related increase in the number of revertants was observed.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

In the preliminary cytotoxicity experiment, the test substance did not show any toxicity to any strain up to the highest dose tested, neither in the presence, nor in the absence of metabolic activation.

According to the result tables of the study report, in the main experiment, cytotoxicity as indicated by a statistically significant reduction in the mean number of revertant colonies, was observed at 5000 µg/plate in strain TA 1537 in the absence of S9 mix. There was no cytotoxicity observed in any other strain, neither in the presence, nor absence of S9 mix. These observations on cytotoxicity listed in the result tables of the study report are inconsistent with the observations described in the text of the study report, where a reduction in the mean number of revertant colonies was observed at 5000 µg/plate for strain TA 1537 in the presence of S9 mix and for strain TA 102 in the absence of S9 mix.

C. SOLUBILITY

Precipitation of the test substance was not reported.

D. MUTATION ASSAY

No substantial increase in revertant colony numbers of any of the five tester strains was observed following treatment at any concentration level, neither in the presence nor absence of metabolic activation. There was also no tendency of higher mutation rates with increasing concentrations in the range below the generally acknowledged border of biological significance.

The number of revertants induced by the vehicle control was within expected range of historical control data and data published in literature for each strain, thus demonstrating an acceptable experimental performance.

Appropriate positive control compounds induced a marked increase in the number of revertants, demonstrating the functionality of the S9 mix and the validity of the test system.

III. CONCLUSION:

According to the results of the present study and under the experimental conditions of the test, the test item is not mutagenic in the Ames plate-incorporation test with and without metabolic activation.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:

Negative for gene mutation in bacteria (*S. typhimurium* TA 98, TA 100, TA 1535, TA 1537 and TA 102) with and without metabolic activation.

The study was performed under GLP conditions and according to OECD guideline 471 (1997), including some deviations from the guideline. No justification was provided for conducting only a single experiment according to the plate incorporation method, however, given the clearly negative result, this is considered acceptable. Further deviations to OECD guideline 471 (1997) were considered to be of minor degree and to not compromise the validity of the study. The study was considered to provide supporting information.

<u>Assessment and conclusion by RMS</u>:

1. Information on the study

Data point	CA 5.4.1/013
Report author	[redacted]
Report year	1996
Report title	Glyphosate Acid: An Evaluation of Mutagenic Potential Using *S. typhimurium* and *E. coli*.
Report No	CTL/P/4874 (Syngenta)
Document No	YV3611
Guidelines followed in study	OECD 471 (1983); OECD 472 (1983); U.S. EPA FIFRA Guidelines, Subdivision F (1991); EEC Directive 92/69 Method B.13/B14 (1992)
Deviations from current test guideline OECD 471 (1997)	No historical control data provided. No information on cytotoxicity reported. Evaluation of cytotoxicity and precipitation were not reported, but concentrations were tested up to limit doses. 2-Aminoanthracene was used as sole indicator of the efficacy of the S9 mix in all strains. No confirmation of bacterial cell density.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535 and TA 1537, and *E. coli* strains WP2P and WP2 uvrA were exposed to glyphosate acid (batch: P24, purity: 95.6 %) in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction). The test was performed using the plate-incorporation method (first experiment) and the pre-incubation method (second experiment) and concentrations in the range of 100 – 5000 µg/plate. Solvent (DMSO) and positive controls were included in each experiment. After 72 hours of incubation at 37 °C, the bacterial background lawn was inspected and the number of revertant colonies was examined.

Evaluation of precipitation and cytotoxicity was not provided in the study report. Cytotoxicity was evaluated retrospectively by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding solvent control. Indications for cytotoxicity were observed in the first experiment in tester strains TA1535, TA 98 and TA 100 at ≥ 2500 µg/plate and in tester strains WP2P and WP2 uvrA at 5000 µg/plate in the absence of S9 mix. In the second experiment, cytotoxicity was observed at ≥ 2500 µg/plate for strain TA 98 in the absence of S9 mix, at 5000 µg/plate for strains TA 1537 and WP2uvrA in the absence of S9 mix and for strains TA 1535, TA 98, TA 100 and WP2P in the presence and absence of S9 mix.

There was no statistically singificant, reproducible increase in in the number of his^+ and trp^+ revertant colony numbers in any of the six tester strains at any dose level, neither in the presence nor absence of metabolic activation. Statistical significance in the mean number of revertant colonies was observed for tester strains TA 100 and WP2P at single concentrations in the presence or absence of S9 mix, however, the results were not reproducible in independent experiments and showed no dose-response relationship and were thus considered to be incidental. The spontaneous reversion rate with and without metabolic activation was demonstrated with vehicle controls. Appropriate positive controls validated the sensitivity of the test system and the functionality of the metabolic activity of the S9 mix.

Based on the results and under the experimental conditions of the present study, there is no indication for mutagenicity in the Ames standard plate and pre-incubation test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate acid

Identification:	Y04707/034
Description:	White solid
Lot/Batch #:	P24
Purity:	95.6 %
Stability of test compound:	The stability of the test item under storage conditions (at ambient temperature in the dark) was guaranteed until the stated expiry date (no date provided). The stability of the test item in solvent (vehicle) was not indicated by the sponsor.
Solvent (vehicle) used:	Dimethylsulfoxide (DMSO)

2. Control materials:

Negative control:	Not specified
Solvent (vehicle) control:	DMSO
Solvent (vehicle)/final concentration:	10 µL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	Sodium azide (NaN_3)	DMSO	0.5, 1.0 and 2.0
	+S9	2-Aminoanthracene (2AA)	DMSO	0.2, 0.5 and 1.0
TA 1535	-S9	Sodium azide (NaN_3)	DMSO	0.5, 1.0 and 2.0
	+S9	2-Aminoanthracene (2AA)	DMSO	0.5, 1.0 and 2.0
TA 98	-S9	Daunorubicin Hydrochloride (DR)	DMSO	0.2, 0.5 and 1.0
	+S9	2-Aminoanthracene (2AA)	DMSO	0.2, 0.5 and 1.0
TA 1537	-S9	Acridine Mutagen ICR191 Dihydrochloride (ACM)	DMSO	0.5, 1.0 and 2.0
	+S9	2-Aminoanthracene (2AA)	DMSO	0.5, 1.0 and 2.0
E. coli strains				
WP2 uvrA	-S9	N-Ethyl-N-nitro-N-nitrosoguanidine (ENNG)	DMSO	0.2, 0.5 and 1.0
	+S9	2-Aminoanthracene (2AA)	DMSO	1, 2 and 5
WP2P	-S9	Mitomycin C (MMC)	DMSO	0.2, 0.5 and 1.0
	+S9	2-Aminoanthracene (2AA)	DMSO	5, 10 and 20

3. Metabolic activation:

S9 mix was obtained from the livers of male Sprague-Dawley rats, dosed once daily by oral gavage for three days with a combined phenobarbital (80 mg/kg bw) and β-naphthoflavone (100 mg/kg bw) corn oil solution. The livers were prepared one day after the third dose. A 25 % (w/v) homogenate fraction was prepared using sucrose-Tris-EDTA buffer (250:50:1 mM), adding 3 mL S9 fraction to 7 mL buffer. Afterwards 20 mL co-factor solution were immediately added containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	150	mM
KCl	49.5	mM
NADPH-generating system		
Glucose 6-phosphate	7.55	mM
NADP, Na salt	6	mM
$MgCl_2$	12	mM
S9	25	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		*E.coli*			
TA 98	✓	WP2 uvrA	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 P	✓	ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

Plate incorporation test ± S9 mix:		
Concentrations:	*100, 200, 500, 1000, 2500 and 5000 µg/plate*	
Tester strains:	TA 1535, TA 1537, TA 98, TA 100, WP2P and WP2 uvrA	
Replicates:	*Triplicates*	
Pre-incubation test ± S9 mix:		
Concentrations:	*100, 200, 500, 1000, 2500 and 5000 µg/plate*	
Tester strains:	TA 1535, TA 1537, TA 98, TA 100, WP2P and WP2 uvrA	
Replicates:	*Triplicates*	

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 28 Nov – 11 Dec 1995
Finalisation date: 16 Feb 1996

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial overnight culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 substitution buffer (in tests without metabolic activation) were added to 2 mL of molten agar (supplemented with 0.5 mg histidine/0.5 mM biotin stock solution (10 mL solution : 100 mL agar) or 10 mL 0.5 mM stock tryptophan per 100 mL agar). The mixture was thoroughly shaken and poured rapidly onto Vogel Bonner agar plates. Each

concentration and the controls were tested in triplicates. After incubation at 37 °C for 72 h in the dark, the plates were checked for microbial contamination, the background bacterial lawn was examined and the number of the bacterial colonies (his^+ or trp^+ revertants) was counted.

3. Pre-incubation test (PIT):

0.1 mL of test solution or vehicle/positive control were prepared by adding 0.02 mL volumes of stock solution in DMSO to phosphate buffered saline. Afterwards, the formulations, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of S9 mix substitution buffer (in tests without metabolic activation) were mixed in a test tube and shaken at 37 °C for 60 minutes. After pre-incubation 2 mL of molten overlay agar (supplemented with 0.5 mg histidine/0.5 mM biotin stock solution (10 mL solution : 100 mL agar) or 10 mL 0.5 mM stock tryptophan per 100 mL agar) was added to each test tube. Each concentration and the controls were tested in triplicates. The mixture was poured onto Vogel Bonner agar plates. After solidification the plates were incubated for 72 h at 37°C in the dark. Subsequently, the plates were checked for microbial contamination, the bacterial background lawn was examined and the number of bacterial colonies (his^+ or trp^+ revertants) was counted.

4. Cytotoxicity

Evaluation of cytotoxicity was not further specified in the study report. Thus, retrospectively, cytotoxicity was evaluated by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding solvent control. Cytotoxicity was considered evident when the mean number of revertant colonies induced by the test item concentration was ≤ 0.5 fold of the mean number of spontaneous revertant colonies induced by the solvent control.

5. Statistics

An assessment of statistical significance was carried out using a one-tailed Student's t-test. Values of $p < 0.01$ are treated as significant with values of $0.01 \leq p < 0.05$ being indicative of a possible effect.

6. Acceptance criteria

The test was valid if

- The concurrent solvent control data were acceptable
- The positive control data showed unequivocal positive responses.

Failure of one or more tester strain/S9 combinations does not invalidate the data for the remainder of a concurrent experiment.

7. Evaluation criteria

A positive response in an individual experiment was achieved when one or both of the following criteria were met:

- A statistically significant dose-related increase in the mean number of revertant colonies was obtained.
- A two-fold or greater increase of statistical significance in the mean number of revertant colonies was observed at one or more concentrations.

For a positive response in an individual experiment to be considered indicative of an unequivocal positive, i.e. mutagenic, result for that strain/S9 combination, then the observed effects must be consistently reproducible.

A negative response in an individual experiment was achieved when

- There was no statistically significant dose-related increase in the mean number of revertant colonies per plate observed for the test substance.
- In the absence of any such dose response, no increase in colony numbers was observed at any test concentration, which exceeded 2x the concurrent solvent control.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

Indications for cytotoxicity were observed in the first experiment in tester strains TA 1535, TA 98 and TA 100 at ≥ 2500 µg/plate and in tester strains WP2P and WP2 uvrA at 5000 µg/plate in the absence of S9 mix and in the second experiment for tester strains TA 1535, TA 1537, TA 98, TA 100 and WP2P with and without S9 mix and in tester strain WP2 uvrA in the absence of S9 mix.

C. SOLUBILITY

There was no precipitation of the test substance reported.

D. MUTATION ASSAY

Although a statistically significant increase in the mean number of revertant colonies was obtained in tester strains TA 100 and WP2P at 500 µg/plate in the presence and absence of S9 mix, respectively, there was no dose response relationship and the observations were not consistent in individual experiments.

The number of revertants induced by the test item were comparable to those of the corresponding solvent controls. The positive control compounds induced the expected results, indicating the functionality of the S9 mix and demonstrating the validity of the test system.

III. CONCLUSION:

In conclusion, under the experimental conditions reported, the test item is not mutagenic in the Ames test (standard plate and pre-incubation method) with and without metabolic activation.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2P and WP2 uvrA) with and without metabolic activation.

The study was performed according to OECD guideline 471 (1997) and compliant with GLP. There were only minor deviations from the guideline, which were considered to not compromise the outcome of the study. The study is therefore considered valid and acceptable.

<u>Assessment and conclusion by RMS</u>:

1. Information on the study

Data point	CA 5.4.1/014
Report author	[redacted]
Report year	1996
Report title	Technical glyphosate: Reverse mutation assay "Ames test" using *Salmonella typhimurium* and *Escherichia coli*
Report No	434/014
Document No	Not reported
Guidelines followed in study	OECD 471 (1983), Commission Directive (EC) 92/69/EEC Method B14 (1992), US EPA (TSCA) guidelines
Deviations from current test guideline OECD 471 (1997)	2-Aminoanthracene was used as sole positive control substance demonstrating the functionality of the S9 mix. It was reported that cytotoxicity was observed, but it was not indicated for which strain and for which concentration. Historical control data on vehicle and positive controls were not provided. In the repeat-experiment, no parameter was changed. Both experiments were conducted under the same conditions using the plate incorporation method.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Technical glyphosate (batch: H95D161A, purity 95.3 %) was investigated in the Ames standard plate test (plate-incorporation method) for its potential to induce gene mutations in bacteria. *S. typhimurium* strains TA98, TA100, TA1535 and TA1537 and *E. coli* strain WP2uvrA were exposed to the test item in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction) for approximately 48 hours at 37 °C. Vehicle (distilled water) and positive controls were included in each experiment. Based on the results of a preliminary toxicity test in strains TA100 and WP2uvrA, the concentrations for the main mutagenicity study were selected.

In two independent experiments, the cells were exposed to test item concentrations in the range of 50 to 5000 µg/plate. After 48 hours of incubation, the plates were scored for revertant colonies and examined for a thinning of the bacterial background lawn.

There was no precipitation of the test item observed. Cytotoxicity was reported, but detailed observations on cytotoxicity of individual strains and concentrations were not specified in the study report. Cytotoxicity was evaluated retrospectively by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding vehicle control. A cytotoxic effect was evident when the number of revertant colonies was 50 % of the value in corresponding vehicle controls. In the main mutagenicity test, cytotoxicity evident as a decrease in the frequency of revertant colonies was observed in the second experiment only at 5000 µg/plate, in tester strains TA98, TA100 and TA1535 in the absence of S9 mix and in tester strain TA1535 in the presence of S9 mix.

There was no significant increase in the frequency of revertant colonies as compared to vehicle controls

recorded for any of the five bacteria strains at any dose level, either with or without metabolic activation.

The number of revertants induced by the vehicle control was within the range of spontaneous revertant rates for each strain. All of the positive control chemicals produced marked increases in the frequency of revertant colonies, demonstrating the activity of the S9 mix.

Based on the experimental results and under the experimental conditions of the present study, technical glyphosate is negative for gene mutation in bacteria in the Ames standard plate test (plate incorporation method) in the presence and absence of metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Technical Glyphosate

Identification:	/
Description:	White powder,
Lot/Batch #:	H95D161A
Purity:	95.3 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) and the stability of the test item in vehicle was not stated in the study report (at the responsibility of the sponsor).
Solvent (vehicle) used:	Sterile distilled water

2. Control materials:

Negative control:	Controls which remained untreated were included in each experiment.
Solvent (vehicle) control:	Sterile distilled water
Solvent (vehicle) /final concentration:	0.1 mL per plate
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Conc. [µg/plate]
S. typhimurium strains			
TA 100	-S9	N-ethyl-N'-nitro-N-nitrosoguanidine (ENNG)	3.0
	+S9	2-Aminoanthracene (2AA)	1.0
TA 1535	-S9	N-ethyl-N'-nitro-N-nitrosoguanidine (ENNG)	5.0
	+S9	2-Aminoanthracene (2AA)	2.0
TA 98	-S9	4-Nitroquinoline-1-oxide (4NQO)	0.2
	+S9	2-Aminoanthracene (2AA)	0.5
TA 1537	-S9	9-Aminoacridine (9AA)	80
	+S9	2-Aminoanthracene (2AA)	2.0
E. coli strain			
WP2 uvrA	-S9	N-ethyl-N'-nitro-N-nitrosoguanidine (ENNG)	2.0
	+S9	2-Aminoanthracene (2AA)	10.0

3. Metabolic activation:

S9 mix was obtained from the livers of male Sprague-Dawley rats, weighing approx. 200 g. The animals received a single intraperitoneal injection of Aroclor 1254 at 500 mg/kg bw. The rats were sacrificed 5 days after administration and the liver homogenate was prepared. Prior to the experiment, the S9 mix was prepared immediately by mixing S9 fraction and co-factor.

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		*E.coli*			
TA 98	✓	WP2 uvrA	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay

Plate incorporation test - S9 mix:	
Concentrations:	*50, 150, 500, 1500 and 5000 µg/plate*
Tester strain:	TA 100 and WP2 uvrA
Replicates:	*Duplicate*

(b) Experiment 1 of the main mutation assay

Plate incorporation test ± S9 mix:	
Concentrations:	*50, 150, 500, 1500 and 5000 µg/plate*
Tester strain:	TA 98, TA 100, TA 1535, TA 1537 and WP2 uvrA
Replicates:	*Triplicate*

(c) Experiment 2 of the main mutation assay

Plate incorporation test ± S9 mix:			
Concentrations:		*50, 150, 500, 1500 and 5000 µg/plate*	
Tester strains:	TA 98, TA 100, TA 1535, TA 1537 and WP2 uvrA		
Replicates:		*Triplicate*	

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 19 Aug – 13 Nov 1995
Finalisation date: 20 Feb 1996

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of S9 phosphate buffer (in tests without metabolic activation) were added to 2.0 mL of molten, histidine/tryptophan supplemented medium. All compounds were mixed and equally distributed onto the surface of sterile Vogel-Bonner minimal agar plates. After approximately 48 hours of incubation at 37 °C, the plates were scored for revertant colonies and examined for a diminution of the bacterial background lawn.

3. Cytotoxicity
Toxicity was detected by

- a reduction in the number of spontaneous revertant colonies
- a clearing or diminution of the background lawn (= reduced his^- and trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

4. Statistics
The test results were analysed for statistical significance according to Kirkland (1989)[11].

5. Acceptance criteria
Acceptance criteria were not defined in the study report. Prior to use, the bacteria strains where checked for characteristics, viability and spontaneous reversion rates.

6. Evaluation criteria
A test item was considered to show a positive response if it induced a dose-related, statistically significant increase in the mutation rate of at least twice the spontaneous reversion rate in one or more strains in the presence and/or absence of metabolic activation in both experiments at sub-toxic levels.
A test item was considered to show a negative response if the number of induced revertants compared to spontaneous revertants were less than two-fold at each dose level, the intervals of which should be between 2 and 5 fold and extent to the limits imposed by toxicity, solubility or up to the maximum recommended dose of 5000 µg/plate.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

[11] Kirkland, D.J., UKEMS Sub-committee on Guidelines for Mutagenicity Testing. Report Part III (1989), Cambridge University Press.

B. CYTOTOXICITY

Although cytotoxicity was noted in the preliminary toxicity study and in the main mutagenicity study, detailed observations on cytotoxicity of individual strains and concentrations were not further specified in the study report. Cytotoxicity was evaluated retrospectively by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding vehicle control. A cytotoxic effect was evident when the number of revertant colonies was 50 % or less of the value in corresponding vehicle controls.

In the preliminary toxicity test (-S9 mix), cytotoxicity was observed in strain TA 100 at 5000 µg/plate.

In the main mutagenicity test, cytotoxicity evident as a decrease in the frequency of revertant colonies was observed in the second experiment only at 5000 µg/plate, in tester strains TA 98, TA 100 and TA 1535 in the absence of S9 mix and in tester strain TA 1535 in the presence of S9 mix.

C. SOLUBILITY

Precipitation of the tests item was not reported.

D. MUTATION ASSAY

There was no significant increase in the frequency of revertant colonies as compared to vehicle controls recorded for any of the five bacteria strains at any dose level, either with or without metabolic activation.

The number of revertants induced by the vehicle control was within the range of spontaneous revertant rates for each strain. All of the positive control chemicals produced marked increases in the frequency of revertant colonies, demonstrating the activity of the S9 mix.

III. CONCLUSION:

Based on the results and under the experimental conditions of the present study, technical glyphosate is negative for gene mutation in bacteria in the Ames standard plate test (plate incorporation method) in the presence and absence of metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535, TA 1537 and *E. coli* WP2 uvrA) with and without metabolic activation.

The study was conducted according to OECD guideline 471 (1983) and in compliance with GLP. There were only minor deviations when compared to the currently valid OECD guideline 471 (1997), which were considered to not compromise the validity of the study. The study was considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/015
Report author	[redacted]
Report year	1995
Report title	HR-001: Reverse Mutation Test
Report No	IET 94-0142
Document No	Not reported
Guidelines followed in study	U.S. EPA FIFRA Guidelines, Subdivision F; similar to OECD guideline 471 (1997)
Deviations from current test guideline OECD 471 (1997)	Compared to OECD 471 (1997) information on historical control data were not reported. In the repeat-experiment, no parameter was changed.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535 and TA 1537, and *E. coli* strain WP2 uvrA were exposed to glyphosate technical (HR-001, batch: 940908-1, purity: 95.68 %) in the presence and absence of metabolic activation (phenobarbital and 5,6 benzoflavone-induced rat liver S9 fraction). The test was performed for 48 hours at 37 °C using the pre-incubation method. Vehicle (sterile water) and positive controls were included in each experiment. The concentrations were selected based on a preliminary dose-range finding test in which the test item did not show cytotoxicity to any strain up to the highest dose of 5000 µg/plate tested. In two independent experiments of the main mutagenicity test, the test item was tested according to the pre-incubation method in triplicates of five concentrations ranging from 156 to 5000 µg/plate.

Precipitation of the test substance was not reported, although test item formulations were used at concentrations exceeding the mentioned range of solubility of the solvent. A relevant increase in the number of his[+] and trp[+] revertants (exceeding a factor of 2 when compared to solvent controls) was not observed in any experiment either with or without S9 mix. Vehicle controls showed low spontaneous reversion rates with and without metabolic activation. The positive controls induced the appropriate response in the corresponding strains, thus demonstrating the sensitivity of the test system and the metabolic activity of the S9 mix employed.

Based on the results of the present study, glyphosate is not mutagenic in the Ames pre-incubation test with and without metabolic activation under the experimental conditions chosen.

I. MATERIALS AND METHODS

A: MATERIALS

1. **Test material:** Glyphosate technical

Identification: HR-001

Description: White crystals

Lot/Batch #: 940908-1

Purity: 95.68 %

Stability of test compound: The stability of the test item under storage conditions (at approx. 5 °C in a dark cold room) and the stability of the test item in vehicle were not specified.

Solvent used: Sterile water

2. **Control materials:**

Negative control: Not specified

Solvent control: Sterile water

Solvent/final concentration: The test substance was applied at concentrations > 12 mg/mL using 0.1 mL per plate.

Positive controls: Please refer to the table below.

Strain	Metabolic activation	Mutagen	Solvent	Conc. [µg/plate]
S. typhimurium strains				
TA 100	-S9	2-(2-furyl)-3-(5-nitro-2-furyl) acrylamide (AF-2)	DMSO	0.01
	+S9	2-Aminoanthracene	DMSO	1.0
TA 1535	-S9	Sodium azide (NaN_3)	Water	0.5
	+S9	2-Aminoanthracene	DMSO	2.0
TA 98	-S9	2-(2-furyl)-3-(5-nitro-2-furyl) acrylamide (AF-2)	DMSO	0.1
	+S9	2-Aminoanthracene	DMSO	0.5
TA 1537	-S9	9-Aminoacridine (9-AA)	Water	80
	+S9	2-Aminoanthracene	DMSO	2.0
E. coli strain				
WP2 uvrA	-S9	2-(2-furyl)-3-(5-nitro-2-furyl) acrylamide (AF-2)	DMSO	0.01
	+S9	2-Aminoanthracene	DMSO	10.0

3. **Metabolic activation:**

S9 mix was purchased from [redacted] ([redacted]; Lot no. RAA-316). The homogenate was produced from the livers of male Sprague-Dawley rats, weighing 192 – 229 g, that received intraperitoneal injections of phenobarbital (30 mg/kg bw on Day 1, each 60 m g/kg bw on Days 2, 3 and 4) and 5,6 benzoflavone on Day 3. The S9 mix was prepared immediately before the experiment by mixing S9 fraction and co-factor.

S9 mix component	**Concentration**	**Unit**
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADH	4	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				**Bacteria batch checked for**	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA	✓	deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 102					
TA 1538				Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Pre-incubation assay ± S9 mix:	
Concentrations:	*0, 200, 500, 1000, 2000 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*A single plate was used per condition.*

(b) Mutation assays:

Pre-incubation assay ± S9 mix:	
Concentrations:	*0, 156, 313, 625, 1250, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98, TA 100 and WP2 uvrA
Replicates:	*Triplicates in two independent experiments*

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 21 Feb – 09 Mar 1995
   Finalisation date: 03 Apr 1995

2. **Pre-incubation test (PIT):**
0.1 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation) or 0.5 mL of 100 mM sodium phosphate buffer (in tests without metabolic activation) were pre-incubated for 20 minutes at 37 °C using a shaker. Subsequently 2 mL of aminoacid-supplemented molten agar was added to each test tube. The contents were mixed uniformly and overlaid on the minimal glucose agar plate. Each concentration and the controls were tested in triplicates. After an incubation period of 48 h at 37 °C, the number of bacterial colonies (his^+ or trp^+ revertants) were counted.

3. **Cytotoxicity**
Cytotoxicity was investigated in a preliminary dose-range finding study. Toxicity was detected by a
- decrease in the number of revertants
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

4. **Statistics**
Results were judged without statistical analysis.

5. **Acceptance criteria**
The test was valid if
- The culture of the tester strains, the solution of the test substance and S9 mix were free from contamination or other bacteria.
- A normal number of spontaneous revertant colonies was observed for the solvent control.
- An at least 3-fold increase above the solvent control in the mean number of revertants was observed in the positive control.

6. **Evaluation criteria**
Results were judged positive without statistical analysis when the following criteria were met:
- A two-fold or greater increase above solvent control in the mean number of revertants was observed.
- This increase in the number of revertants was accompanied by a dose-response relationship.
- This increase in the number of revertants was reproducible.

Reproducibility of results was confirmed by two independent experiments.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
In the preliminary cytotoxicity test, the test substance did not show any cytotoxicity to any strain up to the highest dose of 5000 µg/plate with and without metabolic activation.

In the main mutation study there was also no cytotoxicity observed up to the highest concentration tested.

C. SOLUBILITY

There was no precipitation of the test substance observed.

D. MUTATION ASSAY

A relevant increase in the number of his^+ or trp^+ revertants was not observed in any experiment at any tested concentration either in the presence or absence of metabolic activation.

The number of revertants induced by the vehicle control was within expected range for each strain, thus demonstrating an acceptable experimental performance.

Appropriate positive control compounds induced a marked increase in the number of revertants, demonstrating the validity of the test system and the functionality of the S9 mix.

III. CONCLUSION:

According to the results of the present study, the test item is not mutagenic in the Ames pre-incubation test with and without metabolic activation under the experimental condition of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537 and *E. coli* WP2 uvrA) with and without metabolic activation.

The study was conducted according to OECD guideline 471 (1983) and in compliance with GLP. There were only minor deviations when compared to the currently valid OECD guideline 471 (1997), which were considered to not compromise the validity of the study. The study was considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/016
Report author	[redacted]
Report year	1995
Report title	Study of the ability of the test article glyphosate to induce gene mutations in strains of *Salmonella typhimurium*
Report No	940724
Document No	Not reported
Guidelines followed in study	The study was conducted according to the main criteria of OECD TG 471 (1983)
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	*S. typhimurium* strains TA 98, TA 100, TA 102, TA 1535 and TA 1537 were exposed to glyphosate (purity not reported) in the presence and absence of metabolic activation (liver S9 fraction). Test item concentrations were in the range of 50 – 5000 µg/plate.
Short description of results:	Negative for mutagenicity in bacteria (Ames test) up to limit concentrations of 5000 µg/plate in the presence and absence of metabolic activation.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	Considered invalid based on the information in RAR (2015).
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL.
Category study in AIR5 dossier (L-docs)	Category 4b

1. Information on the study

Data point	CA 5.4.1/018
Report author	[redacted]
Report year	1993
Report title	Mutagenicity – *Salmonella typhimurium* reverse mutation assay (Ames test)
Report No	887-MUT.AMES
Document No	Not reported
Guidelines followed in study	OECD 471 (1983)
Deviations from current test guideline OECD 471 (1997)	The test was conducted in 4 valid strains only. Strains like *S. typhimurium* TA 102 or *E. coli* WP2 enabling the detection of cross-linking mutagens were not included. In addition, the bacterial cell density was not confirmed and no historical control data were provided. Further, acceptance criteria were not specified in the study report.
Previous evaluation	Not accepted in RAR 2015
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Glyphosate technical (batch 046, purity: 96.0 %) was assessed for its ability to cause gene mutations in *S. typhimurium* strains TA 98, TA 100, TA 1535, TA 1537 and TA 1538 in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Based on the results of a preliminary cytotoxicity test, in which no cytotoxicity was noted up to a concentration of 1000 µg/plate, concentrations for the main mutagenicity assay were selected. Two independent plate-incorporation tests (standard plate tests) were performed, using glyphosate concentrations in the range of 1 – 1000 µg/plate. Solvent (distilled water) and appropriate positive controls were included in each experiment. After 48 hours of incubation at 37 °C, the bacterial background lawn was examined and the number of revertant colonies was counted for

each plate.

There was no precipitation up to the highest tested concentration, neither in the presence nor absence of S9 mix. Cytotoxicity, evident as a thinning of the bacterial background lawn, was noted at 1000 µg/plate; however, it was not specified for which strains the observation was made and whether the observation was made in the presence or absence of metabolic activation.

There was no statistically significant, toxicologically relevant increase in the number of revertant colonies observed in any experiment up to the highest concentration, neither in the presence nor in the absence of metabolic activation. Although a statistically significant increase in the number of his$^+$ revertant colonies of about 40 % was observed for strain TA 100 at the top concentration of 1000 µg/plate in the presence of metabolic activation, the increase was less than two-fold compared to the number of revertant colonies induced by the solvent control and therefore considered to be incidental.

The number of revertant colonies induced by the vehicle and appropriate positive controls were in the expected range, demonstrating the functionality of the S9 mix and the sensitivity of the test system.

Under the conditions of the test, glyphosate technical was negative for gene mutation in bacteria in the presence and absence of metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	FSG 03090 h/05, March 1990
Description:	Solid white coloured crystals, odourless
Lot/Batch #:	046
Purity:	96.0 %
Stability of test compound:	The stability of the test item under storage conditions (at room temperature) was guaranteed until the expected expiry date July 1994. The stability of the test item in solvent (vehicle) was not specified.
Solvent (vehicle) used:	Distilled water

2. Control materials:

Negative control:	A negative control was not employed in this study.
Solvent (vehicle) control:	Distilled water
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to table below.

Strain	Metabolic activation	Mutagen	Conc. [µg/plate]
S. typhimurium strains			
TA 100	-S9	Sodium azide	0.5
	+S9	2-Aminofluorene	20.0
TA 1535	-S9	Sodium azide	0.5
	+S9	Sodium azide	0.5
TA 98	+S9	2-Nitrofluorene	2.0
	+S9	2-Aminofluorene	20.0
TA 1537	-S9	9-Aminoacridine	50.0
	+S9	9-Aminoacridine	50.0
TA 1538	-S9	2-Nitrofluorene	5.0
	+S9	2-Aminofluorene	20.0

3. Metabolic activation:

S9 mix was produced from the livers of male Wistar rats, that received a single intraperitoneal injection of Aroclor 1254 at a dose level of 500 mg/kg bw. The livers were prepared five days after the injection. The S9 mix was thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Phosphate buffer (pH 7.4)		
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate, K salt	5	mM
NADP, di-Na salt	4	mM
$MgCl_2$	8	mM
S9	10	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E.coli***			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 1538	✓			Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Plate incorporation test ± S9 mix:	
Concentrations:	*10, 30, 100, 350 and 1000 µg/plate*
Tester strains:	TA 100

Replicates:	*Duplicates*

(b) Mutation assays:

Plate incorporation test ± S9 mix:	
Concentrations:	*1, 3, 10, 100 and 1000 µg/plate*
Tester strains:	TA 98, TA 100, TA 1535, TA 1537 and TA 1538
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: Dec 1992 – Jan 1993
Finalisation date: 30 Apr 1993

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution, vehicle or positive control, an aliquot of 0.1 mL bacterial culture (2 × 10^9 cells/mL) and 0.5 mL S9 mix (in tests with metabolic activation) or 0.5 mL of 0.05 M phosphate buffer (in tests without metabolic activation) were added to 2 mL of soft agar (supplemented with 0.5 mM L-histidine + 0.5 mM D-biotin). After vortexing, the mixture was overlaid onto the surface of minimal bottom agar plates. Each concentration and the controls were tested in triplicates. The cells were incubated at 37 °C for 48 hours. Afterwards, the background bacterial lawn was examined and the bacterial colonies were counted.

3. Cytotoxicity
Toxicity was detected by a

- reduction in the number of spontaneous revertants
- clearing or diminution of the background lawn (= reduced his^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

4. Statistics
For each triplicate plating, an average and standard deviation were calculated. The results were evaluated for statistical analysis; however, it was not specified in the study report which kind of test was used for statistical evaluation.

5. Acceptance criteria
Acceptance criteria were not specified in the study report.

6. Evaluation criteria
A test item was considered as a possible mutagen if the number of revertant colonies was at least two-fold the number of spontaneous revertants observed for the solvent control.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

In the preliminary toxicity test in strain TA 100, a slight thinning of the bacterial background lawn was observed at 350 and 1000 µg/plate in the presence of metabolic activation. The number of revertant colonies was comparable to those of solvent controls.

In the main mutagenicity assay, cytotoxicity, evident as a slight thinning of the bacterial background lawn, was noted at the highest concentration of 1000 µg/plate. However, it was not specified for which strains the observation was made and whether the observation was made in the presence or absence of metabolic activation. Evaluation of the colony shape and size revealed that upon treatment with glyphosate at ≥ 100 µg/plate rough edged colonies were noticed.

C. SOLUBILITY

Precipitation of the test item in minimal basal agar plates was tested in a preliminary precipitation test. There was no precipitation up to the highest concentration of 1000 µg/plate. In the main mutagenicity assay there was as well no precipitation reported at any of the tested concentration, either in the presence or in absence of S9 mix.

D. MUTATION ASSAY

There was no statistically significant, toxicologically relevant increase in the number of revertant colonies observed in any experiment up to the highest concentration, neither in the presence nor in the absence of metabolic activation. A statistically significant increase in the number of his^+ revertant colonies of about 40 % was observed for strain TA 100 at the top concentration of 1000 µg/plate in the presence of metabolic activation, but as the increase was less than two-fold compared to the number of revertant colonies induced by the solvent control, the observation was considered incidental.

The number of revertant colonies induced by the vehicle and appropriate positive controls were in the expected range, demonstrating the functionality of the S9 mix and the sensitivity of the test system.

two-fold compared to the number of revertant colonies induced by the solvent control, the observation was considered incidental

III. CONCLUSION

Based on the experimental results, glyphosate technical did not induce a positive response in the number of revertant colonies in any experiment in any tester strain and was therefore considered negative for mutagenicity in bacteria, both, in the presence and absence of metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 98, TA 100, TA 1535, TA 1537 and TA1538) with and without metabolic activation.

The study was considered as supporting information as it was conducted in 4 valid strains only. Strains like *S. typhimurium* TA102 or *E. coli* WP2 enabling the detection of cross-linking mutagens were not included. Further deviations were of minor degree and considered to not compromise the validity of the study.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/019
Report author	[redacted]
Report year	1993
Report title	Mutagenicity evaluation of glyphosate in *Salmonella* / microsomal reversion assay (Ames test)
Report No	87BMA012-E
Document No	Not reported
Guidelines followed in study	No guideline followed. The test was conducted similarly to OECD 471 (1997).
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	*S. typhimurium* strains TA 98 and TA 100 were exposed to glyphosate isopropylamine salt (SN-750721, batch: not reported, purity: 64.5 %) in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). A single experiment was performed, using the plate-incorporation method and five replicates per condition. Both bacterial strains were exposed to test

	item concentrations in the range of 0.01 – 100 µg/plate in the presence and absence of S9 mix. Untreated, solvent (DMSO) and positive controls were included. After 2 days of incubation at 37 °C, the number of revertant colonies per plate was determined. Evaluation of precipitation and cytotoxicity were not included in the study report.
Short description of results:	When evaluating cytotoxicity based on the number of revertant colonies in comparison to those of negative controls, treatment with glyphosate isopropylamine salt revealed no evidence for cytotoxicity. There was a statistically significant increase in the frequency of revertant colonies noted for strain TA 100 at 0.01, 0.1, 1 and 100 µg/plate in the presence of metabolic activation, however, the increases were less than two-fold of those of untreated / solvent controls and without a clear dose-response relationship, therefore the findings were considered to be incidental. There were no statistically significant increases in the number of revertant colonies observed upon treatment with the test item in strain TA98. The number of revertant colonies obtained by the untreated and solvent controls were in the expected range. The positive controls strongly increased the number of revertant colonies of more than twice than those of untreated controls, demonstrating the functionality of the S9 mix and the sensitivity of the test. Based on the experimental results, glyphosate isopropylamine salt was not mutagenic in the Ames plate incorporation test, neither with nor without metabolic activation.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable as it was conducted in two strains of *S. typhimurium* only (TA 98 and TA 100), with a test material of only 64 % purity. In addition, it was not clear whether the given purity refers to the contents of glyphosate in the formulation or the salt. A single experiment using 5 replicates per conditions was conducted, but a confirmatory experiment was not included. Test item concentrations up to 100 µg/mL were used, but a justification for the selection of concentrations was not given. In addition, no historical control data were provided.
Reasons why the study report is not available for submission

2. Full summary

S. typhimurium strains TA 98, TA 100, TA 1535 and TA 1537 were exposed to glyphosate (batch: 206-JaK-25-1, purity: 98.6 %) in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). A preliminary cytotoxicity test was performed in strain TA98. Cytotoxicity was evident at 1670 and 5000 µg/plate in the absence of S9 mix only, but not in the presence of S9 mix. Based on these observations, the concentrations for the main mutagenicity study were selected. In the main mutation assay two independent experiments were performed, using the plate incorporation (first experiment) and the pre-incubation method (second experiment) with concentrations in the range of 160 - 2500 µg/plate in the absence of S9 mix and concentrations in the range of 310 – 5000 µg/plate in the presence of S9 mix. Negative and positive controls were included in each experiment.

Precipitation of the test item was not reported. Cytotoxicity, evident as a reduction in the mean number of spontaneous revertant colonies, was noted solely for strain TA100 at 2500 µg/plate in the absence of S9 mix in both experiments, at 5000 µg/plate in the first experiment with S9 mix and at 2500 and 5000 µg/plate in the second experiment with S9 mix.

There was no statistically significant increase in the number of his$^+$ revertant colonies observed in any experiment for any strain at any concentration, neither in the presence nor in the absence of S9 mix. The number of revertant colonies induced by the negative and the positive controls were within the expected range, displaying the sensitivity of the test and the functionality of the metabolic activation system.

Based on the results of the present study and under the experimental conditions chosen, glyphosate is not mutagenic in the Ames test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate

Identification: Not specified

Description: White powder

Lot/Batch #: 206-JaK-25-1

Purity: 98.6 %

Stability of test compound:	The stability of tehe test item at storage conditions (at room temperature in the dark) or in solvent (vehicle) was not specified.
Solvent (vehicle) used:	Distilled water

2. Control materials:

Negative control:	Untreated controls were included in each experiment.
Solvent (vehicle) control:	Not examined.
Solvent (vehicle)/final concentration:	0.3 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Conc. [µg/plate]
S. typhimurium strains			
TA 100	-S9	Sodium azide	0.5
	+S9	2-Aminoanthracene	1.25
TA 1535	-S9	Sodium azide	1.0
	+S9	2-Aminoanthracene	1.25
TA 98	-S9	2-Nitrofluorene	0.6
	+S9	2-Aminoanthracene	1.25
TA 1537	-S9	2-Nitrofluorene	0.6
	+S9	2-Aminoanthracene	1.25

3. Metabolic activation:

S9 mix was obtained from livers of Wistar Mol:WIST rats weighing approx. 200 g. The animals received a single intraperitoneal injection of Aroclor 1254 at a dose of 500 mg/kg bw. The livers were prepared 5 days after treatment. The S9 mix was thawed prior to each experiment and co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	8	mM
S9 Standard plate test (plate-incorporation) Pre-incubation test	 4 7	 % (v/v) % (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E. coli***			
TA 98	✓	WP2 uvrA		deep rough character (rfa)	✓
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	✓
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	✓
TA 1537	✓				
TA 1538				Histidine auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

(a) Preliminary cytotoxicity assay:

Plate incorporation test ± S9 mix:	
Concentrations:	*560, 1670 and 5000 µg/plate*
Tester strains:	TA 98
Replicates:	*Triplicates*

(b) Mutation assays:

Plate incorporation test ± S9 mix:	
Concentrations: -S9 mix +S9 mix	*160, 310, 630, 1300 and 2500 µg/plate* *310, 630, 1300, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98 and TA 100
Replicates:	*Triplicates*
Pre-incubation test ± S9 mix:	
Concentrations: -S9 mix +S9 mix	*160, 310, 630, 1300 and 2500 µg/plate* *310, 630, 1300, 2500 and 5000 µg/plate*
Tester strains:	TA 1535, TA 1537, TA 98 and TA 100
Replicates:	*Triplicates*

B: STUDY DESIGN AND METHODS

1. Finalisation date: 10 Sep 1991

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.3 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation only) were added to 2 mL of molten top agar (supplemented with 0.5 mM L-histidine + 0.5 mM biotin). After whirl mixing, the mixture was spread on a Vogel-Bonner agar plate and incubated for 48 – 72 hours at 37 °C. Each concentration and the controls were tested in triplicates. Following incubation, the bacterial background lawn was examined and the number of his^+ revertant colonies was counted.

3. Pre-incubation test (PIT):
0.3 mL of test solution or vehicle/positive control, 0.1 mL pre-cultured bacterial suspension and 0.5 mL of S9 mix (in tests with metabolic activation only) were mixed and pre-incubated in a test tube for 30 minutes at 37 °C under gentle shaking. After pre-incubation, 2.0 mL of top agar was added, the mixture

was whirl-mixed and spread on a Vogel-Bonner agar plate. After an incubation period of 48 – 72 hours at 37 °C the bacterial background lawn was examined and the number of his^+ revertant colonies was counted.

4. Cytotoxicity

Toxicity was detected by a

- reduction in the number of spontaneous revertants
- clearing or diminution of the background lawn (= reduced his^- or trp^- background growth)

and recorded for all test groups both with and without S9 mix in all experiments.

5. Statistics

Statistical analysis of the negative control versus test data was performed using the Analysis of Variance method. Statistical analysis of the negative versus positive control data was performed using the Student's t-test.

6. Acceptance criteria

Acceptance criteria were not specified in the study report.

7. Evaluation criteria

Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations have not been performed in the study, as not required by the test guideline.

B. CYTOTOXICITY

In the preliminary toxicity test in strain TA98, cytotoxicity was observed in the absence of S9 mix at 1670 and 5000 µg/plate. There was no cytotoxicity noted in the presence of S9 mix. Based on these findings, the top concentrations for the main mutagenicity test were chosen to be 2500 µg/plate without S9 mix and 5000 µg/plate with S9 mix.

In the main mutagenicity assay, no clear depression of the bacterial background growth was observed at any concentration with or without S9 mix. However, cytotoxicity evident as a reduction in the mean number of spontaneous revertants was observed for strain TA100 in both experiments at 2500 µg/plate in the absence of S9 mix, at 5000 µg/plate in the first experiment (standard plate test, plate incorporation method) with S9 mix and at 2500 and 5000 µg/plate in the second experiment (pre-incubation test) with S9 mix. There was no relevant cytotoxicity observed in any other tester strain in the presence or absence of metabolic activation.

C. SOLUBILITY

Precipitation was not evaluated in the study report.

D. MUTATION ASSAY

There was no statistically significant increase in the number of his^+ revertant colonies observed in any experiment for any strain at any concentration, neither in the presence nor in the absence of S9 mix. The number of revertant colonies induced by the negative and the positive controls were within the expected range, displaying the sensitivity of the test and the functionality of the metabolic activation system.

Cytotoxicity observed

III. CONCLUSION:

Based on the results of the present study and under the experimental conditions of the test, glyphosate was found to be non-mutagenic in the Ames test in the presence and absence of metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535 and TA 1537) with and without metabolic activation.

The study was performed under GLP conditions and according to OECD guideline 471 (1983). When compared to the currently valid OECD guideline 471 (1997), some deviations became evident. The test was conducted with 4 valid strains only, strains like *S. typhimurium* TA 102 or *E. coli* WP2 enabling the detection of cross linking agents were not included. Further deviations to OECD guideline 471 (1997) were considered to be of minor degree and to not compromise the validity of the study. The study was considered to provide supporting information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/021
Report author	[redacted]
Report year	1990
Report title	Agrichem Glyphosate Active: Reverse Mutation Assay "Ames Test" Using *Salmonella Typhimurium*
Report No	300/1
Document No	Not reported
Guidelines followed in study	OECD 471 (1983), EEC Commission Directive 84/449/EEC (1984)
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	An Ames test was conducted with glyphosate active (batch: 0190A, purity: not reported) in *S. typhimurium* strains TA 98, TA 100, TA 1535, TA 1537 and TA 1538 in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Based on the results of a preliminary toxicity test in strain TA 100, in which no cytotoxicity was evident up to 5000 µg/plate, concentrations for the main mutagenicity test were selected. In the main mutagenicity study, two independent experiments were performed using the plate incorporation method (standard plate test). Triplicate cultures were exposed to test item concentrations in the range of 8 – 5000 µ/plate (first experiment) and 312.5 – 5000 µg/plate (second experiment) with and without S9 mix. Untreated, vehicle (sterile distilled water) and appropriate positive controls were included in each experiment.
Short description of results:	Precipitation of the test material in culture medium was not observed, neither in the presence nor absence of S9 mix. Cytotoxicity, evident as a reduction of the bacterial background lawn, was not observed in any experiment. However, there was a concentration-related reduction in the frequency of revertant colonies observed for most strains. In the first experiment, the frequency of revertant colonies was ≥ 50 % reduced at ≥ 1000 µg/plate for tester strain TA 1538 in the absence of metabolic activation and for tester strains TA 98, TA 100 and TA 1535 at 5000 µg/plate in the absence of metabolic activation. In the second experiment, in the presence of S9 mix, there was a ≥ 50 % reduction in the number of revertant colonies noted for strain TA1537 at ≥ 1250 µg/plate, for strain TA 100 at ≥ 2500 µg/plate and for strain TA 1535 at 5000 µg/plate. There was no statistically significant increase in the number of revertant colonies observed in any experiment for any strain at any concentration, neither in the presence nor in the absence of metabolic activation. The number of revertant colonies induced by the vehicle control was found to be in the expected range. A strong increase in the number of revertant colonies was observed for the

	appropriate positive controls, demonstrating the functionality of the metabolic activation system and the validity of the test. Under the conditions of the test, glyphosate active was considered negative for gene mutation in bacteria (Ames test) in the presence and absence of metabolic activation.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable due to large number of deviations to current guidelines. The test was conducted in 4 valid strains only. Strains like *S. typhimurium* TA102 or *E. coli* WP2 enabling the detection of cross-linking mutagens were not included. The purity of the test material was not reported. In addition, 2-aminoanthracene was used as sole positive control substance in the presence of S9 mix and historical control data were not provided.
Reasons why the study report is not available for submission	
Category study in AIR5 dossier (L-docs)	Category 3b

1. Information on the study

Data point:	CA 5.4.1/022
Report author	[redacted]
Report year	1986
Report title	Report on mutagenicity tests with glyphosate (technical) of Excel Industries Limited, Bombay. Ames bacterial test.
Report No	Not reported
Document No	Not reported
Guidelines followed in study	No guideline followed. The study was conducted according to the main criteria of OECD 471 (1983).
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate technical (batch: not reported, purity: not reported) was evaluated for its potential to induce gene mutations in bacteria in an Ames test conducted with in *S. typhimurium* strains TA 98, TA 100, TA 1535 and TA 1537 and *E. coli* strain WP2 uvrA. A single experiment was performed according to the pre-incubation method. Triplicate cultures were exposed to the test item, negative and positive controls in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Three concentrations of glyphosate technical were tested, covering a concentration range of 10 – 1000 µg/plate. After at least 48 hours of incubation at 37 °C, the number of revertant colonies were counted for each plate.
Short description of results:	Evaluation of precipitation and cytotoxicity were not included in the study report. When evaluating cytotoxicity based on the number of revertant colonies in comparison to those of negative controls, treatment with glyphosate technical revealed no evidence for cytotoxicity. There was no statistically significant increase in the number of revertant colonies observed for any tester strain up to the highest

	tested concentration, neither in the presence nor in the absence of metabolic activation. For all conditions, the number of revertant colonies was comparable to those of negative controls. Treatment with the positive controls revealed a strong increase in the number of revertant colonies, demonstrating the functionality of the S9 mix and the sensitivity of the bacteria strains to respond to mutagenic agents. Based on the experimental results, glyphosate technical did not induce gene mutations in bacteria, neither in the presence nor in the absence of metabolic activation.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable due to a large number of guideline deviations. No details on the experimental performance were given and information on the test item regarding purity, batch no. and solvent were not reported. A single experiment was performed, which was not repeated in a confirmatory experiment. Further, only three concentrations were tested with an interval of factor 10 and a maximum concentration of 1000 µg/plate. There was no justification for the highest concentration given. In addition, positive controls were not included for all strains, but only for strains TA98, TA1537 and WP2uvrA. Although negative controls were included in the experiment, it was not clear whether these controls represented untreated controls or solvent controls. Further, no historical control data were provided.
Reasons why the study report is not available for submission	
Category study in AIR5 dossier (L-docs)	Category 3b

1. Information on the study

Data point:	CA 5.4.1/023
Report author	[redacted]
Report year	1981
Report title	Mutagenic testing of glyphosate active principle and of glyphosate product: Ames- and host mediated test
Report No	Not reported
Document No	Not reported
Guidelines followed in study	No guideline followed.
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate active principle (batch and purity not reported) was assessed for gene mutation in bacteria (Ames test) in *S. typhimurium* strains his-G46, TA 1537 and TA 1538. A single experiment using triplicate cultures was performed (spot test). Glyphosate was dissolved in DMSO and concentrations in the range of 1 – 1000 µg/plate were put into the central point of the agar plates. Solvent (DMSO) and positive controls (streptozotocin, 2.5 µg/plate and ICR 191, 10 µg/plate) were included. After 48 hours incubation at 37 °C, the number of revertant colonies per plate was determined.

Short description of results:	Based on the experimental findings, glyphosate active principal did not induce the frequency of revertant colonies in strains his-G46, TA 1537 and TA 1538. The positive controls streptozotocin and ICR 191 produced a marked increase in the number of revertant colonies.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable. The description of material and methods was so poor that an evaluation of the reliability of the results obtained (the test substance was considered non-mutagenic) was not possible. Further, the test was conducted in two valid strains only and only a single experiment was performed. The experimental procedure is not in line with current standard methods.
Reasons why the study report is not available for submission

1. Information on the study

Data point	CA 5.4.1/024
Report author	[redacted]
Report year	1978
Report title	The report of mutagenic study with bacteria for CP 67573
Report No	ET-78-241
Document No	Not reported
Guidelines followed in study	No guideline followed, the study was conducted similarly to OECD 471 (1983)
Deviations from current test guideline OECD 471 (1997)	A single experiment using duplicate plating was performed but a justification for the missing confirmatory experiment or the missing third replicate was not provided. Instead of *E. coli* strain WP2 uvrA, strain WP2 hcr was used. 2-Aminoanthracene was used as sole positive control substance in the presence of S9 mix. Historical control data were not reported. Evaluation of cytotoxicity and precipitation were not reported, but concentrations were tested up to limit concentrations.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, not conducted under GLP/ Officially recognised testing facilities. When the study was performed, GLP was not compulsory.
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate (CP67573, batch: XHJ-46, purity: 98.4 %) was tested in an Ames test conducted with *S. typhimurium* strains TA 98, TA 100, TA 1535, TA1537 and TA 1538, and *E. coli* strain WP2 hcr in the presence and absence of metabolic activation (Aroclor-induced rat liver S9 fraction). A single experiment (plate-incorporation method) was performed, using test item concentrations in the range of 10 – 5000 µg/plate. Solvent (water) and appropriate positive controls were included. After incubation at 37 °C for 48 hours, the number of bacterial colonies (his^+ or trp^+ revertants) were counted.

Evaluation of precipitation and cytotoxicity were not provided in the study report. Cytotoxicity was re-evaluated by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding vehicle control. Based on these criteria, cytotoxicity was noted at 5000 µg/plate in strains WP2 hcr, TA 100, TA 1537 and TA 98 in the absence of S9 mix and at 5000 µg/plate in strain TA 100 in the presence of S9 mix.

There was no significant increase in the number of his^+ or trp^+ revertants observed in any tester strain at any concentration when compared to solvent controls, neither in the presence nor in the absence of metabolic activation. In contrast, a strong increase in reverse mutations was observed for all positive control compounds in all tester strains, demonstrating the sensitivity of the test and the functionality of the S9 fraction.

Based on the experimental results of the present study, glyphosate is not mutagenic in the Ames plate incorporation test with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate

Identification:	CP67573
Description:	Not provided
Lot/Batch #:	XHJ-46
Purity:	98.4 %
Stability of test compound:	The stability of the test item at storage conditions or in solvent (vehicle) was not specified.
Solvent (vehicle) used:	Water

2. Control materials:

Negative control:	Not examined
Solvent (vehicle) control:	Water
Solvent (vehicle)/final concentration:	0.1 mL per plate.
Positive controls:	Please refer to the table below.

Strain	Metabolic activation	Mutagen	Conc. [µg/plate]
S. typhimurium strains			
TA 100	-S9	2-(2-furyl)-3-(5-nitro-2-furyl) acrylamide (AF-2)	0.05
	+S9	2-Aminoanthracene	10.0
TA 1535	-S9	β-Propiolactone	50.0
	+S9	2-Aminoanthracene	10.0
TA 98	-S9	2-(2-furyl)-3-(5-nitro-2-furyl) acrylamide (AF-2)	0.1
	+S9	2-Aminoanthracene	10.0
TA 1537	-S9	9-Aminoacridine	200.0
	+S9	2-Aminoanthracene	10.0
TA 1538	-S9	2-Nitrofluorene	50.0
	+S9	2-Aminoanthracene	10.0
E. coli strain			
WP2 hcr	-S9	2-(2-furyl)-3-(5-nitro-2-furyl) acrylamide (AF-2)	0.25
	+S9	2-Aminoanthracene	10.0

3. Metabolic activation:

S9 mix was obtained from livers of 11 weeks old male Sprague-Dawley rats with an average body weight of approx. 364 g. The animals received a single intraperitoneal injection of 500 mg/kg bw Aroclor 1254. The livers were prepared five days after treatment. Co-factor was immediately added to prepare S9 mix containing the following components:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
$NADP^+$	4	mM
$MgCl_2$	8	mM
S9	33	% (v/v)

4. Test organisms:

Tester strains				Bacteria batch checked for	
S. typhimurium		***E. coli***			
TA 98	✓	WP2 hcr	✓	deep rough character (rfa)	Not specified
TA 100	✓	WP2 uvrA (pKM101)		ampicillin resistance (R factor plasmid)	Not specified
TA 1535	✓			UV-light sensitivity (absence of uvrB and uvrA genes in *S. typhimurium* and *E. coli* strains, respectively)	Not specified
TA 1537	✓				
TA 1538	✓			Histidine and tryptophan auxotrophy (automatically via the spontaneous rate)	✓

5. Test concentrations:

Plate incorporation test ± S9 mix:	
Concentrations:	*10, 50, 100, 500, 1000 and 5000 µg/plate*
Tester strains:	TA 1538, TA 1535, TA 1537, TA 98, TA 100 and WP2 hcr

Replicates:		*Duplicates in a single experiment*	

B: STUDY DESIGN AND METHODS

1. Finalisation date: 20 Jul 1978

2. Standard plate test (plate-incorporation test, SPT):
An aliquot of 0.1 mL test solution or vehicle/positive control, an aliquot of 0.1 mL fresh bacterial culture and 0.5 mL S9 mix (in tests with metabolic activation only) were added to 2 mL of molten agar (supplemented with 0.5 mM L-histidine + 0.5 mM biotin or 0.5 mM L-tryptophan) and spread onto minimal agar plates with modified Vogel-Bonner E medium. Each concentration and the controls were tested in duplicates. After incubation at 37 °C for 48 hours, the number of bacterial colonies (his^+ or trp^+ revertants) were counted.

3. Cytotoxicity
Criteria for the evaluation of cytotoxicity have not been specified in the study report. Cytotoxicity was indicated only in case no revertant colonies were detected on a plate. Cytotoxicity was evaluated retrospectively by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding vehicle control. A cytotoxic effect was evident when the number of spontaneous revertant colonies was 50 % or less of the value in corresponding vehicle controls.

4. Statistics
Results were judged without statistical analysis.

5. Acceptance criteria
Acceptance criteria were not specified in the study report.

6. Evaluation criteria
Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
Although cytotoxicity was noted in the mutagenicity study, detailed observations on cytotoxicity in individual strains were not reported. Cytotoxicity evident as no bacterial background lawn at all was observed at 5000 µg/plate in *E. coli* strain WP2 hcr in the absence of metabolic activation. Cytotoxicity was re-evaluated by comparing the presented mean numbers of revertant colonies induced by the test item to the mean number of spontaneous revertants observed in the corresponding vehicle control. A cytotoxic effect was evident when the number of spontaneous revertant colonies was 50 % or less of the value in corresponding vehicle controls. Based on these criteria, cytotoxicity was noted at 5000 µg/plate in strains WP2 hcr, TA 100, TA 1537 and TA 98 in the absence of S9 mix and at 5000 µg/plate in strain TA 100 in the presence of S9 mix.

C. SOLUBILITY
Evaluation of precipitation was not reported.

D. MUTATION ASSAY

There was no significant increase in the number of his$^+$ or trp$^+$ revertants observed in any tester strain at any concentration when compared to solvent controls, neither in the presence nor in the absence of metabolic activation.

In contrast, a strong increase in reverse mutations was observed for all positive control compounds in all tester strains, demonstrating the sensitivity of the test and the functionality of the S9 fraction.

[X] = The table shows mean values of duplicate plates which were be lately calculated based on the raw data given in study report.

[§] Information on respective positive control is reported in Material and Method section I.A.2

Toxicity, no revertant colonies on the plate; T: cytotoxicity, re-evaluation as described in Material and Method section.

III. CONCLUSION:

In conclusion, based on the results of the present study and under the experimental conditions chosen, glyphosate is not mutagenic in bacteria (Ames test) with and without metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for gene mutation in bacteria (*S. typhimurium* TA 100, TA 98, TA 1535, TA 1537 and TA 1538 and *E. coli* WP2 hcr) with and without metabolic activation.

The study was performed similar to OECD guideline 471 (1997) but not GLP-compliant. It was considered supplementary, as a number of deviations to the currently valid guideline became evident. A single experiment using duplicate plating was performed but a justification for the missing confirmatory experiment or the missing third replicate was not provided. Instead of *E. coli* strain WP2 uvrA, strain WP2 hcr was used. In addition, 2-aminoanthracene was used as sole positive control

substance in the presence of S9 mix and historical control data were not reported. Evaluation of cytotoxicity and precipitation were not reported, but concentrations were tested up to limit concentrations. In addition, no acceptance or evaluation criteria were specified.

Assessment and conclusion by RMS:

Cytogenicity and gene mutation in mammalian cells

Five *in vitro* chromosome aberration tests have been conducted with glyphosate (Table 5.4.1-). Study CA 5.4.1/029 is considered invalid and studies CA 5.4.1/025 and CA 5.4.1/028 are supportive only due to deficiencies identified in comparison to OECD 473 (2016). However, data from two valid (reliable with restrictions) studies are available that have been conducted with either Chinese hamster lung cells or human lymphocytes. Although some minor deficiencies were identified when the studies are compared to OECD 473 (2016), these deviations are considered to not affect the validity or integrity of the data. Overall, there are sufficient, reliable data to allow thorough evaluation of this data requirement. There is no evidence that glyphosate causes chromosome aberrations or polyploidy in mammalian cells.

Two mouse lymphoma assays (MLA) and one HPRT assay have been conducted with glyphosate (Table 5.4.1-31). These studies are all considered to be valid (reliable with restrictions). Although some minor deficiencies were identified when the studies are compared to either OECD 490 (2016) or OECD 476 (2016), as applicable, these deviations are considered to not affect the validity or integrity of the data. Overall, there are sufficient, reliable data to allow thorough evaluation of this data requirement. There is no evidence that glyphosate causes gene mutations in mammalian cells.

Table 5.4.1-34: Summary of *in vitro* genotoxicity testing with glyphosate acid: Cytogenicity and gene mutation in mammalian cells

Only dose levels listed which were investigated for chromosome aberrations (Chromosome aberrations test) or for mutagenicity (Mouse lymphoma assay and HGPRT assay)
HGPRT: Hypoxanthine guanine phoyphoribosyltransferase
§ Inconsistencies in study report on the duration of exposure. It was assumed that the cells were exposed for 3 hours, followed by 18 hours of incubation (including 2 hours of treatment with colchicine) and chromosome preparation 21 hours after start of exposure.

1. Information on the study

Data point	CA 5.4.1/025
Report author	[redacted]
Report year	1998
Report title	Glyphosate Acid: *In Vitro* Cytogenetic Assay In Human Lymphocytes
Report No	CTL/P/6050
Document No	Not reported
Guidelines followed in study	OECD 473 (1983), Commission Directive 67/548/EEC (1992), Commission Directive 92/69/EEC B.10 (1992)
Deviations from current test guideline OECD 473 (2016)	Only 200 instead of 300 cells in metaphase were evaluated per condition for test item treated cultures and only 25 metaphases were evaluated for the corresponding positive control. There are no information on numerical chromosome aberrations given (polyploidy index could not be determined). Data on the laboratory's historical control range were not provided. Positive controls were only included for the 20 hour sampling time point. A short-term exposure in the absence of metabolic activation as recommended by OECD 473 (2016) was not included. Although pH changes were observed, there was no attempt to buffer the pH change. Acceptance criteria were not specified and evaluation criteria were inconsistent with test guideline OECD 473 (2016).
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate acid (batch: P24, purity: 95.6 %) was evaluated for its clastogenic potential *in vitro* in human lymphocytes. Cells from two different donors were treated in the presence and absence of metabolic activation (phenobarbital and β-naphthoflavone-induced rat liver S9 fraction). Duplicate cultures were exposed to test item concentrations in the range of 50 to 2000 µg/mL. Due to reductions of the pH in the culture medium at a test item concentration of 1250 µg/mL (-0.57 units) and above, the maximum concentration for the cytogenicity assay was 1250 µg/mL. Cultures treated with glyphosate acid at 100, 750 and 1250 µg/mL were selected for chromosomal aberration analysis along with the appropriate solvent (culture medium) and positive control cultures (mitomycin C without S9 mix and cyclophosphamide with S9 mix).

The cells from the first donor (male) were exposed for 20 hours in the absence of S9 mix and for 3 hours in the presence of S9 mix followed by 17 hours of incubation in test item-free medium. Sampling for chromosome preparations were made 20 hours after start of exposure in the presence and absence of S9 mix, corresponding to 68 hours after cell culture establishment. The cells from the second donor (female) were exposed for 20 and 44 hours in the absence of S9 mix, for 3 hours in the presence of S9 mix followed by 17 hours of incubation in test item-free medium and for 3 hours in the presence of metabolic activation followed by 41 hours of incubation in test item-free medium. Cells exposed for 3 hours in the presence of S9 mix were sampled 20 and 44 hours after start of exposure (68 and 92 hours after cell culture establishment). Cells exposed for 20 and 44 hours in the absence of S9 mix were sampled immediately following exposure (68 and 92 hours after cell culture establishment, respectively).

A total of 200 metaphase cells per condition were scored for structural chromosome aberrations and cytotoxicity was assessed as mitotic index (MI) and evaluated for 1000 cells per culture.

Cytotoxicity was evident at 1250 µg/mL in the absence of metabolic activation only, at the 20 hour sampling time point. In both donors, the mean mitotic activity was slightly reduced (-37 % and -33 %, respectively). There was no cytotoxicity at the 44 hour sampling time point or in the presence of metabolic activation.

Treatment with glyphosate acid did not induce a statistically or biologically significant increase in the percentage of aberrant metaphases in none of the experiments, neither in the presence nor in the absence of S9 mix. Frequencies of aberrant metaphases of solvent control cultures remained within the range of the laboratory's historical control data. The positive controls showed a clear clastogenic effect and markedly induced the number of aberrant metaphases, demonstrating the sensitivity of the test and the functionality of the S9 mix.

Based on the results of the present study, glyphosate acid is not clastogenic to cultured human lymphocytes with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate acid

Identification:	Y04707/034
Description:	White solid
Lot/Batch #:	P24
Purity:	95.6 %
Stability of test compound:	From information supplied by the sponsor, the test substance was stable during the period of the study.
Solvent (vehicle) used:	Culture medium

2. Control Materials:

Negative control:	The negative control corresponded to the solvent control.
Solvent (vehicle) control:	Culture medium (RPMI-1640)
Positive control:	-S9 mix: Mitomycin C (MCC): 0.2 µg/mL
	+S9 mix: Cyclophosphamide (CP): 50 µg/mL

3. Metabolic activation:

S9 mix was obtained from the livers of male Sprague-Dawley rats. The animals received intraperitoneal injections of phenobarbital (80 mg/kg bw) and β-naphthoflavone (100 mg/kg bw/day) for three consecutive days. The animals were sacrificed on the day following the third dose. The S9 mix was prepared on the day of culture treatment by mixing S9 fraction and co-factor solution as a 1:1 mixture.

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	150	mM
KCl	49.5	mM
NADPH-generating system		
Glucose 6-phosphate	7.5	mM
NADP Na salt	6	mM
$MgCl_2$	8	mM
S9	25	% (v/v)

4. Test organism:

Human blood samples were obtained by venepuncture in lithium heparin tubes from healthy, non-smoking donors, one male (donor 1) and one female (donor 2). Both donors had a previously established

low incidence of chromosomal aberrations in their peripheral blood lymphocytes.

5. Cell culture:

Medium: RPMI-1640 medium (Dutch modification) supplemented with approx. 10 % foetal bovine serum (FBS), 1.0 IU/mL heparin, 100 IU/mL penicillin and 100 µg/mL streptomycin.

Incubation: At 37 °C

Cell culture establishment prior to exposure: 0.5 mL of whole blood was added to 9.0 mL of culture medium and 5 % (v/v) phytohaemagglutinin. Cells were maintained at approximately 37 °C for 48 hours with gentle daily mixing where possible.

6. Test concentrations and number of replicates:

Exp.	Donor	Metabolic activation	Duration of exposure	Concentrations	Replicates
1	male	(- S9 mix)	20 h	50, 100*, 250, 500, 750*, 1000, 1250*, 1500 and 2000 µg/mL	Duplicate
1	male	(+ S9 mix)	3 h[$]	50, 100*, 250, 500, 750*, 1000, 1250*, 1500 and 2000 µg/mL	Duplicate
2	female	(- S9 mix)	20 h	50, 100*, 250, 500, 750*, 1000, 1250*, 1500 and 2000 µg/mL	Duplicate
2	female	(+ S9 mix)	3 h[$]	50, 100*, 250, 500, 750*, 1000, 1250*, 1500 and 2000 µg/mL	Duplicate
2	female	(- S9 mix)	44 h[#]	50, 100, 250, 500, 750, 1000, 1250*, 1500 and 2000 µg/mL	Duplicate
2	female	(+ S9 mix)	3 h[§]	50, 100, 250, 500, 750, 1000, 1250*, 1500 and 2000 µg/mL	Duplicate

[#] The culture medium was changed after 68 h of culture initiation (= 20 hours after start of treatment)

[$] The cells were exposed for 3 hours, followed by an incubation period of 17 hours (sampling time: 20 hours after exposure

[§] The cells were exposed for 3 hours, followed by an incubation period of 41 hours (sampling time: 44 hours after exposure)

* Dose levels selected for assessment of chromosome aberration

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 03 Jul 1995 – 26 Aug 1998
Finalisation date: 29 Oct 1998

2. Preliminary cytotoxicity test:

A preliminary cytotoxicity test was not performed in this study.

3. Main cytogenicity test:

Treatment: Approximately 48 hours after cell culture establishment, 8 mL aliquots of test item formulations in medium were administered to each culture. Duplicate cultures per condition were exposed to concentrations in the range of 50 to 2000 µg/mL.

The cells from the first donor (male) were treated for 20 hours in the absence of S9 mix and for 3 hours in the presence of S9 mix, followed by 17 hours of

incubation in test item-free medium. Sampling for chromosome preparations were made 20 hours after start of exposure in the presence and absence of S9 mix, corresponding to 68 hours after cell culture establishment
The cells from the second donor (female) were exposed for 20 and 44 hours in the absence of S9 mix, for 3 hours in the presence of S9 mix followed by 17 hours of incubation in test item-free medium and for 3 hours in the presence of metabolic activation followed by 41 hours of incubation in test item-free medium. Cells exposed for 3 hours in the presence of S9 mix were sampled 20 and 44 hours after start of exposure (68 and 92 hours after cell culture establishment, corresponding to 3-hour exposure followed by 17 and 41 hours of test item-free exposure). Cells exposed for 20 and 44 hours in the absence of S9 mix were sampled immediately following exposure (68 and 92 hours after cell culture establishment, respectively).
In cell cultures of the latter sampling time point (44 hours after start of exposure, 92 hours after cell culture establishment) a medium change was performed after 20 hours of exposure.
Corresponding solvent (culture medium) and positive controls (MMC without S9 mix and CP with S9 mix) were included for the 3 hours exposure period with S9 mix and for the 20 hours exposure period without S9 mix.

Spindle inhibition: Colcemid (0.4 µg/mL) was added to the cultures two hours before harvest.

Cell harvest: The cells were harvested by centrifugation and the pellets were re-suspended in 0.075 M potassium chloride solution at room temperature for approximately 10 minutes. Afterwards, the cells were centrifuged again and fixed in methanol:glacial acetic acid fixative (3:1, v/v). the fixative was removed following centrifugation and replaced with freshly prepared fixative. The process was repeated at least twice prior to slide preparation.

Slide preparation: Fixed cells were dropped on clean, moist labelled microscope slides. The slides were air-dried, stained in filtered Giemsa stain (10 % Gurr's R66) for 7 minutes, rinsed with water, air-dried again and mounted with coverslips in DPX.

Metaphase analysis The slides were coded prior to analysis and 100 cells in metaphase (200 metaphases per condition in total), where possible, were analysed from each culture for the incidence of structural chromosomal damage. Recording of chromosomal aberrations was performed according to Scott et al. (1990), including the type and frequency of observed aberrations. Chromosome gaps, breaks and minutes, multiple damage, interchanges and e.g. re-arrangements were noted. For each condition, frequencies of aberrant metaphases were calculated including and excluding gap-type aberrations.

Cytotoxicity: Mitotic indices were determined by examining 1000 lymphocytes per culture and calculating the percentage of cells in metaphase.

4. Statistics

The statistically evaluation of the percentage of metaphases showing aberrations (excluding cells with only gap-type aberrations) was performed using the (one-sided) Fisher's Exact Probability Test. Data from each treatment group in the presence and absence of S9 mix was compared to the respective solvent control value.

5. Acceptance criteria

Acceptance criteria were not specified in the study report.

6. Evaluation criteria

A test substance was judged negative if the following criteria were met:

- There was no statistically significant increase in the percentage of aberrant cells at any concentration above concurrent solvent control values.
- A statistically significant increase in the percentage of aberrant cells above concurrent solvent controls fell into the range of the laboratories historical control data.

A test substance was judged positive if there was an increase in the percentage of aberrant cells, at least at one concentration, which is substantially greater than the laboratory's historical solvent control values.

II. RESULTS AND DISCUSSION

A. ANALYTCAL DETERMINATIONS

Analytical determinations of the test substance in the solvent were not performed, as not required by the test guideline.

B. CYTOTOXICITY

Small reductions in the mean mitotic activity when compared to the respective solvent control were noted at 1250 µg/mL for the 20-hour sampling time point (68 hours after cell culture establishment) in the absence of metabolic activation only. At 1250 µg/mL, which was the highest concentration selected for chromosomal aberration analysis, in the absence of S9 mix, the mitotic indices were reduced by -37 % and -33 % for cultures of donors 1 and 2, respectively. There was no cytotoxicity observed at the 44 hour sampling time point (92 hours after cell culture establishment) in the absence of metabolic activation. In addition, there were no significant reductions in mitotic activity in all approaches in the presence of S9 mix.

Treatment with glyphosate acid caused a concentration-related reduction in the pH of the culture medium. The highest concentration of glyphosate acid selected for chromosomal aberration analysis was 1250 µg/mL, in which the pH of the culture medium was reduced by 0.57 units. Cultures treated with concentrations of glyphosate acid higher than 1250 µg/mL were therefore considered not to be suitable for chromosomal aberration analysis.

C. SOLUBILITY

Evaluation of test item precipitation was not provided in the study report. However, there was a concentration-related reduction in the pH of the culture medium in glyphosate acid treated cultures. Treatment of the culture medium with test item concentrations up to 2000 µg/mL had no significant effect on osmolality.

D. CYTOGENICITY

There was no statistically or biologically significant increase in the percentage of aberrant metaphases observed in none of the experiments, neither in the presence nor in the absence of S9 mix. Frequencies of aberrant metaphases of solvent control cultures remained within the range of the laboratory's historical control data. The positive controls mitomycin C and cyclophosphamide showed a clear clastogenic effect and markedly induced the number of aberrant metaphases, demonstrating the sensitivity of the test and the functionality of the S9 mix.

III. CONCLUSION:

In conclusion, glyphosate acid was not clastogenic to human lymphocytes *in vitro*, either in the presence or absence of metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Negative for cytogenicity in peripheral human lymphocytes with and without metabolic activation.
The study was performed under GLP conditions and in accordance with OECD guideline 473 (1983). When compared to the currently valid guideline OECD 473 (2016), a number of deviations were noted. Only 200 metaphase cells were investigated and numerical chromosome aberrations were obviously not included in the evaluation. A short-term exposure in the absence of S9 mix was not included in the experiment and positive controls were only included for the 20-hour sampling time point.

Further deviations were considered to be of minor degree and to not compromise the outcome of the study. The study is considered to provide supporting information

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/026
Report author	[redacted]
Report year	1996
Report title	Technical glyphosate: Chromosome aberration test in CHL cells *in vitro*
Report No	434/015
Document No	Not reported
Guidelines followed in study	Not specified, experimental procedure similar to OECD 473 (2016)
Deviations from current test guideline OECD 473 (2016)	Only 200 cells in metaphase were evaluated, whereas the evaluation of 300 metaphases is recommended according to OECD guideline 473 (2016). No historical control data from the testing laboratory provided, but values were compared to published control values. Although pH changes were observed and the maximum concentration was limited based on pH changes, there was no attempt to buffer the pH change. Cytotoxicity was measured by counting the number of cells at the end of the culture period relative to control, whereas OECD 473 (2016) recommends to measure the relative population doubling or the relative increase in cell count. Acceptance and evaluation criteria were inconsistent with test guideline OECD 473 (2016).
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: H95D161A, purity: 95.3 %) was tested for clastogenic effects *in vitro* in Chinese hamster lung (CHL) cells in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Test item concentrations were selected based on the results of a preliminary cytotoxicity test. Due to reductions of the pH in culture medium at test item concentrations > 1250 µg/mL, the maximum concentration for the main mutagenicity assay was 1250 µg/mL. Duplicate cultures were exposed to the test substance at concentrations of 39, 78.1, 156.25, 312.5, 625 and 1250 µg/mL for 24 and 48 hours in the absence of metabolic activation and for 6 hours in the presence and absence of metabolic activation. Concurrent vehicle (culture medium) and positive controls (mitomycin C without S9 mix and cyclophosphamide with S9 mix) were included for experiments with and without metabolic activation, respectively.

The cells were sampled after 24 and 48 hours of exposure without S9 mix and 24 h after start of exposure for the 6 hour exposure with and without S9 mix. A total of 200 metaphases per condition were scored for structural and numerical chromosome aberrations. Cytotoxicity was assessed as percentage of growth inhibition when compared to solvent controls.

There was no cytotoxicity observed at any concentration of any sampling time point, neither in the presence, nor in the absence of metabolic activation.

There was no statistically significant increase in the frequency of cells with chromosomal aberrations at any dose level in any treatment group. In addition, the test material did not induce a significant increase in the numbers of polyploid metaphase cells in any of the tested conditions with or without S9 mix. Frequencies of aberrant metaphases of vehicle control cultures were within the expected range. The positive controls gave highly significant increases in the frequency of aberrant metaphase cells, indicating that the metabolic activation system was satisfactory and that the test method itself was operating as expected.

Based on the results of the present study, there is no evidence for induction of chromosome aberrations by glyphosate technical with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Technical Glyphosate

Identification:	Not specified
Description:	White powder
Lot/Batch #:	H95D161A
Purity:	95.3 %
Stability of test compound:	The stability of the test item at storage conditions (room temperature) was guaranteed for > 2 years. The stability of the test item in the solvent (vehicle) was at the responsibility of the sponsor and not further specified.
Solvent (vehicle) used:	Culture medium (Eagle's Minimal Essential medium with Earle's Salts)

2. Control Materials:

Negative control:	The negative control corresponded to the solvent control.
Solvent (vehicle) control:	Culture medium (Eagle's Minimal Essential medium with Earle's Salts)
Positive control:	-S9 mix: Mitomycin C (MCC): 0.05 µg/mL +S9 mix: Cyclophosphamide (CP): 10 µg/mL

3. Metabolic activation:

S9 mix was obtained from the livers of male Sprague-Dawley rats, weighing approx. 200 g. The animals received a single intraperitoneal injection of Aroclor 1254. Five days after administration, the S9 fraction was prepared. Prior to the experiment, an aliquot of S9 mix fraction was mixed with standard co-factors.

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	30	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	5	mM
$MgCl_2$	8	mM
S9	5	% (v/v)

4. Test organism:

CHL cells were used, established from the lung of Chinese hamster. The cells have an average generation time of approximately 11 hours. It was not reported whether the cells were screened for mycoplasma contamination.

5. Cell culture:

Medium: Eagle's MEM medium supplemented with 10 % foetal calf serum

	and antibiotics
Incubation:	At 37 °C with 5 % CO_2 in air
Cell culture establishment prior to exposure:	The cells were seeded approx. 48 hours prior to treatment in 25 cm^2 flasks. 0.15 x 10^6 cells were seeded per flask for the 6 and 24 h cultures and 0.075 x 10^6 cells were seeded per flask for the 48 h cultures.

6. Test concentrations and number of replicates:

(a) Preliminary cytotoxicity assay:

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	24 h	19.5, 39.1, 78.13, 156.25, 312.5, 625, 1250, 2500 and 5000 µg/mL	Duplicate
-S9 mix	48 h	19.5, 39.1, 78.13, 156.25, 312.5, 625, 1250, 2500 and 5000 µg/mL	Duplicate
± S9 mix	6 h	19.5, 39.1, 78.13, 156.25, 312.5, 625, 1250, 2500 and 5000 µg/mL	Duplicate

(b) Main cytogenicity test:

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	24 h	39, 78.1, 156.25, 312.5*, 625* and 1250* µg/mL	Duplicate
-S9 mix	48 h	39, 78.1, 156.25, 312.5*, 625* and 1250* µg/mL	Duplicate
± S9 mix	6 h	39, 78.1, 156.25, 312.5*, 625* and 1250 µg/mL	Duplicate

* Dose levels selected for assessment of chromosome aberration

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 30 Aug 1995 – 04 Jan 1996
Finalisation date: 18 Jan 1996

2. Preliminary cytotoxicity test:
In a preliminary test, CHL cells were treated at concentrations in the range of 19.5 to 5000 µg/mL each with and without metabolic activation. Duplicate cell cultures were exposed to the test item or solvent. The cells were exposed for 24 and 48 hours without metabolic activation and for 6 hours with and without metabolic activation, followed by an 18-hour recovery period in treatment-free medium. Growth inhibition was estimated by counting the number of cells at the end of the culture period and expressing the cell count as a percentage of the concurrent vehicle control value. In addition, slides were prepared from the cells in order to check for the presence of cells in metaphase.

3. Main cytogenicity test:
Treatment: After the 48 hour pre-incubation period, treatment for the main mutagenicity test was initiated. Based on the results of the preliminary cytotoxicity test, duplicate cultures were exposed to test item concentrations in the range of 39 to 1250 µg/mL for 24 and 48 hours in the absence of metabolic activation and for 6 hours in the presence and absence of metabolic activation. Corresponding solvent and positive controls (MMC without S9 mix and CP with S9 mix) were included.
In the absence of S9 mix, chromosome preparations were made at 24 and 48 hours after start of treatment. In case of 6 hour exposure in the presence and absence of S9 mix, the cells were incubated for 18 hours following exposure

and chromosome preparations were made at 24 h after start of exposure.

Spindle inhibition: Colcemid (0.1 µg/mL) was added to the cultures two hours before harvest.

Cell harvest: The cells were harvested by centrifugation of trypsinised cultures and re-suspended in hypotonic potassium chloride solution (0.075 M) for 10 minutes. Afterwards, the cells were centrifuged again and fixed in methanol:glacial acetic acid fixative (3:1, v/v). The fixative was changed several times and the cells stored at 4 °C for sufficient time to ensure complete fixation.

Slide preparation: Fixed cells were dropped onto clean, wet microscope slides and left to air dry. Each slide was labelled with the appropriate identification data. Air-dried slides were stained in 2 % Gurrs Giemsa R66 for 5 minutes, rinsed, dried and coverslipped in mounting medium.

Metaphase analysis Where possible, 100 consecutive well-spread metaphases were examined per culture (200 metaphase cells per condition in total), using microscopic assessment. Concentrations in the range of 312.5 to 1250 µg/mL were evaluated for the number of chromosomes, chromosome gaps, breaks or re-arrangements. Cells with 28-31 chromosomes were scored as aneuploidy cells. In addition, the % incidence of polyploid cells (defined as metaphase cells with > 31 chromosomes) was noted. The percentage of cells showing structural chromosome aberrations (gaps, breaks and exchanges) were calculated including and excluding gap-type aberrations.

Cytotoxicity: Growth inhibition was estimated by counting the number of cells at the end of the culture period and expressing the cell count as a percentage of the concurrent vehicle control value.

4. Statistics

Statistical significance on the number of aberrant metaphases and polyploid cells when compared with those of corresponding solvent controls was identified using the Fisher's Exact test.

5. Acceptance criteria

The cytogenicity test was considered acceptable if the percentage of cells with chromosomal aberrations was within the range of aberration frequencies acceptable for control cultures, which are commonly in the range of 0 – 3 % (Ishidate (1987))[12].

6. Evaluation criteria

A positive response was recorded for a particular treatment if the percentage of cells with aberrations (gaps included) was ≥ 10 %. For polyploid cells, an incidence > 10 % is generally considered as positive.
An equivocal response was recorded for values between 5 and 10 %.
A negative response was obtained if the percentage of cells with aberrations was < 5 %.

II. RESULTS AND DISCUSSION

A. ANALYTCAL DETERMINATIONS

Analytical determinations of the test substance in the solvent were not determined as not required by the test guideline.

[12] Ishidate (1987): Data Book of Chromosomal Aberration Test *in Vitro*

B. CYTOTOXICITY

Preliminary toxicity test:

In the preliminary cytotoxicity test cytotoxicity was observed at ≥ 2500 µg/mL after 24 hours of exposure and at ≥ 1250 µg/mL after 48 hours of exposure, both in the absence of metabolic activation. After 6 hours of exposure in the absence of S9 mix, cytotoxicity was evident at 5000 µg/mL. Growth inhibition was also observed at lower doses in the range of 19.5 – 1250 µg/mL, however, there was no dose-response relationship and no cytotoxicity at 2500 µg/mL. There was no cytotoxicity after 6 hours of exposure in the presence of S9 mix.

After 6 hours of exposure, metaphase cells were observed in the presence and absence of S9 mix up to a concentration of 5000 µg/mL. After 24 and 48 hours of exposure in the absence of metabolic activation, metaphases were present at concentrations up to 2500 µg/mL.

In addition, there was a dose-related reduction in pH value. At 2500 and 5000 µg/mL, the pH was reduced by ≥ 1 unit.

Based on the observations in pH changes in the preliminary test, the maximum dose level selected for the main study was 1250 µg/mL.

Main mutagenicity test

In the main mutagenicity test there was no cytotoxicity observed up the highest tested concentration, both in the presence and absence of metabolic activation.

C. SOLUBILITY

Evaluation of test item precipitation was not provided in the study report. However, there was a dose-related decrease in the pH value noted in all experiments. At 2500 and 5000 µg/mL, the pH was reduced by ≥ 1 unit.

D. CYTOGENICITY

There was no statistically significant increase in the frequency of cells with chromosomal aberrations at any dose level in any treatment group. In addition, the test material did not induce a significant increase in the numbers of polyploid metaphase cells in any of the tested conditions with or without S9 mix. Frequencies of aberrant metaphases of vehicle control cultures were within the expected range. The positive controls mitomycin C in the absence of S9 mix and cyclophosphamide in the presence of S9 mix gave highly significant increases in the frequency of aberrant metaphase cells. No statistically significant increase was observed for cyclophosphamide after 6 hours of exposure in the absence of S9 mix. The test results indicate that the metabolic activation system was functioning satisfactory and that the test method itself was operating as expected.

III. CONCLUSION:

In conclusions, Technical Glyphosate did not induce any statistically significant, dose-related increase in the frequency of cells with chromosome aberrations or in the frequency of polyploid cells, neither in the presence nor absence of a liver enzyme metabolising system or after various exposure times. Technical Glyphosate is therefore considered to be non-c1astogenic to CHL cells in vitro.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Negative for cytogenicity in Chinese hamster lung cells with and without metabolic activation.

The study was performed under GLP conditions and the experimental procedure was similar to OECD guideline 473 (2016), except for some minor deviations. Only 200 metaphase cells were investigated, which was the number of metaphases to be analysed according to previous OECD guidelines 473. In addition, cytotoxicity was evaluated by counting the number of cells at the end of the culture period relative to control, whereas the currently valid guideline (2016) recommends the evaluation based on relative population doubling or relative increase of the cell count. These and further deviations were considered to not compromise the validity of the study. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/027
Report author	[redacted]
Report year	1995
Report title	HR-001: *In vitro* cytogenicity test
Report No	IET 94-0143
Document No	Not reported
Guidelines followed in	OECD 473 (1983), U.S. EPA FIFRA Guidelines, Subdivision F (1991) and

study	Japanese MAFF (1985)
Deviations from current test guideline OECD 473 (2016)	Only 200 cells in metaphase were evaluated, whereas the evaluation of 300 metaphases is recommended according to OECD guideline 473 (2016). Historical control data was provided for untreated and solvent control cultures only, but not for the positive control substances. pH measurements were not performed. Cytotoxicity was evaluated based on mitotic indices, whereas OECD 473 (2016) recommends to measure the relative population doubling or the relative increase in cell count. Acceptance and evaluation criteria were inconsistent with those specified in test guideline OECD 473 (2016).
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (HR-001, batch: 940908-1, purity: 95.68 %) was tested *in vitro* for its potential to induce chromosomal aberrations in Chinese hamster lung (CHL) cells in the presence and absence of metabolic activation (phenobarbital and 5,6 benzoflavone-induced rat liver S9 fraction). Dose levels were chosen based on the results of a preliminary cytotoxicity test, in which cytotoxicity was observed after 48 hours of treatment at 1000 µg/mL in the absence of S9 mix and after 6 hours of treatment at 2000 µg/mL in the presence of S9 mix.

Duplicate cultures were exposed to the test substance at concentrations of 125, 250, 500 and 1000 µg/mL for 24 hours without S9 mix, at concentrations of 62.5, 125, 250 and 500 µg/mL for 48 hours without S9 mix and at concentrations of 250, 500, 1000 and 2000 µg/mL for 6 hours in the presence and absence of S9 mix. Untreated cultures, solvent controls (Hanks´ balanced salt solution) and positive controls (mitomycin C without S9 mix and benzo(a)pyrene with S9 mix) were included for experiments with and without metabolic activation, respectively.

The cells were sampled after 24 and 48 hours of exposure without S9 mix and 24 h after start of exposure for the 6 hour exposure with and without S9 mix. A total of 200 metaphases per condition were scored for structural and numerical chromosome aberrations. Cytotoxicity was assessed as mitotic index (MI) and evaluated for 1000 cells per culture.

Cytotoxicity was observed after 48 hours of treatment at 1000 µg/mL in the absence of S9 mix and after 6 hours of treatment at 2000 µg/mL in the presence of S9 mix. Due to the high cytotoxicity, no cells for chromosome preparations were obtained at these concentrations.

Treatment with the test item did not induce a significant increase in the number of aberrant metaphases in any of the tested conditions. After 24 and 48 hours of treatment in the absence of metabolic activation and after 6 hours exposure in the presence and absence of metabolic activation, the number of chromosome aberrations with and without gaps was comparable to those of controls. In addition, there was no increase in the frequencies of polyploid metaphases in any of the tested conditions with or without S9 mix. Frequencies of aberrant metaphases of untreated and solvent control cultures remained within the range of the laboratory's historical control data. The positive controls showed a clear clastogenic effect and markedly increased the number of aberrant metaphases when compared to untreated and solvent control cultures, demonstrating the validity of the test system.

Based on the results of the present study, there is no evidence for a clastogenic potential of glyphosate technical with and without metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	HR-001
Description:	White crystals
Lot/Batch #:	940908-1
Purity:	95.68 %
Stability of test compound:	The stability of the test item at storage conditions (at room temperature) or in the solvent (vehicle) were not specified.
Solvent (vehicle) used:	Hank's balances salt solution (HBSS) and culture medium

2. Control Materials:

Negative control:	Untreated cell cultures were included.
Solvent (vehicle) control:	Hank's balance salt solution (10 % final concentration in medium)
Positive control:	-S9 mix: Mitomycin C (MCC): 0.1 µg/mL in physiological saline +S9 mix: Benzo(a)pyrene (B(a)P): 40 µg/mL in DMSO

3. Metabolic activation:

S9 mix was purchased from [redacted]). The homogenate was obtained from the livers of 7 weeks old male Sprague-Dawley rats, weighing 192 – 229 g. The animals received intraperitoneal injections of phenobarbital (30 mg/kg bw on Day 1, each 60 mg/kg bw on Days 2, 3 and 4) and 5,6 benzoflavone on Day 3. The S9 mix was prepared immediately before the experiment by mixing S9 fraction and co-factor.

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADH	4	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	30	% (v/v)

4. Test organism:

CHL cells were used, established from the lung of Chinese hamster. Stocks of passage number 11 were stored in liquid nitrogen and thawed immediately before use. Each batch used for mutagenicity testing was screened for mycoplasma contamination.

5. Cell culture:

Medium:	Eagle's MEM medium supplemented with 10 % newborn calf serum
Incubation:	At 37 °C in a humidified atmosphere of 5 % CO_2

Cell culture establishment prior to exposure

Preliminary cytotoxicity assay:	CHL cells were seeded at density of 1.0 x 10^5 cells in 5 mL of medium and incubated for 48 h
Main cytogenicity test:	CHL cells were seeded at density of 2.0 x 10^5 cells in 10 mL of

medium and incubated for 48 h

6. Test concentrations and number of replicates:

(a) Preliminary cytotoxicity assay (growth inhibition test):

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	24 h	3.9, 7.8, 15.6, 31.3, 62.5, 125, 250, 500 and 1000 µg/mL	Duplicate
-S9 mix	48 h	3.9, 7.8, 15.6, 31.3, 62.5, 125, 250, 500 and 1000 µg/mL	Duplicate
+ S9 mix	6 h	3.9, 7.8, 15.6, 31.3, 62.5, 125, 250, 500 and 1000 µg/mL	Duplicate
+ S9 mix	6 h*	1000, 2000, 3000, 4000 and 5000 µg/mL	Duplicate

* Repeated growth inhibition test with metabolic activation at higher concentrations

(b) Main cytogenicity test:

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	24 h	125, 250, 500 and 1000 µg/mL	Duplicate
-S9 mix	48 h	62.5, 125, 250 and 500 µg/mL	Duplicate
± S9 mix	6 h	250, 500, 1000 and 2000 µg/mL	Duplicate

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 13 Mar – 09 May 1995
Finalisation date: 29 May 1995

2. Preliminary cytotoxicity test:
In a preliminary test, CHL cells were seeded at density of 1.0 x 10^5 cells in 5 mL of medium and incubated for 48 h to establish the cell culture. The cells were treated at concentrations in the range of 3.9 to 1000 µg/mL in the presence and absence of metabolic activation. Without S9 mix (direct method) duplicate cultures each were exposed for 24 and 48 hours and relative cell growth was measured by comparing with the staining density in the concurrent solvent control. In the presence of S9 mix, duplicate cell cultures were exposed for 6 hours, followed by an incubation period of 18 hours. About 24 hours after start of exposure, the relative cell growth was determined. As no reduction of cell growth was observed in the presence of metabolic activation, a second growth inhibition test was performed using test item concentrations in the range of 1000 – 5000 µg/mL in the presence of S9 mix.

3. Main cytogenicity test:

Treatment: CHL cells were seeded at a density of 2.0 x 10^5 cells with 10 mL of medium and incubated for 48 h to establish the cell culture. Based on the results of the preliminary cytotoxicity test, the duplicate cultures were exposed to test item concentrations of 125 – 1000 µg/mL for 24 hours in the absence of metabolic activation, at concentrations of 62.5 – 500 µg/mL for 48 h in the absence of metabolic activation and at concentrations of 250 – 2000 µg/mL for 6 hours in the presence and absence of metabolic activation. Corresponding untreated negative control, solvent and positive controls (MMC without S9 mix for 24 and 48 hour treatment and B(a)P with S9 mix) were included.
In the absence of S9 mix, chromosome preparations were made at 24 and 48 hours after start of treatment. In case of 6 hour exposure, the cells were incubated for 18 hours following exposure and chromosome preparations were made at 24 h after start of exposure. The 6-hour experiments in the presence

and absence of S9 mix were set-up as parallel experiments with the one without S9 being a concurrent control experiment against S9 mix treatment (all conditions the same as the exept for the adding S9 mix; in both settings, B(a)P was used as positive control).

Spindle inhibition: Colchicine (0.5 µg/mL) was added to the cultures two hours before harvest.

Cell harvest: The cells were detached by 0.25 % trypsin and swollen with a hypotonic potassium chloride solution (0.075 mM) for 15 minutes at room temperature. Afterwards the cells were fixed with Carnoy's solution (methanol:acetic acid = 3:1) and dropped on glass slides.

Slide preparation: Fixed cells were dropped on glass slides and air-dried. Two slides were prepared per culture and labelled with code numbers. Air-dried slides were stained with 2 % Giemsa solution for 15 minutes at room temperature.

Metaphase analysis A total number of 200 metaphase cells per condition (100 metaphase cells per culture) were examined by light microscopy. Diploid metaphase cells which possessed the typical karyotype of CHL cells and polyploid metaphase cells were analysed for chromosomal aberrations. The following data were recorded:

- Number and frequency of polyploid cells
- Number and frequency of each structural chromosome aberrations
- Number and frequency of metaphase cells with structural chromosome aberrations. Chromosome gaps, -breaks, -exchanges and chromatid breaks and -exchanges, fragmentation and other structural chromosome aberrations such as multiple aberration were recorded.
- Numerical chromosome aberrations. Only polyploid cell having 3 or more copies of haploid number of chromosomes was scored as a numerical chromosome aberration cell.

Cytotoxicity: Mitotic indices were calculated based on the number of cells in metaphase observed per 1000 cells scored.

4. Statistics

The number of aberrant metaphases and polyploid cells at each dose were statistically compared with those of corresponding solvent controls using a chi-square test

5. Acceptance criteria

The cytogenicity test was considered valid if the following criteria were met:

- The frequencies of the aberrant metaphases in the solvent control groups were within the range of the laboratory's historical negative control range (mean ± 3x SD).
- The frequency of the aberrant metaphases in the positive control groups were 10 % or more.

6. Evaluation criteria

A test substance was judged negative if there was no significant increase in the frequencies of aberrant metaphases or polyploid cells at any dose. A test substance was judged positive if reproducible and significant increases in the frequencies of aberrant metaphases or polyploid cells were observed with a dose-related response. Both biological and statistical significance were considered together in a final evaluation.

II. RESULTS AND DISCUSSION

A. ANALYTCAL DETERMINATIONS

Analytical determinations of the test substance in the solvent were not performed, as not required by the test guideline.

B. CYTOTOXICITY

Preliminary cytotoxicity test

In the preliminary cytotoxicity test, cytotoxicity was observed in the presence and absence of metabolic activation. Without S9 mix (24 and 48 h treatment), a reduction in relative cell growth by 50 % or more were observed at 500 and 1000 µg/mL, respectively. With S9 mix, no cell growth inhibition effect was observed in the first growth inhibition test up to 1000 µg/mL. A second growth inhibition test with S9 mix was performed using concentrations up to 5000 µg/mL. Cell growth inhibition of over 50 % was observed at 2000 µg/mL and above. No reduction in relative cell growth by 50 % or more was observed at any concentration in cells exposed for 6 hours without S9 mix.

It was noticed that in both experiments the color of the culture medium was turned to yellow at 500 µg/mL or more, indicating a decline of pH.

Results obtained in this preliminary cytotoxicity test were used to select concentrations for the main cytogenetic assay. The highest test compound concentration was expected to reduce mitotic index to approximately 50 % compared to corresponding solvent controls. Based on the findings of the preliminary test, the highest concentrations for the main cytogenicity assay were chosen to be 1000 µg/mL in the absence of S9 mix and 2000 µg/mL in the presence of S9 mix.

Table 5.4.1-39: Preliminary growth inhibition test

Concentration (µg/mL)	Relative cell growth (%)			
	-S9 mix 24 h	-S9 mix 48 h	+S9 mix 6-18 h (1st exp.)	+S9 mix 6-18 h (2nd exp.)
Solvent control (HBSS)	100	100	100	100
3.9	100	100	100	-
7.8	97	101	99	-
15.6	100	101	108	-
31.3	96	110	104	-
62.5	100	106	97	-
125	102	99	103	-
250	92	82	106	-
500	74	46	112	-
1000	22	9	106	100
2000	-	-	-	22
3000	-	-	-	38
4000	-	-	-	27
5000	-	-	-	25

Main mutagenicity test

In the main mutagenicity test, excessive cytotoxicity was observed after 48 hour treatment at 1000 µg/mL in the absence of S9 mix and after 6 hours treatment at 2000 µg/mL in the presence of S9 mix. Due to the high cytotoxicity, no cells for chromosome preparations were obtained at these concentrations.

It was noticed that in both treatments (with and without S9 mix) pH of the culture medium of the cultures

treated at 500, 1000 and 2000 µg/mL went down.

C. SOLUBILITY

Precipitation of the test item was not reported up to the highest tested concentrations, neither in the presence, nor in the absence of metabolic activation. However, a decrease in pH was noted in all experiments at ≥ 500 µg/mL with and without S9 mix, indicated by a medium color change to yellow. As there was no significant increase in the number of aberrant metaphases at any concentration in any test, this decrease in pH does not have any impact.

D. CYTOGENICITY

There was no significant increase in the number of aberrant metaphases observed in none of the experiments, neither in the presence nor in the absence of S9 mix. After 24 and 48 hours of treatment in the absence of metabolic activation and after 6 hours exposure in the presence and absence of metabolic activation, the number of chromosome aberrations with and without gaps was comparable to those of controls. In addition, there was no increase in the frequencies of polyploid metaphases in any of the tested conditions with or without S9 mix. Frequencies of aberrant metaphases of untreated and solvent control cultures remained within the range of the laboratory's historical control data. The positive controls mitomycin C (- S9) and benzo(a)pyrene (+ S9) showed a clear clastogenic effect and markedly increased the number of aberrant metaphases when compared to untreated and solvent controls, demonstrating the sensitivity of the test and the functionality of the S9 mix. In the 6-hour treatment without S9 (concurrent control experiment against S9 mix treatment), benzo(a)pyrene showed no significant increase in chromosome aberrations (as expected), as this requires metabolic activation.

III. CONCLUSION:

In the chromosome aberration test, there was no significant increase in the frequencies of abnormal metaphases with structural chromosome aberrations or polyploid metaphases in the treated groups compared to the control group whatever were the tested concentrations. Based on the results obtained, it was concluded that, under the conditions of this study, the test substance HR-001 did not induce chromosome aberrations in Chinese hamster CHL cells with or without the metabolic activation system.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for cytogenicity in Chinese hamster lung cells with and without metabolic activation.
The study was performed under GLP conditions and in accordance with OECD guideline 473 (1983). There were only minor deviations when compared to the currently valid OECD 473 (2016). The number of metaphases was only 200, which was the number to be investigated recommended by the previous OCED 473 (1997). In addition, cytotoxicity was evaluated based on mitotic indices instead of

measuring the relative population doubling or the relative increase in cell count.

Historical control data were not provided and evaluation criteria of the test were inconsistent with those specified in the current guideline which requires that for a positive response: a. at least one of the test concentrations exhibits a statistically significant increase compared with the concurrent negative control, b. the increase is dose-related when evaluated with an appropriate trend test, c. any of the results are outside the distribution of the historical negative control data (e.g. Poisson based 95 % control limits).

However, as the increase in the frequencies of abnormal metaphases with structural chromosome aberrations or polyploid metaphases in the treated groups were similar to those of the negative control, the deviations were considered to not compromise the validity of the study. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/028
Report author	[redacted]
Report year	1995
Report title	Evaluation of the ability of glyfosaat to induce chromosome aberrations in cultured peripheral human lymphocytes (with independent repeat)
Report No	141918
Document No	Not reported
Guidelines followed in study	OECD 473 (1983), EEC Directive 92/69
Deviations from current test guideline OECD 473 (2016)	Only 200 cells in metaphase were evaluated, whereas the currently valid OECD 473 (2016) recommends the evaluation of 300 metaphase cells per condition. A short-term exposure in the absence of metabolic activation as recommended by OECD 473 (2016) was not included. There was no historical control data provided for the positive control compounds and historical control data obtained in the testing laboratory were not provided. pH measurements were not performed. Acceptance and evaluation criteria specified in the testing protocol differed from those recommended by OECD 473 (2016).
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

A chromosome aberration test in human peripheral lymphocytes was conducted to investigate the potential of glyphosate (batch: 22021, purity: 96 %) to induce chromosomal aberrations *in vitro* in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Concentrations were selected

based on the results of a preliminary cytotoxicity test, in which a reduction of the mitotic index of ≥ 50 % was observed at 333 µg/mL in the presence of S9 mix and at 333 and 1000 µg/mL in the absence of S9 mix (24- and 48-hours sampling time point).

Two independent experiments were performed. In each experiment, corresponding solvent (DMSO) and positive controls (mitomycin C in the absence of S9 mix and cyclophosphamide in the presence of S9 mix) were included.

In the first experiment, the cultures were treated for 3 hours in the presence of S9 mix at concentrations in the range of 33 - 562 µg/mL, for 24 hours in the absence of S9 mix with concentrations in the range of 33 - 237 µg/mL and for 48 hours in the absence of S9 mix with concentrations in the range of 56 – 333 µg/mL. The cells treated in the presence of S9 mix were sampled 24 and 48 hours after start of exposure, whereas the cells treated in the absence of S9 mix were prepared directly following end of exposure.

In the second experiment, the cultures were exposed for 3 hours in the presence of S9 mix at concentrations in the range of 100 – 562 µg/mL and for 24 hours in the absence of S9 mix at concentrations in the range of 33 – 333 µg/mL. Chromosome preparations in the second experiment were made 24 hours after start of treatment only.

In each experiment, a total of 200 metaphases per condition was scored for structural and numerical chromosome aberrations. Cytotoxicity was assessed as mitotic index (MI) and evaluated for 1000 cells per culture.

Precipitation of the test item in culture medium was noted at concentrations of 562 µg/mL and above, both in the presence and absence of S9 mix. Cytotoxicity, evident as a reduction in the mitotic index of ≥ 50 %, was observed for the 24-hours sampling time point in the absence of metabolic activation at ≥ 133 µg/mL (first experiment) and for the 24-hours sampling time point in the absence of metabolic activation at 178 and 333 µg/mL (second experiment). Cytotoxicity was further observed after tTreatment for 48 hours in the absence of metabolic activation and after treatment for 3 hours in the presence of metabolic activation (24-hours sampling time point), however, the mitotic indices were reduced by < 50 %.

After treatment with glyphosate, there was no statistically significant increase in the number of cells with chromosomal aberrations observed in any experiment at any concentration when compared to solvent controls, neither in the presence nor in the absence of metabolic activation.
In addition, there was no increase in the frequencies of polyploid metaphases in any of the tested conditions with or without S9 mix.

The number of aberrant metaphases found in the solvent control cultures were within the range of the laboratory's historical control data. The positive controls mitomycin C and cyclophosphamide produced statistically significant increases in the frequency of aberrant cells, demonstrating the sensitivity of the test and the functionality of the S9 mix.

Based on the experimental findings there is no evidence for a clastogenic potential for glyphosate in peripheral human lymphocytes, neither in the presence nor in the absence of metabolic activation.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

	Glyfosaat
Identification:	Not specified
Description:	White powder
Lot/Batch #:	22021
Purity:	96 %
Stability of test compound:	The stability of the test item under storage conditions

	(at room temperature in the dark) was guaranteed until the mentioned expiry date 01 Jan 1998. The stability of the test item in solvent was not specified.
Solvent (vehicle) used:	Dimethylsulfoxide (DMSO), final concentration 0.9 % (v/v)

2. Control Materials:

Negative control:	A negative control was not employed in this study.
Solvent (vehicle) control:	DMSO (0.9 % (v/v) final concentration in medium)
Positive control:	-S9 mix: Mitomycin C (MMC): 0.1 and 0.2 µg/mL in Hank's Balanced Salt solution (HBSS) for 24- and 48-hours sampling, respectively +S9 mix: Cyclophosphamide (CP): 15 µg/mL in Hank's Balanced Salt solution (HBSS)

3. Metabolic activation:

S9 mix was routinely prepared from the livers of adult male Wistar rats, which received a single intraperitoneal injection of 500 mg/kg bw Aroclor 1254. Five days after treatment, the animals were sacrificed and the S9 homogenates were isolated. The S9 mix was prepared immediately before the experiment by mixing S9 fraction and co-factor.

S9 mix component	Concentration	Unit
HEPES	4.0	mM
KCl	33.0	mM
NADPH-generating system		
Glucose 6-phosphate	6.5	mM
NADP	4.6	mM
$MgCl_2$	5.0	mM
S9	50	% (v/v)

4. Test organism:

Human peripheral blood was obtained by venepuncture from a healthy, male volunteer and collected in heparinised vessels.

5. Cell culture:

Medium:	Ham's F10 medium without thymidine and hypoxanthine, supplemented with 20 % (v/v) fetal calf serum, 2 mM L-glutamine, penicillin/streptomycin (50 U/mL and 50 µg/mL, respectively), 1.2 g/L sodium bicarbonate and 30 U/mL heparin.
Incubation:	*In a humidified atmosphere (80 – 95 %) containing 5 % CO_2 in the dark.*
Cell culture establishment prior to exposure	*0.5 mL of whole blood was cultured with 5 mL culture medium and 0.1 mL of 9 mg/mL phytohaemagglutinin for 48 hours prior to treatment.*

6. Test concentrations and number of replicates:

(a) Preliminary cytotoxicity assay

Metabolic activation	Duration of exposure (Fixation time)	Concentrations	Replicates
-S9 mix	24 h (24 h)	10, 33, 100, 333 and 1000 µg/mL	Single culture
-S9 mix	48 h (48 h)	10, 33, 100, 333 and 1000 µg/mL	Single culture
+S9 mix	3 h (24 h)	10, 33, 100, 333 and 1000 µg/mL	Single culture

(b) Main cytogenicity test:

Metabolic activation	Duration of exposure (Fixation time)	Concentrations	Replicates
First experiment			
-S9 mix	24 h (24 h)	33*, 56, 100*, 133, 178 and 237* µg/mL	Duplicate
-S9 mix	48 h (48 h)	56, 100, 133, 178, 237* and 333 µg/mL	Duplicate
+S9 mix	3 h (24 h)	33, 100, 133, 178, 237*, 333* and 562* µg/mL	Duplicate
+S9 mix	3 h (48 h)	33, 100, 133, 178, 237, 333 and 562* µg/mL	Duplicate
Second experiment			
-S9 mix	24 h (24 h)	33*, 100, 133, 178, 237* and 333* µg/mL	Duplicate
+S9 mix	3 h (24 h)	100, 333*, 422* and 562* µg/mL	Duplicate

* Samples analysed for chromosomal aberrations

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 15 Mar – 28 May 1995
Finalisation date: 30 Jun 1995

2. Preliminary cytotoxicity test:
In a preliminary cytotoxicity test, human lymphocytes were treated with the test item at concentrations of 10 to 1000 µg/mL both, with and without metabolic activation under the same conditions as in the main mutagenicity test (described below). The highest concentration was selected based on the solubility of the test substance in culture medium. One single cell culture per condition was exposed to the test item for 3 hours in the presence of S9 mix or for 24 and 48 hours in the absence of S9 mix. Cells treated in the presence of S9 mix were prepared about 24 hours after start of exposure while cells treated in the absence of S9 mix were prepared immediately following end of exposure. Slides were prepared and the mitotic index of each culture was determined by counting the number of 1000 metaphases per culture.

Based on the results of the preliminary test, the concentrations for the main cytogenicity assay were selected. The concentrations of the test substance that was expected to show clear indication of toxicity with a mitotic index of ≥ 50 % was selected for scoring of chromosome aberrations.

3. Main cytogenicity test:
Treatment: Following cell culture establishment, duplicate cultures per condition were exposed to the test item, solvent or positive control in the presence and absence of metabolic activation. Two independent experiments were performed. Corresponding solvent (DMSO) and positive controls (mitomycin C in the absence of S9 mix and cyclophosphamide in the presence of S9 mix) were included in each experiment.

In the first experiment, the cultures were treated for 3 hours in the presence of S9 mix at concentrations in the range of 33 - 562 µg/mL, for 24 hours in the absence of S9 mix with concentrations in the range of 33 - 237 µg/mL and for 48 hours in the absence of S9 mix with concentrations in the range of 56 – 333 µg/mL. The cells treated in the presence of S9 mix were prepared for chromosome analysis 24 and 48 hours after start of exposure. After 3 hours of exposure with S9 mix, the cells were rinsed once with Hank's buffered salt solution (HBSS) to remove the test compound, re-suspended in medium and incubated for another 20 – 22 hours (24-hours fixation time) or for 44 - 46 hours (48-hours fixation time). The cells treated in the absence of S9 mix were prepared directly following end of exposure.
In the second experiment, the cultures were exposed for 3 hours in the presence of S9 mix at concentrations in the range of 100 – 562 µg/mL and for 24 hours in the absence of S9 mix at concentrations in the range of 33 – 333 µg/mL. Chromosome preparations in the second experiment were made 24 hours after start of treatment only.

Spindle inhibition: During the last 3 hours of the culture period, cell division was arrested by addition of 0.5 µg/mL colchicine (0.5 µg/mL) to each culture.

Cell harvest: The cell cultures were centrifuged and the remaining cell pellet swollen in 0.56 % hypotonic potassium chloride solution for 5 minutes at 37 °C. Afterwards, the cells were fixed with 3 changes of methanol : acetic acid fixative (3:1 v/v).

Slide preparation: Fixed cells were dropped on glass slides which were immersed for 24 hours in a 1:1 mixture of 96 % (v/v) ethanol/ether and cleaned with a tissue. Two slides were prepared per culture. Slides were allowed to dry, stained for 10 – 30 minutes with 5 % (v/v) Giemsa solution, rinsed with tap water, allowed to dry again and cleared in xylene before embedding in DePeX and mounting.

Metaphase analysis A total number of 200 metaphase cells per condition (100 metaphase cells per culture) were examined by light microscopy. In case the number of aberrant cells (gaps excluded) was ≥ 25 in 50 metaphases no more metaphases were examined. Only metaphases containing 46 chromosomes were analysed. The following data were recorded:

- The number of cells with chromosomal aberrations.

The number and type of structural chromosomal aberrations, Chromosome gaps, -breaks, -exchanges, -intrachanges, chromatid gaps, -breaks and -deletions, centromere state, ring chromosomes, and other structural chromosome aberrations such as multiple aberration.

- Numerical variations such as endoreduplication and polyploidy.

Cytotoxicity: The mitotic index of each culture was calculated based on the number of cells in metaphase observed per 1000 cells scored.

4. Statistics

The number of cells with chromosomal aberrations at each dose were compared with those of corresponding solvent controls and statistically evaluated using a chi-square test

5. Acceptance criteria

The chromosome aberration test was considered acceptable if the following criteria were met:

- The numbers of chromosome aberrations found in the solvent control cultures should reasonably be within the laboratories historical control data range.
- The positive control substances should produce a statistically significant increase in the number

of cells with chromosomal aberrations.

6. Evaluation criteria

A test substance was considered positive (clastogenic) in the chromosome aberration test if the following criteria were met:

- It induced a dose-related statistically significant increase in the number of cells with chromosome aberrations.
- A statistically significant increase in the frequency of aberrations was observed in the absence of a clear dose-response relationship.

A test substance was considered negative (not clastogenic) in the chromosome aberration test if none of the tested concentrations induced a statistically significant increase in the number of cells with chromosomal aberrations.

II. RESULTS AND DISCUSSION

A. ANALYTCAL DETERMINATIONS

Analytical determinations of the test substance in the solvent have not been performed, as not required by the test guideline.

B. CYTOTOXICITY

A detailed description on cytotoxic effects at individual concentrations was not provided in the study report. Description of cytotoxicity in the following section is based on re-evaluation of the raw data provided in the study report. A cytotoxic effect was considered evident when a reduction of the mitotic index of ≥ 50 % was observed.

Preliminary cytotoxicity test

In the preliminary cytotoxicity test, cytotoxicity was observed at 333 µg/mL in the presence of S9 mix and at 333 and 1000 µg/mL in the absence of S9 mix (24- and 48-hours sampling time point). For the 24-hours sampling time point at 333 and 1000 µg/mL in the absence of S9 mix and for the 48-hours sampling time point in the absence of S9 mix no metaphase cells at all were detected.

The results obtained in the preliminary cytotoxicity test were used to select concentrations for the main mutagenicity assay. The highest test compound concentration was expected to reduce mitotic index by ≥ 50 % compared to corresponding solvent controls. Therefore, for the main cytogenetic test concentrations of 237 and 333 µg/mL were selected as highest concentrations in the absence of S9 mix (24- and 48-hours sampling time point, respectively) and 562 µg/mL was chosen as highest concentration in the presence of S9 mix.

Main mutagenicity test

In the main mutagenicity test, cytotoxicity evident as a reduced mitotic index of ≥ 50 % was observed for the 24-hours sampling time point in the absence of metabolic activation at ≥ 133 µg/mL (first experiment) and for the 24-hours sampling time point in the absence of metabolic activation at 178 and 333 µg/mL (second experiment). There was also evidence of toxicity for the 48-hours sampling time point in the absence of metabolic activation (first experiment) and for the 24-hours sampling time point in the presence of metabolic activation (second experiment), but the mitotic indices were < 50 % (please refer to Table 5.4.1-42 and **Error! Reference source not found.**).

C. SOLUBILITY

Precipitation of the test item was reported in the preliminary cytotoxicity test as well as the main cytogenicity test, at 562 µg/mL and at higher concentrations, both in the presence and absence of S9 mix.

D. CYTOGENICITY

There was no statistically significant increase in the number of cells with chromosomal aberrations observed in any experiment at any concentration when compared to solvent controls, neither in the presence nor in the absence of metabolic activation.

In addition, there was no increase in the frequencies of polyploid metaphases in any of the tested conditions with or without S9 mix.

The number of aberrant metaphases found in the solvent control cultures were within the range of the laboratory's historical control data. The positive controls mitomycin C and cyclophosphamide produced statistically significant increases in the frequency of aberrant cells, demonstrating the sensitivity of the test and the functionality of the S9 mix.

III. CONCLUSION:

Based on the experimental findings there is no evidence for a clastogenic potential for glyphosate in peripheral human lymphocytes, neither in the presence nor in the absence of metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Negative for cytogenicity (Chromosome Aberration test) in peripheral human lymphocytes with and without metabolic activation.

The study was performed under GLP conditions and in accordance with OECD guideline 473 (1983). When compared with the currently valid OECD guideline 473 (2016), several deviations became evident. The dose levels investigated were rather low when compared to other studies that were provided for the evaluation of glyphosate. In addition, a short-term exposure in the absence of S9 mix was not included in the experiment. Accordingly, the study was considered to provide supporting information. Further guideline deviations were considered to not impact the validity of the study.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/029
Report author	[redacted]
Report year	1989
Report title	Report on the possible chromosome damaging effect of glyphosate in Chinese hamster ovary cells
Report No	Not reported
Document No	Not reported
Guidelines followed in study	The study was conducted according to Natarajan et al.[13] (1967), according to guidelines and recommendations of the United

[13] Natarajan, A.T., Tates, A.B., van Buul, P.W., Meijery, M. and De Vogel, N.: Cytogenic effects of mutagens/carcinogens after activation in microsomal system in vitro. I. Induction of chromosome aberration and sister chromatid exchange by diethylnitrosamine (DEN) and dimethylnitrosamine (DMN) in CHO cells in the presence of rat liver microsome. Mut. Res., 37, 83-90 (1976)

	Kingdom Environmental Mutagen Society (UKEMS) and similar to OECD 473 (2016).
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate (batch: 978, purity: not specified) was assessed for its ability to induce structural chromosome aberrations in Chinese hamster ovary (CHO) cells *in vitro*. The test was conducted in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Glyphosate concentrations were selected based on the results of a preliminary toxicity test, in which cytotoxicity was observed at ≥ 2500 µg/mL in the presence of S9 mix and at ≥ 1250 µg/mL in the absence of S9 mix. Two independent experiments were performed. In each experiment, solvent (medium) and positive controls (ethylmethane sulfonate, 1 µg/mL without S9 mix and cyclophosphamide, 25 µg/mL with S9 mix were included. Tested glyphosate concentrations were 250 – 1000 µg/mL in the absence of S9 mix and 62.5 – 250 µg/mL in the presence of S9 mix. In both experiments, the cells were exposed for 3 hours in the presence and absence of S9 mix, followed by two washing steps and re-incubation for further 18 hours[14]. Chromosomes were prepared about 21 hours after start of exposure[14]. In each experiment, a total of 200 metaphases per condition was scored for structural chromosome and chromatid aberrations.
Short description of results:	Precipitation of the test item in culture medium was not reported. Cytotoxicity was not monitored in the cytogenicity experiments, as the concentrations selected were chosen to be non-cytotoxic. In the first experiment, there was a mathematically significant increase in the incidence of aberrant cells and the incidence of total chromosome aberrations at 62.5 µg/mL in the presence of metabolic activation. As the effect was noted at the lowest concentration and as a dose-dependency was lacking, the observation was considered incidental. In the second experiment, there was no statistically significant increase in the number of cells with chromosomal aberrations or the total number of aberrations at any concentration when compared to solvent controls, neither in the presence, nor in the absence of metabolic activation. The positive controls induced statistically significant aberrations in both experiments, demonstrating the functionality of the metabolic activation system and the sensitivity of the test. Based on the experimental findings and under the conditions of the test, glyphosate has no clastogenic potential in CHO cells *in vitro*, neither in the presence nor in the absence of metabolic activation.
Reasons for why the study is not considered relevant/reliable or not considered as key	The study is considered not acceptable due to the large number of deviations when compared to the currently valid OECD guideline 473 (2016). Only 100 – 200 metaphase cells were evaluated and only structural chromosome aberrations but no numerical

[14]: There are inconsistencies in the study report regarding the duration of exposure (2 or 3 hours) and the duration of post-exposure incubation (16 - 18 hours incubation followed by 2 hours incubation with colchicine or 16 hours incubation in total) prior to metaphase analysis. It was assumed that the cells were exposed for 3 hours, followed by 18 hours of incubation (including 2 hours of treatment with colchicine) and chromosome preparation 21 hours after start of exposure.

study:	aberrations were considered. In addition, the maximum concentration did not meet the cytotoxicity recommendations specified in the current guideline. Cytotoxicity was not measured in the main cytogenicity test, but evaluated only in a preliminary toxicity test based on cell morphology. Besides a number of further guideline deviations, there were inconsistencies regarding the duration of exposure and reporting deficiencies regarding the source and purity of the test material. The study was therefore considered not valid.
Reasons why the study report is not available for submission

1. Information on the study

Data point	CA 5.4.1/030
Report author	[redacted]
Report year	1998
Report title	Glyphosate Acid: L5178Y TK$^{+/-}$ Mouse Lymphoma Gene Mutation Assay
Report No	CTL/P/4991
Document No	Not reported
Guidelines followed in study	OECD 476 (1984), US EPA OPPTS 870.5300 (1998), Council Directive 2000/32/EEC B.17 (2000)
Deviations from current test guideline OECD 490 (2016)	The newly introduced cytotoxicity parameters RTG (relative total growth), SG (suspension growth) and RSG (relative suspension growth) could not be re-calculated, since no data on suspension growth were available. In the present study, cytotoxicity was evaluated based on cloning efficiency, in accordance with the previous guideline version. Historical control data were only provided for negative/vehicle controls but not for the positive control. pH changes observed upon compound addition were not buffered. Acceptance and evaluation criteria were inconsistent with those specified in OECD 490 (2016).
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate acid (batch: P24, purity: 95.6 %) was tested *in vitro* for its ability to induce forward mutations in mammalian cells by assessing the mutation of the TK locus in Mouse Lymphoma L5178Y TK$^{+/-}$ cells. Two independent experiments with a treatment duration of 4 hours were conducted in the presence or absence of metabolic activation (phenobarbital/β-naphthoflavone-induced rat liver S9 fraction) using two parallel cultures each. Based on the results of a preliminary range-finding experiment, in which the pH value was excessively reduced at a concentration of 2000 µg/mL, concentrations in the range of 296 to 1000 µg/mL were used in the main mutation assay (1500 µg/mL included in experiment I, but not evaluated for mutagenicity; 296 µg/mL included in experiment II). Solvent controls and appropriate positive controls (ethylmethane sulphonate (EMS), without S9 mix and n-nitrosodimethylamine (NDMA), with S9 mix)

were included in each experiment.

After 4 hours of exposure, the cells were incubated for 48 hours to allow expression of the mutant phenotype. The expression period was followed by a selection period, where cells were incubated in selection medium containing trifluorothymidine (TFT) for 10-13 days.

Precipitation of the test substance was not reported. A reduction in pH of the treatment medium was observed at 1000 µg/mL and above, however, only little cytotoxicity was observed at the concentrations tested, both in the presence and in the absence of metabolic activation. A biologically relevant and dose-dependent increase in the mean number of mutant colonies was not observed up to the highest test item dose, independent of the presence or absence of metabolic activation. Appropriate reference mutagens (EMS and NDMA) used as positive controls showed a distinct increase in induced mutant colonies, indicating the test-system to be sensitive and valid. The negative controls gave mutant frequencies within the range of historical control data.

Based on the results of the present study, glyphosate acid did not induce forward mutations in the mouse lymphoma assay with L5178Y $TK^{+/-}$ cells in the absence or presence of metabolic activation. Thus, the test item is considered not mutagenic in mammalian cells *in vitro*.

I. MATERIALS AND METHODS

J.

A: MATERIALS

1. Test material: Glyphosate acid

Identification:	
Description:	White solid
Lot/Batch number:	P24
Purity:	95.6 % (w/w)
Stability of test compound:	The stability of the test item at storage conditions (in an anti-static bag at ambient temperature) and in solvent (vehicle) were not specified.

2. Control material:

Negative control:	A negative control was not employed in this study
Solvent (vehicle) control:	Dimethylsulfoxide (DMSO), final concentration 1 %
Positive control:	- S9 mix: Ethylmethane sulphonate (EMS), 750 µg/mL in DMSO
	+ S9 mix N-nitrosodimethylamine (NDMA), 600 µg/mL in DMSO

3. Metabolic activation:

S9 mix was prepared from the livers of male Sprague-Dawley rats, that received oral doses of phenobarbital (80 mg/kg bw) and β-naphthoflavone (100 mg/kg bw) on three consecutive days. The treated animals were sacrificed on the day following the last dose. The S9 mix was prepared immediately before the experiment by mixing S9 fraction and co-factors. The co-factor solution was prepared as a stock solution of 75 mM NADP (disodium salt) and 1200 mM glucose-6-phosphate (monosodium salt) in RPMI 1640 culture medium with a final pH adjusted to 7.5. S9 fraction was added at 5 % (1 mL S9 added to the 20 mL cell culture) and co-factors at 1 % (200 µL to the 20 mL cell culture).

S9-mix component	Concentration	Unit
RPMI 1640 culture medium (pH 7.5)		
NADPH-generating system		
Glucose 6-phosphate Na salt	12	mM
NADP Na_2 salt	0.75	mM
S9	5	% (v/v)

4. Test organism:
L5178Y $TK^{+/-}$ mouse lymphoma cells were used. Stocks were maintained in liquid nitrogen and thawed immediately before use. Each batch used for mutagenicity testing was screened for mycoplasma contamination.

5. Cell culture media:

Cultivation medium: RPMI 1640 medium with Hepes, supplemented with 4 mM L-glutamine, 200 IU/mL penicillin and 200 µg/mL streptomycin

Growth medium: Cultivation medium supplemented with 10 % horse serum (in case of microwell cultivation 20 % horse serum

Treatment medium (± S9:) Cultivation medium supplemented with 5 % horse serum

Selection medium: Growth medium supplemented with 20 % horse serum and 4 µg/mL trifluorothymidine (TFT)

Incubation: At 37 °C, 5 % CO_2 and 98 % humidity

6. Locus examined Thymidine kinase (TK)

7. Test concentrations and number of replicates:

(a) Preliminary range-finding assay

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	4 h	125, 250, 296, 444, 500, 667, 1000, 1500 and 2000 µg/mL	Duplicate
+S9 mix	4 h	125, 250, 296, 444, 500, 667, 1000, 1500 and 2000 µg/mL	Duplicate

(b) Main mutation assay:

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	4 h	296*, 444*, 667*, 1000* and 1500 µg/mL	Duplicate
+S9 mix	4 h	296*, 444*, 667*, 1000* and 1500 µg/mL	Duplicate

* Samples evaluated for mutagenicity

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 22 Nov 1995 – 12 Mar 1996
Finalisation date: 24 May 1996

2. Preliminary cytotoxicity test:
A preliminary dose-range finding study was performed to determine the concentrations of the test item to be used in the main mutation assay. Toxicity was evaluated based on changes in the pH of the treatment medium and on osmolality. Data of the range-finding test were not included in the study report. Based on the observations in pH changes during the preliminary toxicity experiment, concentrations for the mutation assay were selected.

3. Main mutation assay:

Pre-treatment of cells:

A bulk cell culture with a density in the range of 1 - 1.2 x 10^6 cells per mL was prepared prior to each experiment. The culture was then diluted 50:50 (v/v) with serum-free medium to obtain a reduced serum content of 5 % at treatment time. Each 20 mL treatment culture (5 - 6 x 10^5) cells were used from the bulk culture for each test condition.

Treatment:

Just prior to treatment, the medium was supplemented with S9 mix in the appropriate cell cultures with metabolic activation. Two cultures were treated in parallel for each group. Aliquots of the test substance, solvent or positive control were added and the cultures were exposed for 4 hours, rotating on a roller apparatus at 37 °C. At the end of the treatment period, the cells were centrifuged and the cell pellets were re-suspended in 50 mL fresh culture medium.

Expression period:

After treatment, all cell cultures were incubated for a two days expression period. To maintain exponential growth during the expression time, each culture was counted daily and the cell numbers were adjusted to 2 x 10^5 cells/mL in 50 mL medium, thereby ensuring approximately 10^7 cells at each subculture.

After 48 hours expression period, the cell density of each culture was determined and each culture was divided into two series of dilutions. The first was used for the selection of mutants, the second was to assess the viability of the cultures in the absence of selection medium.

Selection period:

For the selection of mutants, each post-expression culture was diluted to give 50 mL at 1 x 10^4 cells/mL. Trifluorothymidine (TFT) was added and each culture was then dispensed at 200 µL per well into two 96 well microtiter plates (2000 cells/well). After incubation for 10 - 13 days cell growth was assessed. All plates were scored for the number of negative wells (no cell growth) and the number of wells containing small or large colonies. Small colonies were considered to be associated with clastogenic effects, large colonies were considered to be associated with gene mutation effects.

4. Cytotoxicity:

Cloning efficiency CE_1 (survival)

At the end of the exposure period, a sample of each cell culture was collected to assess survival. The cultures were diluted to give 50 mL at 8 cells/mL and dispensed at 200 µL/well into two 96-well plates (1.6 cells/well). After an incubation of 10 - 13 days the plates were scored for empty wells.

Cloning efficiency CE_2 (viability)

After the expression period, 2 days after end of exposure, the cultures were divided into two series of dilutions. The first was used for the selection of mutants, the second was to assess the viability of the cultures in the absence of selection medium. A sample from each mutation culture was diluted to give 50 mL at 8 cells/mL and dispensed at 200 µL per well into two 96 well microtiter plates (1.6 cells/well). After incubation for 10 - 13 days the plates were scored for empty wells.

5. Evaluation:

Cytotoxicity (cloning efficiency CE)

The number of empty wells of the two seeded 96-well plates was scored and recorded.

CE_1 (survival)

The cytotoxicity of the test substance after the exposure period was determined for each test group and is indicated as absolute and relative cloning efficiency (CE_1 and RCE_1, respectively).

CE$_2$ (viability)
The cytotoxicity of the test substance at the end of the expression period was determined for each test group and is given as absolute and relative cloning efficiency (CE$_2$ and RCE$_2$, respectively).

The cloning efficiency (CE, %) was calculated for each test group as follows:

$$CE_x = \frac{-\ln \frac{\text{total number of empty wells}}{\text{total number of seeded wells (96)}}}{\text{number of seeded cells per well (1.6)}} \times 100$$

$$RCE_x = \frac{CE_x \text{ of the test group}}{CE_x \text{ of the negative or vehicle control}} \times 100$$

Mutant frequency (MF)
The number of empty wells and the number of wells containing colonies were scored and reported. The colonies are classified into large colonies (indication of gene mutation) and small colonies (indication of chromosome breakage). Large colonies are defined as more than 25 % of the diameter of the well. A large colony should have shown less densely packed cells, especially around the edges of the well. Small colonies are defined as less than 25 % of the diameter of the well. A small colony should have shown a dense clonal morphology. Any well which contained more than one small colony was scored as a small colony. Any well which contained more than one large colony was scored as a large colony. Any well which contained a combination of large and small colonies was scored as a large colony. An empty well was one which contained no cell growth.

Uncorrected mutant frequency:
The uncorrected mutant frequency per 10^6 cells (MF_{uncorr}) was calculated for each test group as follows:

$$MF_{uncorr.} = \frac{-\ln \frac{\text{total number of empty wells}}{\text{total number of seeded wells (96)}}}{\text{number of seeded cells per well (2000)}} \times 10^6$$

Corrected mutant frequency
The corrected mutation frequency (MF_{corr}) was calculated regarding the values of CE$_2$:

$$MF\ corrected = \frac{MF\ uncorrected}{CE_2} \times 100$$

Determination of borderline mutant frequency based on GEF
The GEF (global evaluation factor) method requires that the MF exceeds a value based on the global distribution of the background MF of the test method. This value is defined as the mean of the negative/vehicle MF distribution plus one standard deviation.
Based on a large data base (n = 493 experiments) from six laboratories a GEF of 126 mutant colonies per 10^6 cells [mean $MF_{corr} = 99 \times 10^{-6}$ colonies; standard deviation = 27×10^{-6} colonies] was calculated for the microwell method. To be judged positive, the mutation frequency has to exceed a threshold of 126 colonies per 10^6 cells (GEF) above the concurrent negative/vehicle control value. The borderline mutant frequency was calculated for each experiment separately as follows:
Borderline MF = $MF_{vehicle\ control\ corr}$ + GEF (126×10^{-6})
The borderline MF was not evaluated as part of the present study, but was determined retrospectively for this evaluation.

6. Statistics:
Statistical analysis was not performed in the study.

7. Acceptance criteria:
The assay was considered valid if the following criteria were met:

- Post-expression cloning efficiencies of 50 % or greater were achieved for the solvent control viability plates.
- Spontaneous mutant frequencies of the solvent controls were within the range of the laboratories historical control data.
- Results obtained with the positive controls gave an unequivocal positive response in the presence and absence of S9 mix.

8. Evaluation criteria:

A substance was considered to be mutagenic if the following criteria are met:

- There was a statistically significant and dose-related increase in mutant frequency, but not only at concentrations eliciting cytotoxicity.
- The increase in mutant frequency was above those of solvent controls and reproducible in an independent experiment.

A substance was considered to be negative for mutagenicity if there was no reproducible statistically significant dose-related increase in mutant frequency observed. When reproducible significant increases in mutant frequency were seen only at levels of excessive toxicity, or when such increases were not accompanied by an increase in absolute numbers of mutants over solvent control values, consideration was given to such factors as statistical significance of the difference between treated and control cultures, and dose response relationships in order to clarify the response. Failing this, results from an independent experiment were obtained to attempt to clarify the result.

II. RESULTS AND DISCUSSION

1. ANALYTICAL DETERMINATIONS

In view of the short-term nature of the study, no analysis of stability, homogeneity or achieved concentrations were carried out on the preparation of the test item or positive control substance formulations either prior to or after addition to the cell cultures. Analytical determinations are not required by the test guideline.

2. CYTOTOXICITY

In the preliminary cytotoxicity test, toxicity was evaluated based on changes in pH of the treatment medium. A concentration of 2000 µg/mL in the presence and absence of S9 mix was found to produce an excessive reduction in the pH of the treatment medium. Based on these findings, a maximum concentration of 1500 µg/mL with and without S9 mix was considered appropriate for the main mutation assay.

In the main mutation assay, 1500 µg/mL was found to produce an excessive reduction in the pH of the treatment medium (0.99 units), whereas reductions in pH seen at 1000 µg/mL (0.59 and 0.40 units in the first and second experiment, respectively) were considered acceptable and not to affect the outcome of the study. Very little cytotoxicity was seen at the concentrations tested.

3. SOLUBILITY

Precipitation of the test item was not reported. pH measurements revealed a reduction of about >0.40 units at 1000 µg/mL and above. A significant effect on osmolality was not observed.

4. MUTANT FREQUENCY

There was no biologically relevant and reproducible increase in the number of mutant colonies observed upon treatment with the test item in both main experiments, neither in the presence, nor in the absence of metabolic activation. Mutant frequencies obtained for solvent controls remained within the range of the laboratory's historical control data. Exposure to the positive controls EMS and NDMA induced substantial increases in the mutation frequency in all experiments, demonstrating the sensitivity of the test system and the activity of the S9 mix.

III. CONCLUSION:

Glyphosate acid did not induce increased mutant frequencies in L5178Y TK$^{+/-}$ cells in the presence or absence of S9-mix. Based on the results of the present study and under the experimental conditions chosen, the test item is negative for mutagenicity in mammalian cells *in vitro*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for mutagenicity in L5178Y TK$^{+/-}$ cells with and without metabolic activation.

The study was performed under GLP conditions and in accordance with OECD guideline 476 (1984). A number of deviations were observed when compared to the currently valid OECD guideline 490 (2016). All deviations were considered to be of minor degree and to not compromising the validity of the study. Mutant frequency and toxicity data given in the study report included data from 10^4 cells. For this evaluation, data were calculated retrospectively for 10^6 cells. In addition, the borderline mutant frequency based on GEF was determined retrospectively. The study was considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.1/031
Report author	[redacted]
Report year	1991
Report title	Mutagenicity test: *In vitro* Mammalian Cell Gene Mutation Test with Glyphosate, batch 206-JaK-25-1
Report No	12325
Document No	Not reported
Guidelines followed in study	OECD 476 (1983), US CFR part 700 (F) §798.5265 (1987)
Deviations from current test guideline OECD 490 (2016)	The newly introduced cytotoxicity parameters RTG (relative total growth), SG (suspension growth) and RSG (relative suspension growth) could not be re-calculated, since no data on suspension growth were available. In the present study, cytotoxicity was evaluated based on cloning efficiency, in accordance with the previous guideline version. Although the growth rates of the cultures were monitored, the data were not provided within the study report. The number of cells treated was below 6×10^6 cells, the number of cells recommended in OECD 490 (2016). No historical control data were provided for the negative and the positive controls. pH measurements were not performed. Acceptance criteria were not defined in the study report and evaluation criteria specified in OECD 490 (2016) were not applied.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially	Yes

recognised testing facilities	
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: 206-JaK-25-1, purity: 98.6 %) was tested in a Mouse Lymphoma assay for its ability to induce forward mutations in mammalian cells *in vitro*. In two independent experiments, duplicate cultures of Mouse Lymphoma L5178Y $TK^{+/-}$ cells were exposed to the test item, medium or appropriate positive controls (100 µg/mL ethylnitrosourea (ENU) without S9 mix and 5-10 µg/mL dimethylbenzanthracene (DMBA) with S9 mix), both, in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Based on the results of a preliminary toxicity test, in which no cytotoxicity was observed up to limit concentrations of 5.0 mg/mL glyphosate in the absence of S9 mix or 4.2 mg/mL glyphosate in the presence of S9 mix, the two experiments of the main mutagenicity assay were conducted at the same concentration ranges.

After 3 hours of exposure with S9 mix or 4 hours of exposure without S9 mix, the cells were incubated for 2-3 days to allow expression of the mutant phenotype. The expression period was followed by a selection period, in which the cells were cultivated in selection medium containing trifluorothymidine (TFT) for a period of 10 days. Cell survival and cell viability were assessed as cloning efficiency 1 and cloning efficiency 2 at the end of the exposure period and after the expression period, respectively.

Precipitation of the test item in the medium was not reported and there was no cytotoxicity observed at any of the tested concentrations, neither in the presence nor in the absence of S9 mix. There was no statistically significant increase in the number of mutant colonies observed upon treatment with glyphosate in both experiments at any of the tested concentrations, neither in the presence, nor in the absence of metabolic activation. Mutant frequencies of the medium control cultures were in the expected range.

A clear increase in mutant frequencies was observed for the positive control ENU in the absence of S9 mix, while the positive control DMBA in the presence of S9 mix showed a rather moderate increase in mutant frequency at 5.0 µg/mL. Thus, the second experiment was conducted with a higher DMBA concentration of 10 µg/mL. The higher dose revealed a much stronger response in mutant colony formation, demonstrating the sensitivity of the test system and the activity of the S9 mix.
Based on the results of the present study, glyphosate technical did not induce increased mutant frequencies in L5178Y $TK^{+/-}$ cells in the presence or absence of S9-mix and is therefore considered non-mutagenic for mammalian cells *in vitro*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate technical

Identification:	Not specified
Description:	White powder
Lot/Batch number:	206-JaK-25-1
Purity:	98.6 %
Stability of test compound:	The stability of the test item at storage conditions (at room temperature in the dark) or in the solvent (vehicle) was not specified.

2. Control material:

Negative control:	Untreated cell cultures which were cultivated in cultivation medium only were included in each experiment.

Solvent (vehicle) control: As culture medium was used as solvent for the test item, the solvent control represents actually the negative control.
Positive control: - S9 mix: Ethylnitrosourea (ENU), 100 µg/mL
+ S9 mix N-nitrosodimethylamine (DMBA), 5 and 10 µg/mL

3. Metabolic activation:

S9 mix was obtained from the livers of Wistar rats weighing approximately 200 g. The animals received a single intraperitoneal injection of Aroclor 1254 at a dose of 500 mg/kg bw. The animals were sacrificed 5 days after treatment following a 16-hour period of fasting until liver homogenates were prepared. The S9 mix was prepared immediately before the experiment by mixing S9 fraction and co-factor.

S9 mix component	Concentration	Unit
HEPES	20	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	3	mM
NADP	4	mM
$MgCl_2$	5	mM
S9	30	% (v/v)

4. Test organism:

L5178Y $TK^{+/-}$ mouse lymphoma cells were used. Stocks were maintained in liquid nitrogen and thawed immediately before use. Each batch used for mutagenicity testing was checked for general morphology, growth characteristics and absence of mycoplasma.

5. Cell culture media:

Cultivation medium: RPMI 1640 medium, supplemented with 10 % horse serum, 200 µg/mL sodium pyruvate and 50 µg/mL gentamycin

Pre-treatment medium A ("THMG medium"): Cultivation medium supplemented with 9 µg/mL hypoxanthine, 15 µg/mL methotrexate and 22.5 µg/mL glycine

Pre-treatment medium B + treatment medium ("THG medium"): Cultivation medium supplemented with 50 % conditioned medium, 9 µg/mL hypoxanthine and 22.5 µg/mL glycine

Selection medium: Cultivation medium, supplemented with 10 % horse serum and 4 µg/mL trifluorothymidine (TFT)

Incubation: *At 37 °C at 5 % CO_2*

6. Locus examined Thymidine kinase (TK)

7. Test concentrations and number of replicates:

(a) Preliminary range-finding assay

Metabolic activatio	Duration of exposure	Concentrations	Replicates

n			
-S9 mix	*4 h*	*0.63, 1.3, 2.5 and 5.0 mg/mL*	*Duplicate*
+S9 mix	3 h	0.52, 1.0, 2.1 and 4.2 mg/mL	Duplicate

(b) Main mutation assay:

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	*4 h*	*0.63, 1.3, 2.5 and 5.0 mg/mL*	*Duplicate*
+S9 mix	3 h	*0.52, 1.0, 2.1 and 4.2 mg/mL*	Duplicate

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 04 Apr – 13 May 1991
Finalisation date: 10 Sep 1991

2. Preliminary cytotoxicity test:

A preliminary dose-range finding study was performed to determine the concentrations of the test item to be used in the main mutation assay. Pre-treatment of cells and exposure with the test item was conducted under the same conditions as in the main mutagenicity assay.

A series of duplicate cultures was exposed for 4 hours at concentrations in the range of 0.63 – 5.0 mg/mL in the absence of S9 mix and for 3 hours at concentrations in the range of 0.52 – 4.2 mg/mL in the presence of S9 mix. Following treatment, the cultures were diluted and a sample of cells from each culture was seeded (2 cells/well) for the determination of cloning efficiency. In addition, the growth rates of the cultures were monitored for a period of 2 days after treatment. The microtiter plates were incubated for 8-10 days at 37 °C and 5 % CO_2, followed by counting the number of clones and determination of the cloning efficiency.

Based on the results of the preliminary toxicity test, the concentrations for the main mutagenicity assay were chosen. The highest concentration of the main mutagenicity assay was selected to induce 20 % cytotoxicity

3. Main mutation assay:

Pre-treatment of cells:

Thawed cells were maintained at a density of 2×10^5 - 1.5×10^6 in sterile NUNC plastic flasks and incubated at 37 °C and 5 % CO_2. Prior to treatment, spontaneous TK deficient mutants (TK-/- cells) were eliminated from the stock cultures by incubating the cells for one day in THMG medium (pre-treatment medium A), followed by a recovery period of 2-3 days in THG medium (pre-treatment medium B).

Treatment:

In two independent experiments using duplicate cultures per condition, glyphosate was tested at 4 concentrations with and without metabolic activation. Based on the results of the preliminary toxicity test, concentrations for the main mutagenesis assay were selected.

For treatment of cells in the absence of S9 mix, cell suspensions of about 6×10^5 cells/mL were mixed 1:1 with corresponding, 2-fold concentrated test item solutions at concentrations in the range of 0.63 – 5.0 mg/mL prepared in cultivation medium. All cultures were set up in final volumes of 15 mL and incubated under gentle shaking for 4 hours at 37 °C.

For treatment of cells in the presence of S9 mix, pre-treated cell cultures were centrifuged and for each culture 1.8×10^6 cells were re-suspended in 2.5 mL cultivation medium containing the test item at concentrations in the range of 0.52 – 4.2 mg/mL. 0.5 mL S9 mix were added to each culture, followed by incubation for 3 hours under gentle shaking.

In each experiment, negative and positive controls (100 µg/mL ethylnitrosourea in the absence of S9 mix and 5 or 10 µg/mL dimethylbenzanthracene in the presence of S9 mix) were included. At the end of the exposure period, the cells were centrifuged, re-suspended in 15 mL fresh medium and a small sample of cells from each culture was diluted and seeded in a microtiter plate at a density of 2 cells/well for determination of relative cell survival (cloning efficiency 1).

Expression period:

After the exposure period, the cells were incubated for a two days expression period, in which each culture was diluted daily and the growth rate was recorded. After the expression period, each culture was divided. One aliquot of each culture was plated to determine the cell viability (cloning efficiency 2) of the cultures, the other one was used for the selection of mutants.

Selection period:

For the selection of mutants, two microtiter plates were prepared from each post-expression culture, seeding 2000 cells per well in medium supplemented with 4 µg/mL trifluorothymidine (TFT). After an incubation period of 10 days, the number of cell clones was counted. The clones were differentiated into large clones and small dense clones. Small colonies were considered to be associated with clastogenic effects, large colonies were considered to be associated with gene mutation effects.

4. Cytotoxicity:

Cloning efficiency (CE_1 survival)

At the end of the exposure period, a sample of each cell culture was collected to assess cell survival. A full 96-well microtiter plate was seeded at a density of 2 cells/well for each culture. After 10 days of incubation, the number of colonies was counted.

CE_2 (viability)

After the expression period, 2-3 days after end of exposure, a sample of each cell culture was collected to assess cell viability. For each culture, a full 96-well microtiter plate was seeded at a density of 2

cells/well. After 10 days of incubation, the number of colonies was counted.

5. Evaluation:

Cytotoxicity (cloning efficiency CE)
The number of colonies divided by the number of cells plated was calculated for each sample. The absolute cloning efficiency was determined for each test group, as well as the relative cloning efficiency in comparison to the solvent control group.
CE_1 (survival)
The cytotoxicity of the test substance after the exposure period was determined for each test group and is indicated as absolute and relative cloning efficiency (CE_1 and RCE_1, respectively).

CE_2 (viability)
The cytotoxicity of the test substance at the end of the expression period was determined for each test group and is given as absolute and relative cloning efficiency (CE_2 and RCE_2, respectively).
The cloning efficiency (CE, %) was calculated for each test group as follows:

$$CE_x = -\frac{1}{2}\ln\frac{\text{Number of empty wells}}{\text{Number of wells seeded}}$$

$$RCE_x = \frac{CE_x \text{ of the test group}}{CE_x \text{ of the negative or vehicle control}} \times 100$$

Mutant frequency (MF)
The number of empty wells and the number of wells containing colonies were scored and reported. The colonies are classified into large colonies (indication of gene mutation) and small colonies (indication of chromosome breakage).

Uncorrected mutant frequency:
The uncorrected mutant frequency per 10^4 cells (MF_{uncorr}) was calculated for each test group as follows:

$$MF_{uncorr.} = -\frac{1}{2000}\ln\frac{\text{Number of empty wells}}{\text{Number of wells seeded}}$$

Corrected mutant frequency
The corrected mutation frequency (MF_{corr}) was calculated regarding the values of CE_2:

$$MF_{corr.} = \frac{MF_{uncorr.}}{CE_2} \times 100$$

Determination of borderline mutant frequency based on GEF
The GEF (global evaluation factor) method requires that the MF exceeds a value based on the global distribution of the background MF of the test method. This value is defined as the mean of the negative/vehicle MF distribution plus one standard deviation.
Based on a large data base (n = 493 experiments) from six laboratories a GEF of 126 mutant colonies per 10^6 cells [mean $MF_{corr} = 99 \times 10^{-6}$ colonies; standard deviation = 27×10^{-6} colonies] was calculated for the microwell method. To be judged positive, the mutation frequency has to exceed a threshold of 126 colonies per 10^6 cells (GEF) above the concurrent negative/vehicle control value. The borderline mutant frequency was calculated for each experiment separately as follows:
Borderline MF = $MF_{\text{vehicle control corr}}$ + GEF (126×10^{-6}).
The borderline MF was not evaluated as part of the present study, but was determined retrospectively for this evaluation.

6. Statistics:
Statistical analysis was conducted using the Analysis of Variance method on the corresponding test and control cultures.

7. Acceptance criteria:
Acceptance criteria were not defined in the study report.

8. Evaluation criteria:
A substance was considered to be mutagenic if the following criteria were met:

- There was a statistically significant and reproducible increase in the mutation frequency as compared to the negative control cultures.
- A dose-response was evident.
- The mutation frequency at the dose level where the highest effect was found more than twice the concurrent spontaneous mutant frequency.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the present study, as not required by the test guideline.

B. CYTOTOXICITY
In the preliminary cytotoxicity test, no cytotoxicity evident as ≥ 20 % reduction of cell survival was observed for any glyphosate concentration, neither in the presence, nor in the absence of metabolic activation. Growth rates of glyphosate treated cells were comparable to those of control cultures (data not provided in study report). Based on these findings, the concentrations used in the preliminary toxicity assay were also applied for the main mutagenicity test.

C. SOLUBILITY
Precipitation of the test item was not reported.

D. MUTANT FREQUENCY
There was no statistically significant increase in the number of mutant colonies observed upon treatment with glyphosate in both experiments at any of the tested concentrations, neither in the presence, nor in the absence of metabolic activation. Mutant frequencies of the medium control cultures were in the expected range.

A clear increase in mutant frequencies was observed for the positive control ethylnitrosourea (100 µg/mL) in the absence of S9 mix. The positive control dimethylbenzanthracene (DMBA) at 5.0 µg/mL showed a rather moderate increase in mutant frequency (1.88 fold induction when compared to medium control), therefore the second experiment was conducted with a higher DMBA concentration of 10 µg/mL. The higher dose revealed a much stronger response in mutant colony formation. Taken together the results of both experiments, the medium and positive controls demonstrated the sensitivity of the test system and the activity of the S9 mix.

III. CONCLUSION:

Based on the experimental findings, glyphosate technical did not induce increased mutant frequencies in L5178Y TK+/- cells in the presence or absence of S9-mix. Under the conditions of the test, the test item is negative for mutagenicity in mammalian cells *in vitro.*

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for mutagenicity in L5178Y TK$^{+/-}$ cells with and without metabolic activation.

The study was conducted in compliance with GLP and in accordance with OECD guideline 476 (1983). When compared to the currently valid OECD guideline 490 (2016), a number of deviations became evident, all of them of minor degree and not compromising the validity of the study. Mutant frequency and toxicity data given in the study report included data from 10^4 cells. For this evaluation, data were calculated retrospectively for 10^6 cells. In addition, the borderline mutant frequency based on GEF was determined retrospectively. The study was considered valid and acceptable.

Assessment and conclusion by RMS:

2. Full summary

Glyphosate (batch: XHJ-64, purity: 98.7 %) was tested for its ability to induce forward mutations in mammalian cells *in vitro* in a HGPRT assay. Chinese hamster ovary (CHO) cells were exposed the test item, medium and positive controls (ethylmethane sulfonate for cultures without S9 mix and benzo(a)pyrene for cultures with S9 mix) in the presence and absence of metabolic activation (Aroclor

1254-induced rat liver S9 fraction).

Based on the results of an initial range-finding test (data not provided in study report), in which approximately 90 % cell-killing was observed in the range of 20-25 mg/mL, concentrations for the mutagenicity test were selected. Two independent experiments, one preliminary cytotoxicity and mutagenicity test and one mutation assay were performed in the present study. In the preliminary cytotoxicity and mutagenicity test, glyphosate concentrations in the range of 5 – 22.5 mg/mL were applied, which were intended to yield approximately 100, 50 and 10 % relative survival of the cells. In addition, S9 mix concentrations in the range of 1-10 % were added to identify the optimal S9 mix concentration. In the main mutagenicity experiment, the cells were exposed to glyphosate concentrations in the range of 2 - 20 mg/mL in the absence of S9 mix and to concentrations in the range of 5 – 25 mg/mL in the presence of S9 mix. Based on the results of the preliminary test, the five test item concentrations for the main mutagenicity assay were chosen to yield 100, 70, 50, 20 and 10 % cell survival at the optimal S9 mix concentration.

After 3 hours of exposure, the cells were incubated for 7-9 days to allow expression of the mutant phenotype. The expression period was followed by a selection period, in which the cells were cultivated in 6-thioguanine-enriched medium for 8-12 days.

Precipitation of the test substance was not reported. In the preliminary cytotoxicity and mutagenicity test, glyphosate-related cytotoxicity was observed at all S9 concentrations tested. In both experiments, cytotoxicity was observed at ≥ 10 mg/mL.

In the preliminary experiment, none of the samples treated with glyphosate exhibited a statistically significant increased mutant frequency compared to the control cultures, neither in the presence nor in the absence of metabolic activation. In addition, mutant frequencies of test item-treated samples were comparable to those of control cultures at all S9 mix concentrations tested. Therefore, an S9 concentration of 5 % was chosen as representative S9 concentration in the main mutagenicity assay.

The negative results were confirmed in the main mutagenicity experiment, in which none of the glyphosate treated samples showed a statistically significant increase in the number of mutant colonies, neither in the presence nor in the absence of metabolic activation. In addition, there was no statistically significant dose-response relationship.

Mutant frequencies of the medium control cultures remained low as expected, whereas the positive control mutagens ethylmethane sulfonate and benzo(a)pyrene yielded large increases in mutant frequencies, demonstrating the sensitivity of the test and the functionality of the S9 mix.

Based on the experimental findings and under the conditions of the test, glyphosate did not induce gene mutations in the HGPRT locus, neither in the presence nor in the absence of metabolic activation and is therefore considered negative for mutagenicity in mammalian cells *in vitro*.

I. MATERIALS AND METHODS

A: MATERIALS

1. **Test material:** Glyphosate

Identification:	Not specified
Description:	White powder
Lot/Batch number:	XHJ-64
Purity:	98.7 %
Stability of test compound:	The stability of the test item at storage conditions (at room temperature) or in the solvent (vehicle) was not specified.

2. **Control material:**

Negative control: Untreated cell cultures which were cultivated in cultivation medium only were included in each experiment.
Solvent (vehicle) control: As culture medium was used as solvent for the test item, the solvent control represents actually the negative control.
Positive control: - S9 mix: Ethyl methane sulphonate (EMS), 200 µg/mL
+ S9 mix Benzo(a)pyrene (B(a)P), 2 µg/mL

3. Metabolic activation:

S9 mix was purchased from [redacted]. The liver homogenate was produced from Aroclor 1254-induced rats and prepared before the experiment by mixing S9 fraction and co-factor as follows:

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.5)	50	mM
KCl	30	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADP	4	mM
$MgCl_2$	10	mg
$CaCl_2$	10	mM
S9*	5	% (v/v)

* In a preliminary experiment, the optimal S9 concentration was determined: 1, 2, 5 and 10 % (v/v) of S9 mix were added to the co-factor solutions. 5 % (v/v) of S9 fraction in the co-factor mix were used for the main mutagenicity study.

4. Test organism:

Chinese hamster ovary (CHO) cells (K1BH4) were used. The cells were routinely maintained as logarithmically growing monolayer cultures in Ham's F12 medium.

5. Cell culture media:

Cultivation medium: Ham's F12 medium, supplemented with 10 % newborn calf serum

Growth medium: Ham's F12 medium, supplemented with 10 % dialysed newborn calf serum

Treatment medium (± S9): *Ham's F12 medium*

Selection medium: Ham's F12 medium supplemented with 5 % dialysed newborn calf serum and 10 µM 6-thioguanine (6TG)

Incubation: *At 37.5 ± 2 °C, 5 % CO_2 and 95 % humidity*

6. Locus examined: Hypoxanthin guanine phosphoribosyltransferase (HGPRT)

7. Test concentrations and number of replicates:

(a) Preliminary cytotoxicity and mutagenicity test:

Metabolic activation	Duration of exposure	Concentrations	Replicates

±S9 mix	*3 h*	*5, 17.5 and 22.5 mg/mL*		*Duplicate*

(b) Main gene mutation test:

Metabolic activation	Duration of exposure	Concentrations	Replicates
-S9 mix	*3 h*	*2, 5, 10, 15 and 20 mg/mL*	*Duplicate*
+S9 mix	3 h	*5, 10, 15, 20 and 25 mg/mL*	Duplicate

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 21 Jun – 09 Sep 1983
Finalisation date: 20 Oct 1983

2. Preliminary cytotoxicity and mutagenicity test:

A preliminary test was performed to initially estimate the mutagenic potential of the test item and to identify the optimal S9 mix concentration.

Based on the results of an initial range-finding test (data not provided in study report), in which approximately 90 % cell-killing was observed in the range of 20 - 25 mg/mL, glyphosate concentrations in the range of 5 – 25 mg/mL were applied in the present preliminary cytotoxicity and mutagenicity test. The test item concentrations for the preliminary test were selected to yield approximately 100, 50 and 10 % relative survival of the cells.

The procedure of the preliminary test was the same as for the main mutation assay described below. The cells were treated under the same conditions as in the main mutagenicity assay at concentrations of 5, 17.5 and 22.5 mg/mL in the presence and absence of metabolic activation. To identify the optimal S9 mix concentration, 1, 2, 5 or 10 % of S9 mix were added to cultures with metabolic activation. Each two cultures per condition were exposed for 3 hours with and without S9 mix. Following exposure, cells were plated for determination of cell survival (cloning efficiency 1) and mutagenicity. Mutant cells were allowed for expression of the mutant phenotype for 7 - 9 days, followed by an 8 - 12 day selection period in 6-thioguanine-enriched medium. In addition, the cell viability (cloning efficiency 2) was determined for mutant cultures in the presence and absence of selection medium. Mutagenicity was assessed by calculation of the mutant frequency for all tested conditions.

Based on the results of the preliminary test, the five test item concentrations for the main mutagenicity assay were chosen to yield 100, 70, 50, 20 and 10 % cell survival at the optimal S9 mix concentration.

3. Main mutation assay:

Pre-treatment of cells:

For each test group, 0.5 x 10^6 cells per flask were seeded into 25 cm^2 flasks and incubated for 18 - 24 hours prior to treatment.

Treatment:

On the day of treatment, the medium was changed to serum-free treatment medium and, for treatment

with metabolic activation, 5 % S9 mix was added. The cells were exposed to glyphosate concentrations in the range of 2 - 20 mg/mL in the absence of S9 mix and to concentrations in the range of 5 – 25 mg/mL in the presence of S9 mix for 3 hours at 37.5 ± 2 °C. Solvent (medium) and the positive controls (ethylmethane sulfonate for cultures without S9 mix and benzo(a)pyrene for cultures with S9 mix) were included. After exposure, the cells were washed with Hank's Buffered Salt Solution (HBSS), trypsinised and counted. 200 cells per sample were seeded for the determination of survival (cloning efficiency 1) after the exposure period and 10^6 cells per sample were seeded to assess mutagenicity.

Expression period:
After treatment, 10^6 cells per culture were plated in 10 mL growth medium and incubated for an expression period of 7 - 9 days. The cells were sub-cultured every 2 - 3 days to maintain exponential growth during the expression time. After the expression period, each culture was divided. One aliquot of each culture was plated to determine the viability (cloning efficiency 2) of the cultures in the absence of selection medium, the other one was used for the selection of mutants.

Selection period:
For the selection of mutants, 10^6 cells of each post-expression culture were seeded into 100 mm plates (5 plates with 2 x 10^5 cells per culture) containing 8 mL of 6-thioguanine enriched selection medium. After an incubation period of 8 - 12 days, the developed colonies were fixed, stained and counted.

4. Cytotoxicity:

Cloning efficiency CE_1 (survival)
The survival (cloning efficiency 1) of glyphosate treated cells relative to solvent controls was determined in parallel to the mutagenicity test. At the end of the exposure period, a sample of each cell culture was collected to assess survival of the cells. 200 cells per culture were plated and re-incubated for 7 - 9 days. After the incubation period, the colonies developed were fixed, stained and counted.

Cloning efficiency CE_2 (viability)
The viability (cloning efficiency 2) was determined in parallel to the selection of mutants. After the expression period, 200 cells of each culture were plated in triplicates in selection medium without 6-thioguanine to assess cell viability. After an incubation period of 8 - 12 days, the developed colonies were fixed, stained and counted.

5. Evaluation:

Cytotoxicity (cloning efficiency CE)
The number of colonies divided by the number of cells plated was calculated for each sample. The absolute cloning efficiency was determined for each test group, as well as the relative cloning efficiency in comparison to the solvent control group.

CE_1 (survival)
The cytotoxicity of the test substance after the exposure period was determined for each test group and is indicated as absolute and relative cloning efficiency (CE_1 and RCE_1, respectively).

CE_2 (viability)
The cytotoxicity of the test substance at the end of the expression period was determined for each test group and is given as absolute and relative cloning efficiency (CE_2 and RCE_2, respectively).

The cloning efficiency (CE, %) was calculated for each test group as follows:

$$CE_{absolute} = \frac{\text{Total number of colonies}}{\text{Total number of cells plated}} \times 100$$

$$RCE_x = \frac{CE_{absolute} \text{ of the test group}}{CE_{absolute} \text{ of the vehicle control group}} \times 100$$

Mutant frequency (MF)
The cloning efficiency of mutant colonies in selective medium divided by the cloning efficiency in non-selective medium measured for the same culture at the time of selection was calculated for each sample.

Uncorrected mutant frequency:
The uncorrected mutant frequency (MF_{uncorr}) was calculated for each test group as follows:

$$\text{MF uncorrected} = \frac{\text{Total number of mutant colonies}}{\text{Number of seeded cells}} \times 10^6$$

Corrected mutant frequency
The corrected mutation frequency (MF_{corr}) was calculated regarding the values of CE_2:

$$\text{MF corrected} = \frac{\text{MF uncorrected}}{CE_2} \times 100$$

6. Statistics:
Mutagenicity data were analysed according to the statistical method of Snee and Irr (1981). Mutant frequency values were transformed according to the equation $Y = (X+1)^{0.15}$, with Y = transformed mutant frequency and X = observed mutant frequency. Student's t-test was then used to compare treatment data to solvent control data.

7. Acceptance criteria:
Acceptance criteria were not specified in the study report.

8. Evaluation criteria:
Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
In the preliminary cytotoxicity and mutagenicity test, glyphosate-related cytotoxicity was observed at all S9 concentrations tested. In both the preliminary and in the main mutagenicity experiment, the test material was shown to be cytotoxic at concentrations of 10 mg/mL and above.

C. SOLUBILITY
Information on precipitation or pH changes of glyphosate in the medium have not been provided in the study report.

D. MUTANT FREQUENCY
In the preliminary experiment, none of the samples treated with glyphosate exhibited a statistically significantly increased mutant frequency compared to the control cultures, neither in the presence nor in the absence of metabolic activation. In addition, mutant frequencies of test item-treated samples were comparable to those of control cultures at all S9 mix concentrations tested. Therefore, an S9 concentration of 5 % was chosen as representative S9 concentration in the main mutagenicity assay.

In the main mutagenicity experiment, there was as well no statistically significant increase in the number of mutant colonies upon treatment with glyphosate, neither in the presence nor in the absence of metabolic activation. In addition, there was no statistically significant dose-response relationship.

Mutant frequencies of the medium control cultures remained low as expected, whereas the positive control mutagens ethylmethane sulfonate and benzo(a)pyrene yielded large increases in mutant frequencies, demonstrating the sensitivity of the test and the functionality of the S9 mix.

III. CONCLUSION:

Based on the experimental findings and under the conditions of the test, glyphosate did not induce gene mutations in the HGPRT locus, neither in the presence nor in the absence of metabolic activation and is therefore considered negative for mutagenicity in mammalian cells *in vitro*.

3. **Assessment and conclusion**

Assessment and conclusion by applicant:

Negative for mutagenicity at the HGPRT locus in CHO cells with and without metabolic activation. This non-GLP study was performed equivalent to OECD 476 (2016). Although a number of deviations became evident when compared with the currently valid guideline, these were considered to be of minor degree and to not compromise the validity of the study. Therefore, the study is considered valid and acceptable.

Assessment and conclusion by RMS:

DNA damage and repair

Seven studies investigating glyphosate in *in vitro* DNA repair assays are available. Two of these studies (CA 5.4.1/033 and CA 5.4.1/035) are considered as supportive data, the remaining studies are considered invalid for use in the evaluation of glyphosate genotoxicity. These assays are no longer a data requirement and either have no OECD guideline or the OECD guideline was deleted in 2014. However, none of these studies show any adverse activity associated with glyphosate and therefore provide supportive evidence assessment that glyphosate is not genotoxic.

Table 5.4.1-50: Summary of *in vitro* genotoxicity testing with glyphosate acid: DNA damage and repair

Annex Point	Study	Study type Test system	Substance Dose levels Exposure Metabolic activation Purity	Status	Result
CA 5.4.1/033	[redacted], 1994	UDS assay Primary rat hepatocytes (Sprague-Dawley)	Glyphosate 0.20 - 48.98 mM (1st exp.) and 1.14 - 111.69 mM (2nd exp.) Exposure: 18 h Purity: > 98 %	Supportive, Category 2a	negative
CA 5.4.1/034	[redacted], 1983	UDS assay Primary rat hepatocytes (Fischer 344)	Glyphosate 0.0125 - 125 µg/mL Exposure: 18 - 20 h Purity: not reported	Invalid, Category 3b	negative
CA 5.4.1/035	[redacted], 1995	Rec assay *B. subtillis* strains H17 and M45	Glyphosate 7.5 - 240 µg/disk ± S9 Exposure: 24 h Purity: 95.68 %	Supportive, Category 2a	negative
CA 5.4.1/036	[redacted] 1978	Rec assay *B. subtillis* strains H17 and M45	Glyphosate 20 - 2000 µg/disk - S9 Exposure: over night Purity: 98.4 %	Invalid, Category 3b	negative

SCE: Sister chromatid exchange

1. Information on the study

Data point	CA 5.4.1/033
Report author	[redacted]
Report year	1994
Report title	DNA repair test with primary rat hepatocytes
Report No	931564
Document No	Not reported
Guidelines followed in study	OECD 482 (1986)
Deviations from current test guideline	Not applicable. OECD 482 was deleted in 2014. When compared to the previous OECD 482 (1986), several deviations became evident. Instead of autoradiography or liquid scintillation counting procedures, incorporation of radioactivity into the DNA was determined based on UV absorbance and mathematical calculations. According to OECD 482 (1986) at least two cell cultures per condition are required. In the current study only one culture per condition was tested. However, a second experiment at concentrations in a similar range was conducted. As no individual value of glyphosate treated cultures at all showed an increase in ^{3}H-dCyd, this deviation seems to not compromise the validity of the study.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate (batch: F/93/032, purity > 98 %) was tested in primary rat hepatocytes *in vitro* for its ability to induce unscheduled DNA synthesis (UDS) according to the bromodeoxyuridine density shift method. Hepatocytes were isolated from the livers of adult male Sprague-Dawley rats and used for two separate experiments. Based on the results of a preliminary solubility and cytotoxicity test (data not provided in the study report), appropriate glyphosate concentrations were selected for the UDS assay.

In both experiments, freshly isolated hepatocytes were exposed to test item concentrations in the range of 0.20 – 48.98 mM (first experiment) and 1.14 – 111.69 mM (second experiment) in the presence of tritiated deoxycytidine (^{3}H-dCyd) and bromodeoxyuridine (BrdUrd). Medium and positive controls (dimethylnitrosamine (DNM) and 2-acetamidofluorene (2-AAF)) were included in each experiment. After 18 hours of incubation, the cells were lysed, nucleated DNA was extracted and the replicated, BrdUrd containing DNA as well as the repaired ^{3}H-dCyd and BrdUrd containing DNA were separated by centrifugation on an alkaline cesium salt gradient. Repaired and replicated DNA was quantified by measuring the incorporated radioactivity. Genotoxicity was evaluated based on the induction of DNA repair and expressed as incorporated ^{3}H-dCyd per µg DNA, whereas cytotoxicity was assessed based on the degree of inhibition of replicative DNA synthesis (incorporated BrdUrd per µgDNA).

Precipitation of the test substance in medium, as well as cytotoxic effects were observed at 111.69 mM in the second experiment only. Treatment with glyphosate did not induce a significant increase in DNA repair above those of control conditions in none of the experiments at any tested concentration. Incorporation of

^{3}H-dCyd of the medium control was within the normal range of control data, while the two positive controls DNM and 2-AAF showed a significant increase in ^{3}H-dCyd incorporation, confirming the responsiveness and metabolic activity of the test system.

Under the conditions of the test, glyphosate did not induce unscheduled DNA synthesis in primary rat hepatocytes *in vitro*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate

Identification:	Not specified
Description:	Not specified
Lot/Batch number:	F/93/032
Purity:	> 98 %
Stability of test compound:	The stability of the test item at storage conditions (light protected, at 20 – 25 °C) or in solvent was not specified.

2. Control material:

Negative control:	Untreated cell cultures which were cultivated in cultivation medium only were included in each experiment.
Solvent (vehicle) control:	As culture medium was used as solvent for the test item, the solvent control represents actually the negative control.
Positive controls:	Dimethylnitrosamine (DMN, 10 mM) and 2-acetamidofluorene (2-AAF, 0.2 mM)

3. Hepatocyte isolation:

Primary rat hepatocytes were obtained by *in situ* collagenase perfusion from the livers of a single adult male Sprague-Dawley rat weighing approximately 200 – 350 g. The liver was perfused with a Ca^{2+}-free modified Hank's solution containing 500 µM EGTA, continued by the same Ca^{2+}-free solution without EGTA. Finally, the liver was perfused with Dulbecco's modified Eagle's medium (DMEM) including Ca^{2+} and collagenase (0.13 U/mL) and harvested. After filtration through a nylon mesh gauze, the cells were washed in DMEM three times and the viability was determined by trypan blue exclusion. Only hepatocyte preparations with a viability > 80 % were used.

4. Cell culture:

Cell culture establishment:	Freshly isolated hepatocytes were seeded in plating medium at a density of 6 x 10^6 cells in 75 cm^2 flasks, incubated and allowed to attach for 2 hours. Afterwards, the cells were washed twice with pre-warmed salt solution prior to treatment.
Plating medium:	William's medium E, supplemented with 10 % fetal calf serum, 100 U/mL penicillin and 100 µg/mL streptomycin
Pre-treatment medium:	*William's medium E, supplemented with 40 µM fluorodeoxyuridine (FdUrD) and 200 µM Bromodeoxyuridine (BrdUrd)*
Treatment medium:	*William's medium E, supplemented with 40 µM FdUrD, 200 µM BrdUrd and 10 µCi/mL ^{3}H-*

	deoxycytidine (^{3}H-dCyd)
Incubation:	*Not specified*

5. Test concentrations:

Experiment	Concentrations
First experiment:	0.20, 0.61, 1.81, 5.44, 16.32 and 48.98 mM
Second experiment:	1.14, 3.41, 10.23, 30.69, 92.08 and 111.69 mM

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 01 Feb – 18 Mar 1994
Finalisation date: 28 Mar 1994

2. Cytotoxicity

A preliminary dose-range finding test was not conducted as part of the described study. However, solubility and cytotoxicity have been examined in a pre-test (data not provided in study report), which enabled the selection of the test item concentrations for the UDS assay. In the present study, cytotoxicity was estimated based on the degree of inhibition of replicative DNA synthesis.
The degree of cytotoxicity was therefore determined as part of the genotoxicity test (described below), indicated by a reduction in the incorporation of radioactivity in semiconservatively replicated (dense) DNA strands.

3. Unscheduled DNA synthesis

Cell treatment and harvest:
After cell culture establishment, the cells were incubated in pre-treatment medium containing fluorodeoxyuridine(FdUrD) and BrdUrd for one hour. Following pre-incubation, the medium was exchanged to treatment medium containing additionally ^{3}H-dCyd.

Two independent experiments were performed in parallel, using hepatocytes from the same animal. The cells were exposed to test item concentrations in the range of 0.20 – 48.98 mM (first experiment) and 1.14 – 111.69 mM (second experiment). Medium and positive control cultures (10 mM dimethylnitrosamine and 0.2 mM 2-acetamidofluorene) were included in each experiment.

After 18 hours of incubation, the cells were washed with phosphate buffered saline, lysed with sodium dodecylsarcosine and digested with proteinase K.

Preparation of DNA and determination of radioactivity:
The DNA was precipitated with ethanol, dried and stored at -80 °C. DNA pellets were dissolved and centrifuged to equilibrium in alkaline $CsCl/Cs_2So_4$ gradients at 20 °C for 16 hours. Following centrifugation, the lower half of each gradient was removed. The remaining part containing parental DNA strands was mixed with $CsCl/Cs_2SO_4$ rebanded by centrifugation. After fractionation of the gradients, the UV absorbance and the acid precipitable incorporated radioactivity were determined for each fraction.

Evaluation:
Repair synthesis (cpm/µg DNA) was estimated from the gradient profiles by calculating the radioactivity incorporated into light (parental) DNA, i. e. by integrating the radioactivity binding

exactly coincident with the UV-absorbance peak, and dividing it by the amount of parental DNA. DNA was quantitated by integrating the UV-absorbance peak and converting it into DNA by means of a calibration curve. Normal (semiconservative) DNA synthesis (cpm/µg DNA) was determined from the gradient profiles as radioactivity incorporated into dense DNA.

4. Statistics:
Statistical analysis was not performed in the study.

5. Acceptance criteria:
Acceptance criteria were not defined in the study report.

6. Evaluation criteria:
A substance was considered genotoxic if it produced a reproducible and significant dose-related increase in radiolabel incorporation. A substance was considered non-genotoxic if it produced neither a significant, dose-related increase in ^{3}H incorporation, nor a reproducible positive response at any test point.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not required by the test guideline.

B. CYTOTOXICITY
Cytotoxicity, indicated by inhibition of replicative DNA synthesis, was observed in the second experiment only at a glyphosate concentration of 111.69 mM (refer to Table 5.4.1-51).

C. SOLUBILITY
Precipitation of the test item in culture medium was observed at the highest concentration of 111.69 mM.

D. UNSCHEDULED DNA SYNTHESIS
There was no significant increase in ^{3}H-dCyd incorporation for glyphosate treated hepatocytes when compared to control levels observed, in any experiment and at any tested concentration.

Radiolabel incorporations of ^{3}H-dCyd in the untreated medium control cultures were within the variability of the control values of individual experiments. The two positive compounds DMN and 2-AAF markedly enhanced DNA repair in the hepatocytes, confirming the responsiveness and metabolic activity of the test system.

2-AAF [0.2 mM]	728.5	829.9

2-AAF: 2-acetamidofluorene; DMN: Dimethylnitrosamine
[#] Mean value of 2 replicates, calculated based on raw data given in study report

III. CONCLUSION:

Under the conditions of the test, glyphosate did not induce any increase in tritiated cytidine incorporation more than 10 % when compared to control values. Thus, glyphosate did not induce DNA damage leading to unscheduled DNA synthesis in primary rat hepatocytes *in vitro*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for unscheduled DNA synthesis in primary rat hepatocytes *in vitro*.

The study was performed under GLP conditions and in accordance with OECD guideline 482 (1986), which was deleted in 2014. As the Unscheduled DNA Synthesis (UDS) assay is no longer a standard method described by current guidelines, the study was considered to provide supporting information. When compared to OECD guideline 482 (1986), a number of deviations became evident, all of them of minor degree and not compromising the validity of the study.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/034
Report author	[redacted]
Report year	1983
Report title	The hepatocyte primary culture / DNA repair assay on compound JJN-1020 using rat hepatocytes in culture
Report No	AH-83-181
Document No	M-645649-01-1
Guidelines followed in study	Similar to OECD 482 (1986)
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate (batch: XHJ-64, purity not specified) was tested for unscheduled DNA synthesis (UDS) in primary rat hepatocytes *in vitro*. Hepatocytes were isolated from the livers of adult male F344 rats and triplicate cultures per condition were exposed to test item concentrations in the range of 0.0125 to 125 µg/mL in medium supplemented with radiolabeled tritiated thymidine (^{3}H-TdR). Medium, solvent (DMSO and 0.1 N NaOH), negative (50 µM pyrene) and positive controls (50 µM benzo(a)pyrene) were tested in parallel. After 18 - 20 hours of incubation at 37 °C, the cells were processed for slide preparation and autoradiographs developed. Cytotoxicity was assessed by the absence of S-phase cells in the autoradiographs and by morphology. Unscheduled DNA synthesis was quantified by determining the net increase in nuclear grain counts induced by the test item or corresponding controls in a total of 20 - 80 cells per culture.
Short description of results:	Precipitation of the test item in culture medium was not reported and there was no cytotoxicity observed up to the highest tested concentration of 125 µg/mL. Glyphosate did not induce a significant increase in the mean number of net nuclear grain counts when compared to solvent controls at any of the tested concentrations. The values obtained with the solvent and negative controls were in the expected range, whereas the positive control B(a)P significantly increased the number of mean net nuclear grain counts, thus demonstrating the sensitivity of the test system towards DNA damaging substances. Based on the experimental findings and under the conditions of the test, glyphosate did not induce unscheduled DNA synthesis indicated by DNA repair activity in primary rat hepatocytes *in vitro*.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was not conducted under GLP. The corresponding OECD 482 (1986) was deleted in 2014. When compared to OECD 482 (1986), a number of deviations became evident. The selection of test concentrations was not justified in the study report and the highest concentration tested did not cause cytotoxicity. In addition, there is no information on the test items analytical purity. According to OECD 482 (1986) at least 50 cells per culture should be counted and evaluated for nuclear grain counts. In the present

	study, 20 -80 cells per culture were evaluated. A confirmatory experiment was performed, but raw data of the repeat assay were not included in the study report. The study is therefore considered not acceptable.
Reasons why the study report is not available for submission

2. Full summary

The DNA-damaging activity of glyphosate (HR-001, batch: 940908-1, purity: 95.68 %) was investigated in an DNA repair test with *Bacillus subtilis* strains H17 and M45. In a well diffusion assay, the bacteria were exposed to test item concentrations in the range of 7.5 to 240 µg/disk in the presence and absence of metabolic activation (phenobarbital and 5,6 benzoflavone-induced rat liver S9 fraction). Each concentration was tested in duplicates.

Vehicle (sterile water), negative (kanamycin) and positive controls (mitomycin c without S9 mix and 3-amino-1,4-dimethyl-5H-pyrido [4,3-b] indole (Trp-p-1) in the presence of S9 mix) were included. After an incubation time of 24 h at 37 °C the diameter of the growth inhibition zone was measured for each strain.

Precipitation of the test item was not reported.

A relevant growth inhibition of bacteria strains H17 (rec^+) or M45 ($recE^-$) was not observed at any tested condition, neither in the presence, nor in the absence of metabolic activation. Although a growth inhibition zone of 1 mm diameter was noted at the highest test concentration of 240 µg/disk in strain M45 in the absence of metabolic activation, the differences of growth inhibitory zones between the strains H17 and M45 were 1 mm or less. There was no growth inhibition in strain M45 in the presence of S9 mix nor in strain H17 in the presence or absence of S9 mix.

Positive, negative and vehicle controls showed the expected results and demonstrated the validity of the test system and the functionality of the S9 mix.

Based on the results of the present study, glyphosate technical has no DNA-damaging activity in bacteria.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate

Identification:	HR-001
Description:	Solid crystals
Lot/Batch #:	940908-1
Purity:	95.68 %
Stability of test compound:	The stability of the test item at storage conditions (in a dark cold room at approx. 5 °C) or in the solvent (vehicle) were not specified.
Solvent (vehicle) used:	Sterile water

2. Control materials:

Negative control:	Kanamycin, 0.2 µg/disk
Solvent (vehicle) control:	Sterile water
Solvent (vehicle) /final concentration:	20 µL/disk
Positive controls:	- S9 mix: Mitomycin C, 0.01 µg/disk + S9 mix: 3-amino-1,4-dimethyl-5H-pyrido [4,3-b] indole (Trp-p-1), 5 µg/disk

3. Metabolic activation:

S9 mix was purchased from [redacted] ([redacted]; Lot no. RAA-314). The homogenate was produced from the livers of 7 weeks old male Sprague-Dawley rats, weighing 188 – 238 g, that received intraperitoneal injections of phenobarbital (30 mg/kg bw on Day 1, each 60 mg/kg bw on Days 2, 3 and 4) and 80 mg/kg bw 5,6 benzoflavone on Day 3. The S9 mix was prepared immediately before the experiment by mixing S9 fraction and co-factor.

S9 mix component	Concentration	Unit
Sodium phosphate buffer (pH 7.4)	100	mM
KCl	33	mM
NADPH-generating system		
Glucose 6-phosphate	5	mM
NADH	4	mM
NADP	4	mM
$MgCl_2$	8	mM
S9	1	% (v/v)

4. Test organisms:

Tester strains			
B. subtilis		**Bacteria batch checked for**	
Recombination wild (rec^+) H17	✓	UV-light sensitivity (recE)	✓
Recombination deficient ($recE^-$) M45	✓	Response to negative and positive control chemicals	✓

5. Test concentrations:

Diffusion assay ± S9 mix:		
Concentrations:	*7.5, 15, 30, 60, 120 and 240 µg/disk*	
Tester strains:	H17, M45	
Replicates:	*Duplicates in a single experiment*	

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 14 – 15 Feb 1995
   Finalisation date: 14 Mar 1995

2. **Diffusion assay**

0.1 mL pre-cultured bacterial suspension (3 x 10^7 cells/mL), 5 mL molten B2 top agar and, in experiments with metabolic activation, 0.05 mL of S9 mix were mixed uniformly in an 90 mm petri dish and the agar plates were left at room temperature for solidification. Paper discs (8 mm diameter) impregnated with 20 µL test solution, positive, negative or vehicle control were placed on the prepared spore agar plate. Each concentration was tested in duplicates. After an incubation time of 24 h at 37 °C the diameter of the growth inhibition zone was measured for each strain.

3. **Statistics**

Results were judged without statistical analysis.

4. **Acceptance criteria**

The test was valid if

- Growth inhibition was not observed in solvent controls of either strain.
- For the positive control, the growth inhibitory zone in strain M45 was larger than the zone in strain H17 and the difference in diameter was ≥ 5 mm.
- For the negative control, the difference in diameter of growth inhibitory zone between the strains was ≤ 4 mm.

5. **Evaluation criteria**

In case the test item caused growth inhibition in at least one strain, results were judged positive when the following criteria were met:

- The growth inhibitory zone of M45 was larger than that of H17 and
- The difference in diameter was 5 mm or more at one or more dose levels that caused growth inhibitory zones with diameters of 4 mm or less in the H17 strain.

If a positive result was obtained, a re-test was conducted to confirm the reproducibility of the positive result.

Results were judged negative when the test substance causes no growth inhibition in either strain.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required for this type of *in vitro* study.

B. SOLUBILITY

Precipitation of the test substance was not reported.

C. MUTATION ASSAY

A relevant growth inhibition of bacteria strains H17 (rec$^+$) or M45 (recE$^-$) was not observed at any tested condition, neither in the presence, nor in the absence of metabolic activation. Although a growth inhibition zone of 1 mm diameter was noted at the highest test concentration of 240 µg/disk in strain M45 in the absence of metabolic activation, the differences of growth inhibitory zones between the strains H17 and M45 were 1 mm or less. There was no growth inhibition in strain M45 in the presence of S9 mix or in strain H17 in the presence nor absence of S9 mix.

Negative controls treated with kanamycin induced growth inhibition zones with differences between 2 - 3 mm between M45 and H17, while positive controls treated with mitomycin C (-S9 mix) or Trp-p-1 (+S9 mix) caused large growth inhibitory zones with differences in diameter of 19 and 11 - 12 mm.

Table 5.4.1-52: DNA Repair Test (Rec-Assay) ([redacted], 1995)

Compound	Dose (µg/disk)	S9 fraction (-)			S9 fraction (+)		
		Inhibitory zone* (mm)		Difference** (mm)	Inhibitory zone* (mm)		Difference** (mm)
		M45	H17		M45	H17

		20	1	19			
Positive control (Trp-p-1)	5				11	0	11
					12	0	12

Trp-p-1: 3-amino-1,4-dimethyl-5H-pyrido [4,3-b] indole, positive control in the presence of S9 mix

III. CONCLUSION

According to the results of the present study and under the experimental conditions chosen, the test item does not show DNA-damaging activity in the DNA repair test (Rec-Assay) in the presence or absence of metabolic activation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for genotoxicity in bacteria (*B. subtilis* H17 and M45) with and without metabolic activation. The study was conducted under GLP conditions and according to US EPA FIFRA guidelines subdivision F. It was considered to provide supplementary information only because the Rec assay is not a standard method for this endpoint (DNA damage and repair). Furthermore, the dose selection was not explained and viability data were not included in the study report.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/036
Report author	[redacted]
Report year	1978
Report title	The report of mutagenic study with bacteria for CP67573
Report No	ET-78-241
Document No	Not reported
Guidelines followed in study	No guideline followed, the study was conducted similar to U.S. EPA FIFRA Guidelines, Subdivision F
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	The DNA-damaging activity of glyphosate (CP67573, batch: XHJ-46, purity: 98.4 %) was investigated in a DNA repair test with *Bacillus subtilis* strains H17 and M45. In a single experiment, the two bacterial strains were exposed to the test item at concentrations in the range of 20 – 2000 µg/disk. Solvent (water), negative (kanamycin, 10 µg/disk) and positive controls (mitomycin C, 0.1 µg/plate were included in the experiment. After overnight incubation at 37 °C, the growth inhibitory zones were measured for both strains.
Short description of results:	Precipitation of the test item was not investigated. Treatment with CP67573 did not induce any inhibitory zone in any of the two tester strains at any tested concentration. Solvent controls showed the expected results and negative controls treated with kanamycin induced growth inhibition zones of similar lengths in both strains. The positive control mitomycin C caused a marked difference in the length of the inhibitory zones, demonstrating the functionality of the test. Based on the results of the present study, glyphosate was negative for DNA-damaging activity in bacteria.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was not conducted under GLP and not according to current testing guidelines. The test was performed in the absence of S9 mix only and no viability data (actual plate count) were provided. In addition, there were some reporting deficiencies. The study is therefore considered not acceptable.
Reasons why the study report is not available for submission	
Category study in AIR5 dossier (L-docs)	Category 3b

1. Information on the study

Data point:	CA 5.4.1/037
Report author	[redacted]
Report year	1993 (Finalisation of the English translation of report 87BME014

	in Chinese language dated 03 Mar 1987)
Report title	Mutagenicity evaluation of glyphosate in *Escherichia coli.* DNA repair (poly A^+/A^-) assay.
Report No	87BME014-E
Document No	Not reported
Guidelines followed in study	No guideline followed. The study was conducted according to the main criteria of U.S. EPA FIFRA Guidelines, Subdivision F.
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	A DNA damage repair ($polA^+$/ $polA^-$) assay in *E. coli* strains W3110 ($polA^+$) and p3478 ($polA^-$) was performed to detect the mutagenic potential of glyphosate isopropylamine salt (code: SN-750721, purity: 64 %) on DNA damage level. In a single experiment with five replicates per condition, both bacterial strains were exposed to test item concentrations in the range of 0.1 – 10000 µg/mL. Solvent and positive controls (methyl methanesulfonate, 10 µL/disk) were included. After 48 hours of incubation at 37 °C, the length of inhibition zones around the disk was determined for both strains.
Short description of results:	Precipitation was not investigated in the study report. At the highest concentration of 10000 µg/mL, there was a strong growth inhibition observed in both strains, with a statistically significantly increased inhibition zone in strain p3478 ($polA^-$) when compared to strain W3110 ($polA^+$). There was no growth inhibition observed at lower test item concentrations. The solvent and positive control showed the expected results, demonstrating the sensitivity of the test. As growth inhibition induced by the test item was observed at one concentration only, the test result did not match the evaluation criteria for a positive result. Although growth inhibition was observed at the top dose level, the result was not confirmed in an independent experiment. Therefore, the test substance was considered equivocal for mutagenicity on DNA-damage level.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was not conducted under GLP and not according to current testing guidelines. The test was performed in the absence of metabolic activation only and no viability data (actual plate count) were provided. In addition, the title is misleading because not glyphosate acid but the isopropylamine salt has been tested. It is not clear whether the given purity refers to the contents of glyphosate in the formulation or the salt. A confirmatory experiment was not conducted even though there was some inhibition of cell growth at the top dose level. The study is therefore considered not acceptable.
Reasons why the study report is not available for submission	
Category study in AIR5 dossier (L-docs)	Category 3b

1. Information on the study

Data point:	CA 5.4.1/038

Report author	[redacted]
Report year	1993 (Finalisation of the English translation of report 87BMS013-E in Chinese language dated 03 Mar 1987)
Report title	Mutagenicity Evaluation of Glyphosate in Sister Chromatid Exchange Assay (SCE Test)
Report No	87BMS013-E
Document No	Not reported
Guidelines followed in study	No guideline followed. The study was conducted similarly to OECD 479 (1986)
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate isopropylamine salt (code: SN-750721, purity: 64 %) was tested in a sister chromatid exchange assay in Chinese hamster ovary (CHO) cells in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver S9 fraction). Untreated, solvent (DMSO) and positive controls (3.14 mM ethylmethane sulfonate without S9 mix and 0.01 mM cyclophosphamide with S9 mix) were included. A single experiment was performed. Duplicate cultures were exposed to test item concentrations in the range of 0.1 – 100 µg/mL for 1 hour, followed by 22 hours of incubation in the presence of 5-bromo-2-deoxyuridine. After 24 hours of incubation, the cells were harvested and a total of 30 metaphase cells per culture was scored for sister chromatid exchanges (SCEs) per chromosome.
Short description of results:	Cytotoxicity and solubility / precipitation were not investigated in the present study. Treatment with glyphosate isopropylamine salt did not induce a statistically significant increase in the frequency of SCEs per chromosome up to the highest tested concentration, neither in the presence nor in the absence of S9 mix. SCE frequencies of the untreated and solvent controls matched the acceptability criteria. A strong increase in the frequency of SCEs was noted for the positive control compounds, showing the activity of the S9 mix and demonstrating the sensitivity of the test. Under the experimental conditions reported, the test item was considered negative for sister chromatid exchange in CHO cells *in vitro*, with and without metabolic activation.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was not conducted under GLP and not according to current testing guidelines. In addition, it is not clear whether the given purity refers to the contents of glyphosate in the formulation or the salt. The study is therefore considered not acceptable.
Reasons why the study report is not available for submission

1. Information on the study

Data point:	CA 5.4.1/039

Report author	[redacted]
Report year	1990
Report title	Agrichem glyphosate active: OECD 479 sister chromatid exchange in human lymphocytes *in vitro*
Report No	300/2
Document No	Not reported
Guidelines followed in study	OECD TG 479 (1986)
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate active (batch: 0190A, purity: not reported) was tested in a sister chromatid exchange assay in human lymphocytes (lymphocyte preparation not further specified). The cells were exposed to the test item, solvent (medium) or positive controls (ethyl methane sulfonate, 500 µg/mL without S9 mix and cyclophosphamide, 20 µg/mL with S9 mix) in the presence and absence of metabolic activation (Aroclor 1254-induced rat liver fraction). A single experiment was performed. Duplicate cultures were exposed to test item concentrations in the range of 78.125 – 2500 µg/mL in medium containing bromodeoxyuridine (BrdU). In the presence of S9 mix, the cells were exposed for 2 hours, followed by re-incubation in test substance-free medium for further 22 hours. In the absence of S9 mix, the cells were exposed for 24 hours. Afterwards, the mitotic cells were collected and prepared for staining. A total of 25 metaphase cells per culture (50 per condition) were scored for sister chromatid exchanges (SCE) per cell and per chromosome.
Short description of results:	Precipitation of the test substance in medium was not reported. Cytotoxicity (absence of metaphases) was observed at 1250 and 2500 µg/mL in the presence and absence of metabolic activation. Based on these findings, 625 µg/mL was selected as highest concentration for the evaluation of SCE. Treatment with glyphosate active did not induce a statistically significant, dose-related increase in the frequency of SCE per cell or per chromosome, neither in the presence, nor in the absence of metabolic activation. SCE values for the solvent and positive controls showed the expected results, indicating that the metabolic activation system was functional and demonstrating the sensitivity and validity of the test system. Under the conditions of the test, glyphosate active did not induce SCE in human lymphocytes *in vitro*, neither with nor without S9 mix.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable as only a single experiment was performed and the negative test result was not confirmed in an independent experiment. In addition, the purity of the test material was not stated. Furthermore, there were some reporting deficiencies, as lymphocyte preparation was not described in detail (remaining uncertainty about exposure of isolated lymphocytes or whole blood cell culture). The study is therefore considered invalid.
Reasons why the study report is not available for submission

CA 5.4.2 *In vivo* studies in somatic cells

Thirteen *in vivo* micronucleus studies have been conducted with glyphosate, one conducted in the rat (CA 5.4.2/014) and the remaining studies conducted in the mouse (Table 5.4.2-1). Although three of the mouse studies are considered invalid and a further two as supportive only, the remaining studies (including the study in rats) are considered to provide a robust assessment of glyphosate mutagenicity *in vivo*. Seven of the nine valid studies (and also the five invalid or supportive only studies) summarized below are clearly negative; administration of glyphosate to rats or mice did not induce any increases in micronuclei. Very weak increases in micronuclei were reported in only two studies: CA 5.4.2/010 ([redacted], 1993) and CA 5.4.2/007 [redacted], 2006). CA 5.4.2/010 ([redacted], 1993) was reviewed in the 2001 EU glyphosate evaluation and it was concluded that the result of this study was unlikely to be relevant because the effect was only seen in females (usually the less sensitive sex in a micronucleus test) and the variation in the % of polychromatic erythrocytes with micronuclei was considerably high among female dose groups compared to controls, whereas the results in the male groups were much more homogeneous. In addition, in a chromosome aberration study conducted in the same laboratory, under nearly identical conditions using the same doses and test material, did not provide any evidence of chromosome aberrations but did indicate a certain degree of cytoxicity at the highest dose level to bone marrow cells. In CA 5.4.2/007 ([redacted], 2006), a small but statistically significant increase in micronuclei was observed at the highest dose but only at the 24 hour sample (48 hour data were clearly negative). The increase in micronuclei was within the range of the laboratory's historical control data and was accompanied by a reduction in the target cells (polychromatic erythrocytes), thus indicating that the increase in micronuclei was the consequence of a haematopoetic response to bone marrow toxicity rather than to a specific genotoxic effect.

Two *in vivo* chromosome aberration studies have been conducted with glyphosate, one was performed in mice by oral gavage and one performed in rats by intraperitoneal (IP) injection. Although both studies are considered as supportive only, due to deficiencies when compared with OECD 475 (2016) they provide further evidence that glyphosate is not clastogenic *in vivo*.

The overwhelming weight of evidence from this large database of *in vivo* somatic cell mutagenicity studies is that glyphosate is not genotoxic to rodents. These studies were conducted in rats and mice using two different administration routes (oral gavage and IP injection) and there are several lines of evidence that demonstrate exposure to the bone marrow (thus validating the negative conclusions).

1. Section 5.1 of MCA 5 confirms that following oral administration of glyphosate to rats, there is rapid absorption from the gastrointestinal tract and subsequently approximately 20 % of administered glyphosate is systemically available. Furthermore, radiolabel studies confirmed the presence of glyphosate in the bone and bone marrow following oral administration (CA 5.1.1/011 and CA 5.1.1/006)
2. Evidence of bone marrow toxicity was observed in three mouse studies (CA 5.4.2/004: IP injection, CA 5.4.2/007: IP injection; CA 5.4.2/015: oral gavage)
3. Several studies were conducted using IP injection, thus ensuring high systemic exposure, and the doses tested caused clinical signs of toxicity consistent with systemic exposure.

Furthermore, the lack of any convincing evidence of glyphosate genotoxicity *in vivo* is consistent with the clear negative conclusions for *in vitro* genotoxicity. It can be concluded that the glyphosate active ingredient does not pose any mutagenic, clastogenic, or aneuploidy risk to humans.

Table 5.4.2-1: Summary of *in vivo* cytogenicity testing with glyphosate acid

Micronucleus tests in the bone marrow of mice *in vivo*:

1. Information on the study

Data point	CA 5.4.2/001
Report author	[redacted]
Report year	2012
Report title	Glyphosate TGAI: Micronucleus test of glyphosate TGAI in mice.
Report No	485-1-06-4696
Document No	DR-0112-6927-003
Guidelines followed in study	OECD 474 (1997), US EPA OPPTS 870.5395 (1998), EC 440/2008 B.12 (2008)
Deviations from current test guideline OECD 474 (2016)	According to the current guideline OECD TG 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study only 2000 polychromatic erythrocytes were evaluated, since that was required in the previous OECD guideline (1997). In addition, the percentage of polychromatic erythrocytes among total erythrocytes was determined for 200 erythrocytes instead of 500

	erythrocytes. Bone marrow exposure, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, was not confirmed and there was no systemic toxicity observed, but dose levels included limit concentrations specified in the current guideline. In addition, the evaluation criteria specified in the study report did not consider historical control data of solvent controls.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate TGAI (TSN105914, batch: 20061109, purity: 98.9 %) was assessed for its genotoxic potential in a micronucleus test. Based on the results of a preliminary toxicity study, in which no systemic toxicity was observed at 2000 mg/kg bw/day, groups of six male mice were treated with a limit dose of 2000 mg/kg bw/day for two consecutive days. The test item was dissolved in vegetable oil and administered by oral gavage at a constant dosage volume of 10 mL/kg bw. In addition, 6 male mice were treated with the solvent under the same experimental conditions or received a single intraperitoneal injection of the positive control (1.0 mg/kg bw/day mitomycin C).

Mortality, clinical signs of toxicity and individual body weights were monitored. 24 hours following the last dose, the animals were sacrificed and bone marrow smears were prepared. For each animal, a minimum of 2000 polychromatic erythrocytes (PCE) was scored for the presence of micronuclei. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was recorded from a minimum of 200 erythrocytes.

Treatment with 2000 mg/kg bw/day glyphosate TGAI did not induce any clinical signs of systemic toxicity and no changes in body weight. Furthermore, there was no statistically significant difference in the ratio of PCE/NCE, confirming that the test item did not induce bone marrow toxicity in the animals.
In addition, there was no statistically significant increase in the frequency of micronucleated PCE in glyphosate TGAI-treated mice when compared with the solvent control group.

Incidences of micronucleated PCE in the solvent and positive control groups were within the range of the laboratory's historical control data, demonstrating the capability of the test animals to respond to mutagenic substances and confirming the sensitivity of the test.

Based on the experimental findings and under the conditions of the test, glyphosate TGAI has no potential to induce micronuclei in the bone marrow of Swiss albino mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate TGAI

Identification:	TSN105914
Description:	White to off-white crystals
Lot/Batch #:	20061109
Purity:	98.9 %
Stability of test compound:	The stability of the test item at storage conditions was guaranteed until the expiry date 20 Apr 2014. The stability of the test item in solvent was not specified.
Solvent (vehicle) used:	Vegetable oil

2. Control materials

Solvent (vehicle) control:	Vegetable oil
Positive control:	Mitomycin C, 1 mg/kg bw/day

3. Test animals:

Species:	Mouse
Strain:	NMRI
Sex:	Males
Source:	[redacted]
Age at dosing:	8 - 9 weeks
Mean weight at dosing:	35 – 50 g
Acclimation period:	6 days
Diet/Food:	Teklad Certified Global 16 % Protein Rodent Diet, *ad libitum*
Water:	UV sterilized drinking water, filtered through a reverse osmosis water filtration system, *ad libitum*
Housing:	In groups of 6/cage polypropylene mouse cages measuring 29 x 37.5 x 14 cm with stainless steel grid top and clean rice husk bedding

4. Environmental conditions:

Temperature:	19 - 22 °C
Humidity:	64 – 65 %
Air changes:	Minimum 15/hour
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels:	2000 mg/kg bw
Concentrations:	Not specified
Dose volume:	Not specified
Number of animals:	3/sex
Route of administration:	Oral gavage

b) Main micronucleus test

Dose levels:	2000 mg/kg bw/day
Concentrations:	200 mg/mL
Dose volume:	10 mL/kg bw
Number of animals:	6 males/group
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 28 May – 07 Aug 2012
Finalisation date: 13 Sep 2012

2. Animal assignment and treatment:

Preliminary toxicity study:
A dose range finding study was conducted to determine the maximum tolerated dose (MTD). Three male and three female mice were treated at the dose level of 2000 mg/kg bw/day for two consecutive days.
Mortality, clinical symptoms and change in body temperature were monitored up to 72 hours after the initial dose. The rectal temperature was measured prior to dosing, approx. 2, 5 and 24 hours after dosing and before sacrifice.
Based on the results of the preliminary toxicity study, 2000 mg/kg bw/day were selected as dose level for the micronucleus test.

Main micronucleus test:
Groups of 6 male mice received a dose of 2000 mg/kg bw/day for two consecutive days. The test item was dissolved in vegetable oil and administered by oral gavage at a constant dosage volume of 10 mL/kg bw. Similar constituted groups of mice were treated twice with the vehicle following the same route or received a single intraperitoneal injection of the positive control (1.0 mg/kg bw/day mitomycin C).
The animals were observed for clinical signs of toxicity post-dosing and pre-sacrifice. In addition, individual body weights were recorded prior to dosing and before sacrifice. The animals were sacrificed by CO_2 asphyxiation 24 hours after the second dose.

3. Slide preparation:

Femur bones from the sacrificed animals were excised and the epicondyle tips were removed. Bone marrow was flushed out with foetal bovine serum and the collected cells were pelleted by centrifugation. After re-suspension in 0.2 – 0.3 mL medium, the pellet was dissociated with a pipette and a drop of cell suspension was smeared on a clean slide and allowed to air-dry. For each animal two slides were prepared. The cells were fixed with absolute methanol and air-dried for 15 – 20 minutes, followed by 5 % Giemsa staining for 25 minutes. Subsequently, the slides were rinsed with distilled water, air-dried and mounted.

4. Slide evaluation:

Slides were randomly coded and evaluated by microscopical analysis. A minimum of 2000

polychromatic erythrocytes (PCE) per animal were scored for the presence of micronuclei. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was recorded from a minimum of 200 erythrocytes.

5. Statistics:

The percentage of micronucleated polychromatic erythrocytes (PCE) and the ratio of PCE to normochromatic erythrocytes (NCE) was statistically analysed using Bartlett's test and Analysis of Variance (ANOVA), followed by Dunnett's test to determine the level of significant differences between the vehicle control and the treatment group. Where data did not meet the homogeneity of variance, Student's t-test was performed to determine the level of significant difference between the vehicle control, treatment group and the positive control group.

6. Acceptance criteria:

The study was considered valid if the following criteria were met:

- The prepared slides had uniform staining properties and a sufficient number of polychromatic erythrocytes (PCE) to allow accurate micronucleus determination.
- The solvent controls were in the range of the laboratories historical control data.
- The positive controls were in the range of the laboratories historical control data.
- At least 5 animals per group and sex were evaluated.
- The PCE to erythrocyte ratio was not less than 20 % of the solvent control.

7. Evaluation criteria:

A test substance was considered positive for induction of micronuclei when the following criteria were met:

- There was a dose-dependent, statistically significant increase in the incidence of micronuclei or increase in a single dose group.
- The result was of biological relevance.

A test item was considered negative for induction of micronuclei if no evident statistically significant increase in the numbers of micronucleated polychromatic erythrocytes (mPCE) was observed, relative to the concurrent and established historical control frequencies for PCE induction.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in this study, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

There was no mortality and no adverse effects of systemic toxicity observed upon treatment with glyphosate TGAI. In addition, there was no impact on body temperature 24 and 48 hours after treatment.

Based on these findings, 2000 mg/kg bw/day were selected as the limit dose level for the micronucleus test.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

Clinical signs of toxicity were not observed.

Body weight:
Body weights were comparable among all groups during the experimental period.

Evaluation of bone marrow slides:
Upon treatment with glyphosate TGAI, there was no statistically significant change in the ratio of polychromatic (PCE) to normochromatic erythrocytes (NCE), indicating that there was no evidence of cell proliferation or bone marrow cytotoxicity.
In addition, there was no statistically significant increase in the frequency of micronucleated PCE (mPCE) in glyphosate TGAI-treated mice when compared with the solvent control group.
Incidences of mPCE in the solvent and positive control groups were within the range of the laboratory's historical control data, demonstrating the capability of the test animals to respond to mutagenic substances and confirming the sensitivity of the test.

Table 5.4.2-2: Glyphosate TGAI: Micronucleus test of glyphosate TGAI in mice ([redacted], 2012), summary of genotoxicity data

Treatment	Dose (mg/kg bw/day)	Number of animals	Total number of PCE	Total number of mPCE	Mean mPCE	Mean% PCE	Mean PCE/NCE ratio

mean ± SD						1.40 ± 0.36	0.57 ± 0.04
range						0.81 - 2.52	0.45 - 0.69

mPCE: micronucleated polychromatic erythrocytes

MMC: Mitomycin C, positive control

* and **: statistically significant at $p < 0.05$ and $p < 0.011$, respectively

Historical control data, generated in the laboratory from Sep 2009 - Feb 2012 (data from male animals only)

III. CONCLUSION:

Based on the experimental findings glyphosate TGAI, administered at a limit dose of 2000 mg/kg bw/day, did not induce micronuclei in bone marrow in mice *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male Swiss albino mice i*n vivo*.
The study was performed in compliance with GLP and according to OECD guideline 474 (1997). There

were some deviations when compared to the current OECD guideline 474 (2016), which were considered to be of minor degree. The number of polychromatic erythrocytes investigated was 2000, corresponding to the number required by the previous guideline (1997). In addition, the percentage of polychromatic erythrocytes among total erythrocytes was determined for 200 erythrocytes instead of 500 erythrocytes. Evaluation criteria specified in the study report did not consider historical control data, but the values obtained in the present study were in line with historical controls. Bone marrow toxicity, indicated by a reduced polychromatic to normochromatic erythrocyte ratio or signs of systemic toxicity, was not evident, but the test was performed at limit dose levels in line with the current guideline. Therefore, the deviations were considered to not compromise the scientific validity of the study. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.2/002

2. Full summary

Glyphosate technical (BX20070911, batch: 569753, purity: 96.3 %) was tested for its genotoxic potential in mice using the micronucleus test. Based on the results of a preliminary toxicity study, in which no toxicity was observed at 2000 mg/kg bw, groups of seven male mice each received a single oral dose of 2000 mg/kg bw. The test item was dissolved in 1 % (w/w) carboxymethyl cellulose and administered at a constant dosage volume of 20 mL/kg bw. Groups of 5 male control animals received the vehicle or the positive

control (40 mg/kg bw cyclophosphamide in sterile water).

About 1, 2-4, 6, 24 and 48 hours after dosing, the animals were examined for signs of systemic toxicity. Bone marrow was sampled 24 and 48 hours after dosing and for each animal 2000 polychromatic erythrocytes (PCE) were scored for the presence of micronuclei. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was determined per 2000 erythrocytes.

Treatment with glyphosate technical did not induce signs of systemic toxicity or mortality in the animals. Further, based on the ratio of PCE among the total number of erythrocytes, there was no evidence for bone marrow toxicity.

In addition, there was no biologically relevant and no statistically significant increase in the frequency of micronucleated PCE of test item-treated animals at any sampling time point when compared to vehicle controls.

Incidences of micronuclei in the solvent and positive control groups were within the range of the laboratory's historical control data, confirming the sensitivity of the test and demonstrating the capability of the test animals to respond to mutagenic substances.

Based on the experimental findings, the test item did not induce clastogenic/aneugenic effects in mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate Technical

Identification:	BX20070911
Description:	White solid
Lot/Batch #:	569753
Purity:	96.3 %
Stability of test compound:	The stability of the test item under storage conditions (< 30° C) was guaranteed until March 2015. The stability of the test item in solvent (vehicle) was not indicated by the sponsor.
Solvent (vehicle) used:	1 % carboxymethyl cellulose (CMC)

2. Control materials:

Solvent (vehicle) control:	1 % carboxymethyl cellulose (CMC)
Positive control:	Cyclophosphamide, 40 mg/kg bw in sterile water

3. Test animals:

Species:	Mouse
Strain:	NMRI
Sex:	Males
Source:	[redacted]
Age at study initiation:	8 - 9 weeks
Mean weight at dosing:	35.5 ± 1.8 g (range: 32.4 – 38 g)
Acclimation period:	Minimum 5 days

Diet/Food:	Pelleted standard diet (Harlan laboratories B.V., Horst, The Netherlands), *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	Individually in Macrolon type II/III cages with wire mesh top and granulated soft wood bedding

4. Environmental conditions:

Temperature:	22 ± 2 °C
Humidity:	45 – 65 %
Air changes:	Not specified
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels:	2000 mg/kg bw
Concentrations:	Not reported (calculated: 100 mg/mL)
Dose volume:	20 mL/kg bw
Number of animals:	2 males and 2 females
Route of administration:	Oral gavage

b) Main micronucleus test

Dose levels:	2000 mg/kg bw
Concentrations:	Not reported (calculated: 100 mg/mL)
Dose volume:	20 mL/kg bw
Number of animals:	7 males/group
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 04 – 25 Apr 2012
Finalisation date: 28 Sep 2012

2. Animal assignment and treatment:

Preliminary toxicity study:
The test item was dissolved in 1 % carboxymethyl cellulose (CMC) and administered by oral gavage at a constant dosage volume of 20 mL/kg bw to groups of 2 male and 2 female mice at a single dose of 2000 mg/kg bw.
The animals were examined for acute toxic symptoms about 1, 2-4, 6, 24, 30 and 48 hours after administration of the test substance. Since no signs of toxicity were evident at 2000 mg/kg bw, testing of lower doses was not regarded to be required.
Based on the results of the preliminary toxicity study, 2000 mg/kg bw were selected as dose level for the micronucleus test.

Main micronucleus test:
Groups of 7 male mice per dose level were administered a single dose of 2000 mg/kg bw by oral gavage at a constant dosage volume of 20 mL/kg bw. Similar constituted groups of 5 mice/dose level received the vehicle (1 % carboxymethyl cellulose) or the positive control (40 mg/kg bw cyclophosphamide).
Except for the positive control group, all mice were examined for acute toxic symptoms about 1, 2-4, 6, 24 and 48 hours after dosing. The animals were sacrificed 24 and 48 hours after test substance

administration by CO_2 asphyxiation followed by bleeding.

3. Slide preparation:

After sacrifice the femurs of the animals were removed, the epiphysis were cut off and the marrow was flushed out with foetal calf serum. After centrifugation and re-suspension, a small drop of re-suspended cell pellet was spread on a slide. The smear was air-dried, stained with May-Grünwald/Giemsa and mounted with coverslips. At least one slide was made from each bone marrow sample.

4. Slide evaluation:

Slides were coded and evaluated by microscopical analysis at 100 x magnification. For each animal, 2000 polychromatic erythrocytes (PCE) were scored for the presence of micronuclei. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was determined from the same slide and expressed in PCE per 2000 erythrocytes.

5. Statistics:

The results were evaluated using the non-parametric Mann-Whitney U-test.

6. Acceptance criteria:

The study was considered valid if the following criteria were met:

- At least 5 animals per group were evaluated.
- The PCE to erythrocyte ratio was not less than 20 % of the negative control.
- The positive control showed a statistically significant and biologically relevant increase of micronucleated PCE (mPCE) compared to the negative control.

7. Evaluation criteria:

The test item was considered mutagenic if the following criteria were met:

- It induced either a dose-related or a clear increase in the number of micronucleated polychromatic erythrocytes in a single dose group.
- There was a biological relevance of the result.

A test item that failed to produce a biologically relevant increase in the number of micronucleated polychromatic erythrocytes was considered non-mutagenic in this system.
A test item failing to meet the criteria for a positive or negative response was judged equivocal in this assay and considered for further investigation.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in this study, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

There were no signs of systemic toxicity observed. Based on these findings, 2000 mg/kg bw were selected as dose level for the micronucleus test.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

Clinical signs of toxicity were not observed.

Evaluation of bone marrow slides:

Treatment with glyphosate technical did not affect the mean number of polychromatic erythrocytes (PCE) when compared to the mean value of PCE in the solvent control, indicating that the test item did not induce bone marrow toxicity.
In addition, there was no biologically relevant and no statistically significant increase in the frequency of micronucleated PCE of test item-treated animals at any sampling time point when compared to vehicle controls.
Incidences of micronuclei in the solvent and positive control groups were within the range of the laboratory's historical control data, confirming the sensitivity of the test and demonstrating the capability of the test animals to respond to mutagenic substances.

CPA: cyclophosphamide

HCD#: Historical control data from 2006 - 2011

III. CONCLUSION:

Based on the experimental findings glyphosate technical did not induce micronuclei in bone marrow in mice and is therefore considered negative for clastogenicity/aneuploidy *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male NMRI mice i*n vivo*.

The study was performed under GLP conditions and in accordance with OECD guideline 474 (1997). There were only minor deviations when compared to the current OECD 474 (2016). The number of polychromatic erythrocytes investigated was 2000, corresponding to the number required by the previous guideline (1997). In addition, the evaluation criteria specified in the study report did not

consider historical control data, but the values obtained in the present study were in line with historical controls. Bone marrow toxicity, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, or signs of systemic toxicity were not evident, but the test was performed at limit dose levels in line with the current guideline. The deviations were considered to not compromise the validity of the study. The study is therefore considered valid and acceptable

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.2/003
Report author	[redacted]
Report year	2008
Report title	Evaluation of the mutagenic potential of Glyphosate Technical Micronucleus assay in mice
Report No	[redacted]-3996.402.395.07 (Helm AG)
Document No	Not reported
Guidelines followed in study	OECD 474 (1997)
Deviations from current test guideline OECD 474 (2016)	According to the current guideline OECD 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study, 2000 polychromatic erythrocytes were evaluated (requirement of previous OECD guideline (1997)). In addition, the test item was administered via intraperitoneal injection, which is not representative for a human route of exposure. Historical control data on the mean number of micronucleated polychromatic erythrocytes / 2000 polychromatic erythrocytes were reported, but no standard deviations were given. Acceptance criteria were not reported and evaluation criteria specified in the study report were inconsistent with the historical control data provided.

Data point	CA 5.4.2/004
Report author	[redacted]
Report year	2010
Report title	First amendment to the report: Evaluation of the mutagenic potential of Glyphosate Technical Micronucleus assay in mice
Report No	[redacted]-3996.402.395.07
Document No	Not reported
Guidelines followed in study	OECD 474 (1997)
Deviations from current test guideline OECD 474 (2016)	According to the current guideline OECD 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study, 2000 polychromatic erythrocytes were

	evaluated (requirement of previous OECD guideline (1997)). In addition, the test item was administered via intraperitoneal injection, which is not representative for a human route of exposure. Historical control data on the mean number of micronucleated polychromatic erythrocytes / 2000 polychromatic erythrocytes were reported, but no standard deviations were given. In addition, evaluation criteria specified in the study report were inconsistent with the historical control data provided.
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Glyphosate technical (batch: 20070606, purity 98.0 %) was tested for its genotoxic potential in a micronucleus test conducted in male and female Swiss mice (main study and amendment).

Based on the results of a preliminary toxicity study, in which mortality was observed at ≥ 500 mg/kg bw/day and bone marrow toxicity was evident at ≥ 250 mg/kg bw, dose levels for the main micronucleus test were selected. 5 mice per sex and dose received on two consecutive days (24 hours apart) doses of 15.62, 31.25, 62.5, 125, 250 and 375 mg/kg bw/day by intraperitoneal injection. Similar constituted groups of mice received the vehicle (corn oil) or the positive control (25 mg/kg bw/day cyclophosphamide). Bone marrow sampling was performed 24 hours after the second dose administration, followed by preparation and staining of smears. For each animal, 2000 polychromatic erythrocytes (PCE) were scored for the presence of micronuclei. At the same time, normochromatic erythrocytes (NCE) with micronuclei were recorded. The ratios of PCE/NCE were determined among the first 2000 PCE.

Intraperitoneal injection of glyphosate technical was associated with clinical signs of toxicity in males and females at ≥ 125 mg/kg bw/day. Common signs of toxicity were bristling and tachypnea, which were observed in both sexes at 125, 250 and 375 mg/kg bw/day throughout the whole study period. After the second dose, lethargy was observed in the animals, which was reversible in the 125 mg/kg bw/day dose group but remained until study termination in the animals of the 250 and 375 mg/kg bw/day dose groups. The animals of the high dose group (375 mg/kg bw/day) further showed loss of motor coordination 30 minutes after the second dose, which was reversible up to 4 hours post dosing. These signs of systemic toxicity were clearly attributed to treatment with glyphosate technical and considered to be of toxicological relevance.

A statistically significant increase in the ratio of PCE/NCE when compared to solvent control animals was observed at ≥ 250 mg/kg bw/day in males and at 375 mg/kg bw/day in females. The observation indicated that strong bone marrow toxicity was evident in the animals.
There was no statistically significant increase in the incidence of micronucleated PCE (mPCE) when compared to solvent control animals, up to the highest dose tested.

The frequency of mPCE of solvent and positive control animals were within the range of the laboratories historical control data, demonstrating the validity and the sensitivity of the test.

Based on the experimental findings and under the conditions of the test, glyphosate technical did not induce micronuclei in bone marrow in male and female mice and was therefore considered negative for clastogenicity/aneugenicity *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate Technical

Identification:	AGR-0790/07
Description:	Not specified
Lot/Batch #:	20070606
Purity:	98.0 %
Stability of test compound:	As given in the study report, the substance was described[15] to not photochemically degrade in buffered water and to be stable in air. It was further stated to be stable to hydrolysis at pH 3, 6 and 9 at 5 – 35 °C.
Solvent (vehicle) used:	Corn oil

2. Control materials

Solvent (vehicle) control:	Corn oil
Positive control:	Cyclophosphamide monohydrate, 25 mg/kg bw/day in physiological solution

3. Test animals:

Species:	Mouse
Strain:	Swiss albino
Sex:	Male and female
Source:	[redacted]
Age at study initiation:	7 - 12 weeks
Mean weight at dosing:	Approximately 30 g
Acclimation period:	5 days
Diet/Food:	Purina Labina (Purina do Brasil Ltda.), *ad libitum*
Water:	*ad libitum*
Housing:	5/sex in polypropylene cages closed with a metallic grid and padded out with sterile sawdust bedding.

4. Environmental conditions:

Temperature:	20 - 24 °C
Humidity:	50 - 70 %
Air changes:	10 – 15/h
Photoperiod:	12-hour light and dark cycle

[15] Tomlin, C.D.S. (2006-2007): The e-Pesticide Manual (14th Edition) Version 4.0; Software engineered by P.J. Mann – Web Design & Consultancy. BCPC (British Crop Protection Council) ISBN 1 901396 42 8

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels:	62.5, 125, 250, 500 and 1000 mg/kg bw/day
Concentrations:	Not specified
Dose volume:	Not specified
Number of animals:	3/sex/group
Route of administration:	Intraperitoneal injection

b) Main micronucleus test

Dose levels:	15.62, 31.25, 62.5, 125*, 250* and 375* mg/kg bw/day [16] *
Concentrations:	1.04, 2.08, 4.16, 8.33*, 16.66*, 25.00* mg/mL
Dose volume:	15 mL/kg bw
Number of animals:	5/sex/group
Route of administration:	Intraperitoneal injection

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 29 May – 13 Aug 2008
Finalisation date: 29 Sep 2008 (study report) and 31 Aug 2010 (first amendment to study report)

2. Animal assignment and treatment:

Preliminary toxicity study:
The test item was dissolved in corn oil and administered via intraperitoneal injection to groups of six mice per dose level (3/sex/group). The animals received two injections 24 hours apart at doses of 62.5, 125, 500 and 1000 mg/kg bw/day. Following administration, the animals were observed for signs of mortality. Surviving animals were sacrificed 24 hours following the second dose administration.

Bone marrow toxicity was assessed in surviving animals by determining the ratio of polychromatic (PCE) to normochromatic erythrocytes (NCE) among 200 PCE per animal.
Based on the results of the preliminary toxicity study, the dose levels for the main micronucleus test were chosen. In the original study report, 62.5 mg/kg bw/day was selected as highest dose level. In the first amendment to the study report, 3 higher dose levels were tested with a maximum dose level of 375 mg/kg bw/day.

Main micronucleus test:
Groups of 5 mice/sex received two separate intraperitoneal injections of 15.62, 31.25, 62.5, 125*, 250* and 375* mg/kg bw/day 24 hours apart[16]. Similar constituted groups received the vehicle (corn oil) or positive control (25 mg/kg bw/day cyclophosphamide in physiological solution).
About 24 hours after the second injection, the animals were sacrificed by CO_2 asphyxiation and bone marrow slides were prepared from each animal.

3. Slide preparation:

After sacrifice, the femurs of the animals were excised, dissected and the marrow was flushed out with fetal calf serum. After centrifugation and re-suspension in fetal calf serum, a drop of re-suspended cells was smeared on microscope slides. Two slides were prepared for each animal. The smears were air-dried, fixed in 70 % ethanol for 10 minutes, stained with Wright's concentrated solution for 3 minutes, placed in Wright's phosphate buffer solution and rinsed. Thereafter, the slides were immersed for 10 minutes in Giemsa buffer – deionised water solution, washed in streamed water, dried and assembled in Permount.

* tested in amendment to study report.

4. Slide evaluation:

Slides were coded and evaluated by microscopical analysis at 1000 x magnification. For each animal, 2000 polychromatic erythrocytes (PCE) were scored for the presence of micronuclei. At the same time, normochromatic erythrocytes (NCE) were screened for micronuclei. The ratios of PCE/NCE were determined among the first 2000 PCE.

5. Statistics:

Differences in the incidence of micronucleated polychromatic (PCE) and normochromatic erythrocytes (NCE) per 2000 cells and the relation of PCE/NCE were compared using the Mann-Whitney U-test and the K'test for independent variable in accordance with Kruskal & Wallis Test.

6. Acceptance criteria:

Acceptance criteria were not specified in the study report.

7. Evaluation criteria:

The test item was considered positive for induction of micronuclei if the following criteria were met:

- There was a statistically significant, dose-related increase in the number of micronucleated polychromatic erythrocytes when compared to the solvent control.
- There was a reproducible and statistically significant positive response for at least one of the dose levels tested.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed. The substance was described to not photochemically degrade in buffered water and to be stable in air. It was further stated to be stable to hydrolysis at pH 3, 6 and 9 at 5 – 35 °C.

B. PRELIMINARY TOXICITY STUDY

Mortality was observed at 500 mg/kg bw/day in 1/3 males and 2/3 females and at 1000 mg/kg bw/day in 3/3 males and 3/3 females.

Bone marrow cytotoxicity, evident as a ratio of polychromatic (PCE) to normochromatic erythrocytes (NCE) lower than 20 % when compared to solvent control animals, was observed at 250 and 500 mg/kg bw/day.

Based on the results of the preliminary toxicity study, the dose levels for the main micronucleus assay were selected. In the original study report, 62.5 mg/kg bw/day was chosen as highest dose level. In the first amendment to the study report, 3 higher dose levels were included with a maximum dose level of 375 mg/kg bw/day.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

Clinical signs of toxicity were observed at 125, 250 and 375 mg/kg bw/day.

At 125 mg/kg bw/day, bristling was observed in 5/5 males and 5/5 females and tachypnea in 1/5 males and 1/5 females starting 30 minutes after the first dose. After the second dose, all males and females of this dose group showed bristling, tachypnea and lethargy starting 30 minutes post administration. Bristling and tachypnea were observed in all animals until study termination.

At 250 mg/kg bw/day, bristling and tachypnea was observed in 5/5 males and 5/5 females after the first and second dose until study termination. About 30 minutes after the second dose, all animals showed lethargy, which was still present in 1/5 males 4 hours after dosing and remained in 2/5 females until study termination.

At 375 mg/kg bw/day, 5/5 males and 5/5 females showed bristling and tachypnea immediately following test item administration (first and second dosing), which was observed in all animals until bone marrow sampling. 24 hours after the first dose, 5/5 males and 2/5 females showed agitation. After the second dose, 5/5 males and 5/5 females showed lethargy and loss of motor coordination within the first 30 minutes post dosing. The animals recovered from the loss of motor coordination within 4 hours post dosing, while lethargy was observed in 4/5 males and 3/5 females until study termination.

The signs of systemic toxicity were attributed to treatment and considered to be of toxicological relevance.

Evaluation of bone marrow slides:
Treatment with glyphosate technical at concentrations of 250 mg/kg bw/day and above caused a statistically significant change in the PCE/NCE ratio, indicating that bone marrow toxicity was evident at these concentrations. Bone marrow toxicity was observed in males at ≥ 250 mg/kg bw/day and in females at 375 mg/kg bw/day.

There was no statistically significant increase in the incidence of mPCE when compared to solvent control animals up to the highest dose tested.

The frequency of mPCE of solvent and positive control animals were within the range of the laboratories historical control data, demonstrating the validity and the sensitivity of the test.

Table 5.4.2-4: Evaluation of the mutagenic potential of Glyphosate Technical Micronucleus assay in mice ([redacted], 2008), summary of genotoxicity data for males and females

III. CONCLUSION

Based on the experimental findings and under the conditions of the test, glyphosate technical did not induce micronuclei in bone marrow in male and female mice *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male and female Swiss albino mice i*n vivo*.

The study was performed under GLP conditions and according to OECD guideline 474 (1997). There were only minor deviations when compared to the current OECD guideline 474 (2016). The number of polychromatic erythrocytes investigated per animal was 2000 (instead of 4000), which was the number recommended by the previous OECD guideline (1997). In addition, the test item was administered via intraperitoneal injection, which does not represent a typical human route of exposure. There was clear evidence of systemic toxicity and bone marrow toxicity in animals of both sexes, but there was no evidence for induction of micronuclei at any dose level.

The study is considered to provide supporting information, because two different batches of the test material were used in the original study and in the amendment to the study. In addition, the treatment of the animals used in the amendment was not described and the amendment does not replace a full study report. However, it can be assumed that the treatment was the same as in the original study.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.2/005
Report author	[redacted]
Report year	2008
Report title	Glyphosate Technical – Micronucleus Assay in Bone Marrow Cells of the Mouse
Report No	1158500
Document No	Not reported
Guidelines followed in study	OECD 474 (1997), EPA OPPTS 870.5395 (1998), 2000/32/EEC B.12 (2000)
Deviations from current test guideline OECD 474 (2016)	Only 2000 polychromatic erythrocytes were evaluated per animal instead of 4000 polychromatic erythrocytes as recommended by OECD guideline 474 (2016). Bone marrow exposure, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, was not confirmed and there was no systemic toxicity observed, but dose levels included limit concentrations specified in the current guideline. Acceptance criteria were not specified in the study report. In addition, historical controls were not considered in the evaluation criteria.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: 20070545, purity: 99.1 %) was tested for its genotoxic potential in mice using the micronucleus test. Based on the results of a preliminary toxicity study, groups of six mice each received a single oral dose of 500, 1000 and 2000 mg/kg bw glyphosate technical. The test item was dissolved in 0.5 % (w/w) carboxymethyl cellulose and administered at a constant dosage volume of 20 mL/kg bw. Similar constituted groups of control animals received the vehicle (0.5 % carboxymethyl cellulose) or the positive control (40 mg/kg bw cyclophosphamide in deionised water). All animals were observed for clinical signs of toxicity at regular intervals. 24 and 48 hours after administration, the animals were sacrificed and bone marrow smears were prepared. For the incidence of micronucleated cells, 2000 polychromatic erythrocytes (PCE) per animal were scored. To describe a cytotoxic effect, the ratio between PCE and normochromatic erythrocytes (NCE) was determined and expressed in PCE per 2000 erythrocytes.

Oral administration of glyphosate technical did not induce any clinical signs of toxicity or mortality in the animals. In addition, there was no statistically significant decrease in the ratio of PCE to the total amount of erythrocytes in any dose group or at any preparation interval, indicating that glyphosate technical did not induce cytotoxicity in the bone marrow.

A biologically relevant or statistically significant increase in the frequency of micronucleated polychromatic erythrocytes was not observed for the test item at any preparation interval and any dose level.

The positive control cyclophosphamide showed a marked increase in the frequency of induced micronuclei, demonstrating the sensitivity of the test system.
Based on the results of the test and under the experimental conditions chosen, the test item was considered to be negative for clastogenicity/aneugenicity in mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate Technical

Identification:	S846011
Description:	White solid
Lot/Batch #:	20070545
Purity:	99.1 % (w/w)
Stability of test compound:	The stability of the test item at storage conditions (< 10° C) was guaranteed until the expiry date Oct 2009. The stability of the test item in solvent was not specified.
Solvent (vehicle) used:	0.5 % carboxymethyl cellulose (CMC)

2. Control materials

Solvent (vehicle) control:	0.5 % carboxymethyl cellulose (CMC), 20 mL/kg bw
Positive control:	Cyclophosphamide, 40 mg/kg bw in deionised water, 10 mL/kg bw

Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. **Dates of experimental work:** 25 Feb – 13 Mar 2008
   Finalisation date: 09 Jun 2008

2. **Animal assignment and treatment:**

Preliminary toxicity study:
A preliminary study on acute oral toxicity was performed in male and female mice. Two animals per sex received a single dose of 2000 mg/kg bw by oral gavage. Formulations were applied at a constant dosage volume of 20 mL/kg bw. The animals were examined for acute toxic symptoms at intervals of around 1 hour, 2-4 hours, 6 hours, 24, 30 and 48 hours after administration of the test item.

Main micronucleus test:
Based on the results of the preliminary toxicity study, groups of six mice each received a single oral dose of 500, 1000 and 2000 mg/kg bw glyphosate technical, which was administered at a constant dosage volume of 20 mL/kg bw. Similar constituted groups of control animals received the vehicle (0.5 % carboxymethyl cellulose) or the positive control (40 mg/kg bw cyclophosphamide in deionised

water). All animals were observed for acute toxic symptoms at intervals of around 1 hour, 2-4 hours, 6 hours (except for high dose group animals), 24 and 48 hours after test item administration.

Bone marrow sampling was performed 24 and 48 hours after treatment; the latter sampling time point was performed for the control and high dose group only. The animals were sacrificed by CO_2 asphyxiation followed by bleeding.

1. Slide preparation:

After sacrifice the femurs of the animals were removed, dissected and the marrow was flushed out with foetal calf serum. After centrifugation and re-suspension, a small drop of re-suspended cell pellet was spread on a glass slide. The smear was air-dried, stained with May-Grünwald/Giemsa and mounted with coverslips. At least one slide was made from each bone marrow sample.

2. Slide evaluation:

Slides were coded and examined using a NIKON microscope with 100x oil immersion objectives. For the incidence of micronucleated cells, 2000 polychromatic erythrocytes (PCE) per animal were scored. To evaluate a potential cytotoxic effect, the ratio between PCE and normochromatic erythrocytes (NCE) was determined and expressed in PCE per 2000 erythrocytes.

The presence of micronuclei was scored for 5 males per group. The remaining 6th animal in the respective test group was kept as backup in case of spontaneous death.

3. Statistics:

All data were statistically analysed using the nonparametric Mann-Whitney U-test.

4. Acceptance criteria:

The test was considered valid when the following criteria were met:

- The negative controls were in the range of the laboratory's historical control data.
- The positive controls were in the range of the laboratory's historical control data.
- At least 4 animals per group were evaluated.
- The PCE to erythrocyte ratio was not less than 20 % to those of the negative control value.

5. Evaluation criteria:

The test substance was considered to be mutagenic if it induced either a statistically significant, dose-related increase or a clear statistically significant increase in the number of micronucleated PCE in a single dose group.

A test item was considered to be non-clastogenic if it failed to produce a biologically relevant increase in the number of micronucleated PCE.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations have not been performed in this study, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

Animals treated at the limit dose of 2000 mg/kg bw did not express any toxic reactions. Based on the results of the preliminary toxicity study, 2000 mg/kg bw was selected as high dose level for the main micronucleus test. Since gender-specific differences in the sensitivity towards glyphosate technical were not observed, the main experiment was performed using only males.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:
No mortality occurred.

Clinical signs of toxicity:
There were no clinical signs of toxicity observed.

Evaluation of bone marrow slides:
There was no decrease in the mean number of polychromatic erythrocytes among total erythrocytes in test item treated groups when compared to vehicle controls, indicating that glyphosate technical did not induce cytotoxicity in the bone marrow.

In addition, there was no biologically relevant or statistically significant increase in the frequency of micronucleated polychromatic erythrocytes at any preparation interval and any dose level.

A dose of the positive substance cyclophosphamide showed a marked increase in the frequency of induced micronuclei, demonstrating the capability of the test animals to respond to mutagens.

Table 5.4.2-6: Micronucleus Assay in Bone Marrow Cells of the Mouse ([redacted], 2006) summary of genotoxicity data

Treatment	Dose (mg/kg bw)	Sampling time	mPCE ± SD /2000 PCE	% cells with micronuclei	PCE/2000 erythrocytes (mean ± SD)

mPCE: micronucleated polychromatic erythrocytes

CPA: cyclophosphamide, positive control

[#] HCD Historical control data from the laboratory generated in 2002 - 2007 (vehicle control: 293 experiments in males, 275 experiments in females; positive control: 292 experiments in males, 274 experiments in females)

III. CONCLUSION

Based on the results of the present study, glyphosate technical did not induce micronuclei in bone marrow of male mice *in vivo*. Thus, the test item was considered to be negative for clastogenicity/aneugenicity under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male mice *in vivo*.
The study was performed under GLP conditions and in accordance with OECD guideline 474 (1997). There were only minor deviations when compared to the current OECD 474 (2016), which were considered to not compromise the validity of the study. The number of polychromatic erythrocytes investigated was 2000, corresponding to the number required by the previous guideline (1997). Bone marrow toxicity, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, or systemic toxicity were not observed. However, the test was performed at limit dose levels in line with the current guideline, therefore the deviation is considered negligible. The study is considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.2/006
Report author	[redacted]
Report year	2007
Report title	Mammalian Erythrocyte Micronucleus Test for GLIFOSATO TÈCHNICO HELM
Report No	RL33393/2007-3.0MN-B
Document No	Not reported
Guidelines followed in study	OECD 474 (1997), Commission Directive 2000/32/EC B.12
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate technical (batch: 2007091801, purity: 98.01 %) was assessed for genotoxic effects in a micronucleus test in male Swiss mice *in vivo*. The dose levels for the micronucleus assay were selected based on the results of a preliminary toxicity study, in which 30 mg/kg bw/day turned out to be the maximum tolerated dose. Groups of six mice received on two consecutive days doses of 8.0, 15.0 and 30.0 mg/kg bw/day by oral gavage. Concurrent control animals received the vehicle (deionized water) or 75 mg/kg bw/day of the well-known mutagen cyclophosphamide (positive control). Bone marrow sampling was performed 24 hours after administration of the second dose. Smears were prepared from the femoral bone marrow of each animal and 3000 polychromatic erythrocytes (PCE) were scored for the presence of micronuclei. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was determined for each animal by counting a total of 2000 erythrocytes.
Short description of results:	Oral treatment with glyphosate technical did not induce any mortality in the animals and signs of systemic toxicity were as well not reported. In addition, the ratio of PCE to NCE was not affected upon treatment with the test item up to the highest dose level. When compared to solvent control animals, treatment with

	glyphosate doses of 8.0 and 15.0 mg/kg bw/day did not lead to a statistically significant increase the frequency of micronucleated PCE. At 30 mg/kg bw/day, a statistically significant increase in micronucleated PCE was observed, but the values remained within the range of historical control data and were therefore considered to be without biological relevance. Micronuclei formation in the solvent controls was consistent to the historical control data. The positive control cyclophosphamide showed the expected result and demonstrated the functionality of the test system. Under the conditions of the test, glyphosate technical was considered negative for clastogenic/aneugenic activity in male mice *in vivo*.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study is considered to be not acceptable since the dose levels were far too low for any meaningful conclusion with regard to micronucleus formation. In the original report, some justification for dose selection is given, based on a range-finding test suggesting effects at even lower dose levels. These findings were obviously in contradiction to more reliable acute toxicity tests with glyphosate in the mouse. In other micronucleus assays described in this section, much higher dose levels were assessed.
Reasons why the study report is not available for submission	Not applicable

2. Full summary

Glyphosate technical (batch: H05H016A, purity: 95.7 %) was tested for its genotoxic potential in mice using the micronucleus test. Prior to the micronucleus test, a preliminary toxicity study was performed. Due to severe clinical signs of toxicity and mortality at 800 and 1000 mg/kg bw, a maximum tolerated dose of 600 mg/kg bw was established and selected for the main study. No marked difference in toxicity was observed between male and female mice.

Based on these findings, the main micronucleus test was performed in male mice with dose levels of 150, 300 and 600 mg/kg bw. Seven mice per group received a single intraperitoneal injection at a constant dosage volume of 10 mL/kg bw. Similarly constituted groups received the vehicle (phosphate buffered saline, 7 mice/group) or the positive control (cyclophosphamide, 5 mice/group). Animals were sacrificed 24 (all treatment groups, vehicle and positive control animals) and 48 hours (vehicle control and high dose group) followed by preparation of bone marrow smears from the femoral bone marrow from each animal. After staining of the preparations, 2000 erythrocytes per animal were scored for the presence of micronucleated polychromatic and normochromatic cells. In addition, 1000 erythrocytes were counted to determine the percentage of polychromatic to normochromatic erythrocytes.

Intraperitoneal injection of the test item induced clinical signs of toxicity at ≥ 150 mg/kg bw in all animals of the 24 and 48 hour sacrifice. The observations comprised hunched posture, ptosis, ataxia and lethargy.

A statistically significant decrease in the ratio of polychromatic cells per 1000 erythrocytes was observed compared to the vehicle control in the 24-hour 600 mg/kg bw group, as well as a statistically non-significant decrease in the 48-hour 600 mg/kg bw group. This observation, as well as the occurrence of clinical signs demonstrated systemic absorption and confirmed exposure of the bone marrow.

There was a small but statistically significant increase in the incidence of micronucleated polychromatic erythrocytes in animals dosed with 600 mg/kg bw in the 24-hour sampling group when compared to the concurrent vehicle control group. However, the increase was very modest, within the range of the laboratory's historical control data and did not include any individual value that would not be acceptable for vehicle control animals. The observed response was attributed to a haematopoietic effect induced by the cytotoxic effect of the test material on the bone marrow rather than to any specific genotoxic effect and was therefore not considered to be of toxicological relevance. No statistically significant increase in the incidence of micronucleated polychromatic erythrocytes was observed after 48 hours in animals dosed at 600 mg/kg bw.

The positive control group showed a marked increase in the incidence of micronucleated PCE hence demonstrating capability of the test animals to show mutagenic effects in response to known mutagenic agents and confirming the sensitivity of the test.

Based on the results of the test and under the experimental conditions chosen, the test item was considered to be negative for clastogenicity/ aneugenicity in mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

Identification:	Glyphosate Technical
Description:	White crystalline solid
Lot/Batch #:	H05H016A
Purity:	95.7 %
Stability of test compound:	At room temperature stable until March 2008

Solvent (vehicle) used: Phosphate buffered saline (PBS)

2. Control materials

Solvent (vehicle) control: Phosphate buffered saline (PBS)
Positive control: Cyclophosphamide, 50 mg/kg bw in PBS

3. Test animals:

Species: Mouse
Strain: CD-1
Sex: Males
Source: [redacted]
Age at study initiation: Approx. 5 - 8 weeks
Weight at dosing: 21 - 29 g
Acclimation period: At least 7 days
Diet/Food: Certified Rat and Mouse Diet Code 5LF2, BCM (IPS Ldt., London UK), *ad libitum*
Water: Tap water, *ad libitum*
Housing: In groups up to seven in solid-floor polypropylene cages with wood flake bedding.

4. Environmental conditions:

Temperature: 19 - 25°C
Humidity: 30 - 70 %
Air changes: Approximately 15/hour
Photoperiod: 12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels: 600, 800 and 1000 mg/kg bw
Concentrations: 60, 80 and 100 mg/mL
Dose volume: 10 mL/kg bw
Number of animals: 600 and 800 mg/kg bw: 1 male and 1 female
1000 mg/kg bw: 2 males and 2 females
Route of administration: Intraperitoneal injection

b) Main micronucleus test

Dose levels: 150, 300 and 600 mg/kg bw
Concentrations: 15, 30 and 60 mg/mL
Dose volume: 10
Number of animals: 7 males/group
Route of administration: Intraperitoneal injection

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 07 Jun – 20 Jul 2005

Finalisation date: 13 Feb 2006

2. Animal assignment and treatment:

Preliminary toxicity study:
To examine the toxicity caused by glyphosate technical, single doses of 600, 800 and 1000 mg/kg bw were administered by intraperitoneal injection. One male and one female were used for the low and mid dose group whereas 2 males and females were used for the high dose group. Formulations were applied at a constant dosage volume of 10 mL/kg bw. The animals were observed for one hour following dosing and subsequently once daily for two consecutive days. Clinical signs of toxicity and mortality were recorded.

Main micronucleus test:
Groups of seven mice each received an intraperitoneal injection of 150, 300 and 600 mg/kg bw glyphosate technical, which was administered at a constant dosage volume of 10 mL/kg bw. Similar constituted groups of control animals received the vehicle (PBS, 7 mice) or the positive control (50 mg/kg bw cyclophosphamide in PBS, 5 mice/group). All animals were observed for clinical signs of toxicity and mortality one hour post dosing and once daily thereafter and immediately prior to termination.

About 24 hours post-injection, the animals were sacrificed by cervical dislocation. For the high dose (600 mg/kg bw) as well as for the vehicle control group, a second group of 7 mice was sacrificed 48 hours post-injection.

3. Slide preparation:
Immediately following termination both femurs were dissected from each animal, aspirated with foetal calf serum and bone marrow smears prepared following centrifugation and re-suspension. The smears were air-dried, fixed in absolute methanol, stained in May-Grünwald/Giemsa, allowed to air-dry and coverslipped using mounting medium.

4. Slide evaluation:
Slides were randomly coded and examined under a light microscope at 1000x magnification. For the incidence of micronucleated cells, 2000 polychromatic erythrocytes (PCE) per animal were scored. In addition, the number of normochromatic erythrocytes (NCE) associated with 1000 erythrocytes was counted and also scored for incidences of micronuclei. After decoding the slide number, the percentage of PCE per 1000 erythrocytes was calculated.

5. Statistics:
The number of micronucleated PCE occurring in each test item treated group was compared to the number occurring in the corresponding solvent control. All data were statistically analysed following a √(x 1) transformation using Student's t-test (two tailed) and any significant results were confirmed using the one-way analysis of variance.

6. Acceptance criteria:
Acceptance criteria were not specified in the study report.

7. Evaluation criteria:
The test substance was judged positive for genotoxicity in vivo if the there was a dose-related, toxicologically relevant increase in the number of micronucleated PCE observed for either the 24 or 48 hour sacrifice time point when compared to solvent controls.
If these criteria were not fulfilled, then the test material was considered to be non-genotoxic under the conditions of the test.

A positive response for bone marrow toxicity was demonstrated when the dose group mean percentage

of PCE per 1000 erythrocytes was shown to be statistically significantly lower than the concurrent vehicle control group.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

Severe clinical signs of toxicity were observed at 800 mg/kg bw and above. The animals showed hunched posture, lethargy, ataxia, ptosis, piloerection, tip toe gait, distended abdomen and hypothermia. At 600 mg/kg bw, clinical signs comprised hunched posture, ptosis, piloerection and ataxia of moderate severity. 2/2 and 2/4 animals at 800 and 1000 mg/kg bw, respectively, were killed in extremis due to the severity of clinical signs.

The test material showed no marked difference in its toxicity to male or female mice, it was therefore considered to be acceptable to use males only for the main test.

Based on the results of the preliminary toxicity study, 600 mg/kg bw was identified as maximum tolerated dose and chosen as highest dose level for the main micronucleus test.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

Clinical signs of toxicity were observed at 150 mg/kg bw and above in all animals. The observations comprised hunched posture, ptosis, ataxia and lethargy.

Evaluation of bone marrow slides:

A statistically significant decrease in the ratio of PCE (immature) to total erythrocytes compared to the vehicle control was observed in the 24-hour 600 mg/kg bw group, as well as a statistically non-significant decrease in the 48-hour 600 mg/kg bw group. The decreased ratio of PCE accompanied by the presence of clinical signs indicated systemic absorption and confirmed exposure of the bone marrow. Compared to solvent controls, a small but statistically significant increase in the incidence of micronucleated PCE was evident in the 24 hour 600 mg/kg bw group, but the values remained within the range of the laboratory's historical control data. The response was attributed to a haematopoetic effect due to bone marrow toxicity rather than to a specific genotoxic effect. The authors suggested that the increased erythropoiesis caused by test material toxicity might cause some cells to cycle more quickly than in the vehicle control animals and, therefore, there may also be less opportunity to repair spontaneously-occurring DNA damage before the final mitosis and enucleation, resulting in small increases in micronucleated cells. Therefore, the response was considered to have no toxicological significance. No statistically significant increase in the incidence of micronucleated PCE was observed in the remaining dose groups.

The positive control group showed a marked increase in the incidence of micronucleated PCE hence demonstrating validity and sensitivity of the conducted test to identify mutagenic effects in response to known mutagenic agents.

III. CONCLUSION:

Based on the results of the present study, glyphosate technical did not lead to clastogenic/aneugenic effects in bone marrow of male mice *in vivo*. Therefore, the test item was considered to be non-genotoxic under the conditions of the test.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:

The study was performed under GLP conditions and in accordance with OECD guideline 474 (1997). Under the conditions of the test, the test material was considered negative for clastogenic/aneugenic effects in the bone marrow of male mice *in vivo*. The small but statistically significant increase in the

incidence of micronucleated PCE in the 24 hour 600 mg/kg bw group remained within the range of the laboratory's historical control data. Moreover, no increase was seen after 48 hours. Thus, the response is interpreted as a haematopoetic effect due to bone marrow toxicity rather than to a specific genotoxic effect.

There were only minor deviations when compared to the currently valid OECD guideline 474 (2016), which were considered to be of minor degree. The number of polychromatic erythrocytes investigated per animal was 2000, which was the number recommended by the previous OECD guideline (1997). Further deviations were considered to not compromise the validity of the study. Therefore, the study was considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.2/008
Report author	[redacted]
Report year	1999
Report title	A micronucleus study in mice for glifosate técnico Nufarm
Report No	[redacted]-G12.79/99
Document No	Not reported
Guidelines followed in study	Not specified. The test was conducted similary to OECD 474 (2016).
Deviations from current test guideline OECD 474 (2016)	Only 1000 polychromatic erythrocytes (PCE) per animal were evaluated for the presence of micronuclei, whereas at least 4000 PCE should be evaluated according to the current guideline OEC 474 (2016). The animals were injected intraperitonealy for test substance administration, which is not represetative for a human route of exposure. Bone marrow exposure, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, was not confirmed and there was no systemic toxicity reported. However, due to the route of exposure it can be assumed that bone marrow exposure was achieved. Historical control data for the positive or vehicle controls were not provided. In addition, acceptance and evaluation criteria specified in the study report were inconsistent with those specified by the guideline.
Previous evaluation	Yes, accepted in RAR (2015)

Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: 3578/99, purity: 95 %) was tested in a mouse bone marrow micronucleus assay. Prior to the micronucleus test, a preliminary toxicity study was performed. Based on the results of the toxicity study, the dose levels for the main mutagenicity study were selected to represent 25, 50 and 75 % of the LD_{50} in mice. The test item was dissolved in water and two intraperitoneal injections at dose levels of 187.5, 375 and 562.5 mg/kg bw/day were administered to two groups of 5 male and 5 female mice. The injections were performed on two consecutive days at an interval of 24 hours. A group of vehicle (water) and positive control animals (25 mg/kg bw/day cyclophosphamide in physiological solution) were

treated in an identical manner.

All animals were sacrificed 24 hours after the second injection, followed by preparation and staining of bone marrow smears for all animals.

A total of 1000 polychromatic erythrocytes (PCE) and 1000 normochromatic erythrocytes (NCEs) were scored for the presence of micronuclei and the percentage of PCE to NCE was determined among 1000 erythrocytes.

Intraperitoneal injection of the test material did not induce clinical signs of toxicity in the mice. In addition, there was no increase in the number of micronucleated polychromatic or normochromatic erythrocytes when compared to the vehicle control and the ratio of PCE to NCEs was unaffected by treatment.

Treatment with the positive control cyclophosphamide revealed a marked increase in the incidence of micronucleated PCE, hence demonstrating capability of the test animals to show mutagenic effects in response to known mutagenic agents and confirming the sensitivity of the test.

Based on the results of the test and under the experimental conditions chosen, the test item was considered to be negative for induction of micronuclei in mice *in vivo*.

Route of administration: Intraperitoneal injection

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 28 Oct – 10 Dec 1999
Finalisation date: 27 Dec 1999

2. Animal assignment and treatment:

Preliminary toxicity study:
The LD_{50} of the test material was determined in a preliminary toxicity study. Groups of five animals received two intraperitoneal injections of 250, 500, 1000 or 2000 mg/kg bw/day on two consecutive days. The animals were observed for four days and occurrence of mortality was recorded. Based on the findings of the study, the dose levels for the main micronucleus test were selected as 25, 50 and 75 % of the LD_{50}.

Main micronucleus test:
Groups of ten mice (5 per sex) received on two consecutive days (24 hours apart) two intraperitoneal injections of 187.5, 375 and 562.5 mg/kg bw/day glyphosate technical. Similar constituted groups of control animals were treated in an identical manner with the vehicle (water) or the positive control (25 mg/kg bw/day cyclophosphamide in physiological solution).

About 24 hours after the second injection, the animals were sacrificed by cervical dislocation.

3. Slide preparation:

Immediately after sacrifice both femurs were dissected from each animal, flushed with foetal calf serum and bone marrow smears prepared following centrifugation and re-suspension. The following day the smears were fixed in 70 % ethanol, air-dried and stained with Eosin methylene blue solution.

4. Slide evaluation:

Slides were randomly coded and examined under a light microscope at 1000x magnification. For

each animal 1,000 polychromatic erythrocytes (PCE) and 1,000 normochromatic erythrocytes (NCE) were examined for the presence of micronuclei (MN). The relation PCE to NCEwere determined in the first 1,000 PCE or NCE enumerated.

5. Statistics:

Differences in the ratio of PCE to NCE and the incidence of micronucleated PCE and NCE per 1000 cells scored were compared using the Kruskal Wallis test for independent variables.

6. Acceptance criteria:

The test was considered valid only if the number of micronuclei in the vehicle control was within the range of the laboratory's historical control data.

7. Evaluation criteria:

The test substance was judged positive for genotoxicity in vivo if the following criteria were met:

- There was a reproducible and statistically significant positive response for at least one dose level and
- The increase in the number of micronuclei was at least twice the vehicle control.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Information on the stability of the test substance in the vehicle was not given in the study report.

B. PRELIMINARY TOXICITY STUDY

Based on the occurrence of mortality within 4 days after treatment, the acute lethal dose for intraperitoneal toxicity (LD_{50}) was determined to be 750 mg/kg bw/day. Dose levels for the main micronucleus test were chosen to represent 25, 50 and 75 % of the LD_{50} obtained in the preliminary toxicity study.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

Clinical signs of toxicity were not reported.

Evaluation of bone marrow slides:

No statistically or biologically significant increases in the incidence of micronucleated polychromatic erythrocytes or in the percentage of polychromatic erythrocytes were observed for the test substance either in male or female mice when compared to vehicle controls (water).

The positive control group revealed a statistically significant increase in the incidence of micronucleated PCE, demonstrating the sensitivity of the test.

CPA: cyclophosphamide, positive control

III. CONCLUSION:

Based on the results of the present study, glyphosate technical did not increase the frequency of micronuclei in the bone marrow of mice in vivo. Thus, the test item was considered to be non-genotoxic under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male and female mice *in vivo*.

The study was performed under GLP conditions and the experimental procedure was similar to the main criteria of OECD guideline 474 (2016), except for some deviations of minor degree. The number of polychromatic erythrocytes (PCE) evaluated was less than the 2000 PCE which are recommended by the current guideline (2016). However, there was no positive effect and no trend at all for induction of micronuclei, therefore it can be assumed that the outcome of the study would be the same if more cells were evaluated.

Dose levels were selected based on LD_{50} values which were determined in a preliminary toxicity study. Although clinical signs of systemic toxicity were not reported and there was no bone marrow toxicity evident, it can be assumed that due to the route of exposure (intraperitoneal injection) bone marrow exposure was achieved. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.2/009
Report author	[redacted]
Report year	1996
Report title	Glyphosate Acid: Mouse Bone Marrow Micronucleus Test
Report No	[redacted]/P/4954
Document No	Not reported
Guidelines followed in	OECD 474 (1997); US EPA (1991) and EEC Annex V B.12 (1992)

study	
Deviations from current test guideline OECD 474 (2016)	The currently defined highest dose for an administration of less than 14 days is exceeded (5000 mg/kg bw/day instead of 2000 mg/kg bw/day), however, no signs indicative of severe toxicity are reported. Only 2000 polychromatic erythrocytes were screened for the presence of micronuclei, instead of 4000, which are recommended by OECD 474 (2016). Bone marrow exposure, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, was not confirmed and there was no systemic toxicity observed, but dose levels exceeded limit concentrations specified in the current guideline. Historical control data established in the testing laboratory were not provided. In addition, acceptance criteria differed from those specified in the current guideline and evaluation criteria were not specified in the study report.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate acid (batch: P24, purity: 95.6 %) was tested for its genotoxic potential in mice using the micronucleus test. Prior to the micronucleus test, a preliminary toxicity study was conducted in order to identify the maximum tolerated dose in the animals.

Based on the results of the toxicity study, the test item was dissolved in physiological saline and groups of 5 male and 5 female mice received a single oral dose of 5000 mg/kg bw. Similarly constituted groups received the vehicle (physiological saline) or positive control (65 mg/kg bw cyclophosphamide in physiological saline) and were treated in an identical manner. The animals were sacrificed 24 or 48 hours after dosing, followed by preparation and staining of bone marrow smears.

A total of 2000 polychromatic erythrocytes (PCE) was evaluated for the presence of micronuclei. In addition, 1000 erythrocytes were counted to determine the percentage of PCE in the total erythrocyte population.

Oral administration of 5000 mg/kg bw did not induce any adverse reactions to treatment in any animal. In addition, there was no statistically significant change in the ratio of PCE among the total fraction of erythrocytes when compared to control animals, indicating that no relevant cytotoxicity occurred up to the maximum tolerated dose of 5000 mg/kg bw.

There was no statistically or biologically significant increases in the incidence of micronucleated PCE over the vehicle control values observed in either males or females at any sampling time investigated.

The positive control cyclophosphamide induced a statistically and biologically significant increase in the frequency of micronucleated polychromatic erythrocytes in both male and female mice, demonstrating the sensitivity of the test system and the capability of the test animals to respond to known mutagens.

Based on the results of the test and under the experimental conditions chosen, the test item was considered to be negative for induction of micronuclei in mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate acid

Identification:	17984
Description:	White solid
Lot/Batch #:	P24
Purity:	95.6 %
Stability of test compound:	The stability of the test item under storage conditions (at ambient temperature in the dark) was guaranteed when used within the stated expiry date. The stability of the test item in solvent (vehicle) was not specified.
Solvent (vehicle) used:	Physiological saline

2. Control materials

Solvent (vehicle) control:	Physiological saline
Positive control:	Cyclophosphamide, 65 mg/kg bw in physiological saline

3. Test animals:

Species:	Mouse
Strain:	CD-1
Sex:	Male and female
Source:	[redacted]
Age at study initiation:	6-7 weeks
Weight at dosing:	22.8 – 37.6 g
Acclimation period:	At least 5 days
Diet/Food:	CT1 (supplied by Special Diets Services, Stepfield, Witham, Essex, UK, *ad libitum*
Water:	Water, supplied by an automated watering system, *ad libitum*
Housing:	In groups of 5/sex per cage on mobile mouse cage racks

4. Environmental conditions:

Temperature:	19-23 °C
Humidity:	40-70 %
Air changes:	15/hour
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels: 5000 mg/kg bw
Number of animals: 5 /sex / group
Route of administration: Oral gavage

b) Main micronucleus test

Dose levels: 5000 mg/kg bw
Dose volume: 20 mL/kg bw
Number of animals: 5 /sex / group
Route of administration: Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 11 Dec 1995 – 30 Jan 1996
Finalisation date: 21 Mar 1996

2. Animal assignment and treatment:

Preliminary toxicity study:
The maximum tolerated dose (MTD), was determined in a preliminary toxicity study (termed as "Phase 1" in the study report). 5 male and 5 female mice received a single dose of 5000 mg/kg bw by oral gavage. Based on the occurrence of mortality and clinical signs of toxicity within 4 days after treatment, the maximum tolerated dose was determined.

Main micronucleus test:
Groups of ten mice (5 per sex) were given a single oral dose of 5000 mg/kg bw by oral gavage, representing the maximum tolerated dose. Similar constituted groups of control animals were treated in an identical manner with the vehicle (physiological saline) or the positive control (65 mg/kg bw cyclophosphamide in physiological saline).

The animals were observed for adverse reactions to treatment and sacrificed 24 and 48 hours after dosing by asphyxiation of halothane followed by cervical dislocation.

3. Slide preparation:

Immediately after sacrifice both femurs were dissected from each animal. The iliac end of the femur was removed and a fine paint brush wetted in a solution of 6 % (w/v) albumin in saline was dipped into the marrow canal. From each marrow, four smears in total were painted on appropriately labelled, clean and dry microscope slides. The slides were allowed to air-dry and stained with polychrome methylene blue and eosin.

4. Slide evaluation:

Slides were coded and scored by microscopy. For each animal 2000 polychromatic erythrocytes (PCE) were examined for the presence of micronuclei. In addition, 1000 erythrocytes were counted to determine the percentage of PCE in the total erythrocyte population.

5. Statistics:

The incidence of micronucleated PCE and the percentage of PCE in the erythrocyte sample were considered by analysis of variance at 24 and 48 hours, separately for males and females. Prior to analysis, the data for the incidence of micronucleated PEC was transformed using a square root transformation and the data for the ratio of PCE among the total number of erythrocytes was

transformed using the double arcsin transformation of Freeman and Tukey (1950)[17]. Each treatment group mean was compared with the control group mean at the corresponding sample time using a one-sided Student's t-test based on the error mean square in the analysis.

6. Acceptance criteria:

The test was considered valid if the following criteria were met:

- The positive control substance induced a significant elevation in micronucleated polychromatic erythrocytes when compared to vehicle controls.
- The test material was tested at a level that caused a decrease in the percentage of erythrocytes (indicating a cytotoxic effect on the bone marrow) or at the maximum tolerated dose level.

7. Evaluation criteria:

Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

During the four days observation period, no patterns of lethality or severe toxicity were observed. As no clinical signs and no lethality was evident at the limit dose level, 5000 mg/kg bw were taken to represent the maximum tolerated dose for males and females.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

No adverse reactions to treatment were observed for either males or females.

Evaluation of bone marrow slides:

No statistically significant differences in the percentage of polychromatic erythrocytes was observed for glyphosate acid treated animals when compared to control animals, indicating that no relevant cytotoxicity occurred up to the maximum tolerated dose of 5000 mg/kg bw.

In addition, no statistically or biologically significant increases in the incidence of micronucleated polychromatic erythrocytes over the vehicle control values were observed in either males or females at either sampling time investigated.

The positive control cyclophosphamide induced a statistically and biologically significant increase in the frequency of micronucleated polychromatic erythrocytes in both male and female mice, demonstrating the sensitivity of the test system.

III. CONCLUSION:

Based on the results of the present study, glyphosate acid has no clastogenic/aneugenic activity in bone marrow of male and female mice when tested up to the limit dose of 5000 mg/kg bw. Thus, the test item was considered to be non-genotoxic under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male and female mice *in vivo*.

The study was conducted under GLP conditions and in line with OECD guideline 474 (1997). There were a number of deviations when compared to the currently valid OECD guideline 474 (2016), all of them considered to be of minor degree. Only 2000 polychromatic erythrocytes were investigated, which was the number required according to the previous guideline (1997) that was in force when the test was conducted. Bone marrow toxicity, indicated by a shifted polychromatic to normochromatic erythrocyte ratio or systemic toxicity were not observed. However, test item doses included the dose level of 5000 mg/kg bw, which exceeds the limit value specified in the current guideline (2016). The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.2/010
Report author	[redacted]
Report year	1993
Report title	Glyphosate technical: Mutagenicity - Micronucleus Test in Swiss Albino Mice
Report No	889-MUT.MN
Document No	Not reported
Guidelines followed in study	OECD 474 (1983)
Deviations from current test guideline	The currently defined highest dose for an administration of less than 14 days is exceeded (5000 mg/kg bw/day instead of 2000 mg/kg bw/day), however,

OECD 474 (2016)	no signs indicative of severe toxicity are reported. According to the current guideline OECD 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study 2000 erythrocytes (RBC) were evaluated, including approx. 800 – 1100 polychromatic erythrocytes per animal. In addition, no data on proficiency and/or historical control data were provided. Acceptance and evaluation criteria were not specified in the study report.

Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: FSG 03090, purity: 96.8 %) was assessed for its ability to induce cytogenetic effects in Swiss albino mice. Based on the results of a preliminary range-finding study, dose levels for the micronucleus test were selected. Groups of 5 mice/sex were treated by oral gavage at dose levels of 50, 500 and 5000 mg/kg bw/day at a constant dosage volume of 10 mL/kg bw for two consecutive days. Similar constituted groups received the vehicle (refined groundnut oil, 10 mice/sex) or the positive control cyclophosphamide (100 mg/kg bw/day, 5 mice/sex).

The animals were observed for clinical signs of toxicity and mortality twice daily and the time of onset, duration and severity were recorded. In addition, the body weight of the individual animals was recorded on study Days 1, 2 and at sacrifice. 24 hours after the second dose administration the animals were sacrificed and femoral bone marrow smears were prepared for each animal. At least 2000 erythrocytes per animal were scored for the presence of micronuclei and the ratio of polychromatic to normochromatic erythrocytes was determined.

Oral administration of glyphosate technical did not induce any clinical signs of toxicity or mortality. However, at sacrifice, animals of the 500 and 5000 mg/kg bw/day group had lost body weight. The ratio of polychromatic to normochromatic erythrocytes (NCEs) of glyphosate treated mice was unaffected and comparable to those of mice treated with the vehicle, indicating that no bone marrow toxicity had occurred.

In female mice, there was a slight but statistically significant increase in the frequency of micronucleated polychromatic erythrocytes (PCEs) at the highest dose level of 5000 mg/kg bw/day when compared to control animals. There was no increase in the frequency of micronucleated PCEs at the low and the mid dose level and no effect in male mice at any dose level.

The frequency of micronucleated PCE, NCE and total erythrocytes in the solvent control animals were comparably low for all animals. The positive control cyclophosphamide showed the expected statistically significant increase in the incidence of micronucleated PCE and NCE in both sexes and a high degree of bone marrow cytotoxicity evident as markedly affected PCE/NCE ratio, demonstrating the sensitivity of the test system.

Under the conditions of the test and based on the experimental findings, glyphosate technical was considered weakly positive for induction of micronuclei in female mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate (N-(Phosphonomethyl) glycine)

Identification:	C140500
Description:	Odorless white crystals
Code:	FSG 03090 h/05, March 1990
Purity:	96.8 %
Stability of test compound:	The stability of the test item at storage conditions (at ambient temperature) was guaranteed until the expiry date Jul 1992. The stability of the test item in solvent was not specified. Dosing formulations were prepared fresh prior to treatment. Homogeneity of the test compound suspension was maintained by constant stirring/mixing in mortar during treatment.
Solvent (vehicle) used:	Refined groundnut (peanut) oil

2. Control materials

Solvent (vehicle) control:	Refined groundnut (peanut) oil
Positive control:	Cyclophosphamide, 100 mg/kg bw/day

3. Test animals:

Species:	Mouse
Strain:	Swiss albino
Sex:	Male and female
Source:	[redacted]
Age at study initiation:	8 - 10 weeks
Weight at dosing:	25 - 35 g
Acclimation period:	At least one week
Diet/Food:	Gold Mohur pelleted mice feed (Lipton India Ltd., Bangalore, India), *ad libitum*
Water:	Protected, deep borewell water, passed through activated charcoal filter and exposed to UV rays in Aquaguard on-line water filter-cum-purifier, *ad libitum*
Housing:	In groups of 5/sex in sterilised standard polypropylene cages measuring 290 x 220 x 140 mm with paddy husk bedding

4. Environmental conditions:

Temperature:	22 ± 3 °C
Humidity:	40 - 70 %
Air changes:	Approximately 12-15/hour
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

Dose levels:	50, 500 and 5000 mg/kg bw/day
Concentrations:	5, 50, 500 mg/mL
Dose volume:	10 mL/kg bw
Number of animals:	5/sex/group (test item and positive control) and 10/sex/group (vehicle control)
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 10 Aug – 10 Dec 1991
Finalisation date: 06 May 1993

2. Animal assignment and treatment:

Groups of five mice per sex received two doses of 50, 500 and 5000 mg/kg bw/day on two consecutive days. The test item was dissolved in refined groundnut (peanut) oil and administered via oral gavage at a constant dosage volume of 10 mL/kg bw. Groups of 10 mice/sex received the vehicle. Groups of 5 mice/sex were treated with the positive control (100 mg/kg bw/day cyclophosphamide).

The animals were observed for clinical signs of toxicity and mortality twice daily and the time of onset, duration and severity were recorded. In addition, the body weight of the individual animals was recorded on study Days 1, 2 and at sacrifice.

24 hours after the last treatment, the animals were sacrificed by cervical dislocation and bone marrow smears were prepared.

3. Slide preparation:

After sacrifice, the femur bones from both sides were removed, dissected and marrow cells were flushed out with sterile physiological saline. The cells were centrifuged, re-suspended in physiological saline, smeared evenly on microscopic glass slides and air-dried. 4-6 slides were prepared for each animal. Finally, the slides were fixed in methanol for 30 minutes by immersing them in a coplin jar and stained with May-Grünwald/Giemsa. Afterwards, the slides were blow-dried, immersed in xylene and coverslip mounted with DPX.

4. Slide evaluation:

For each animal a minimum of 2000 erythrocytes was scored for the incidence of polychromatic (PCE) and normochromatic (NCE) erythrocytes and for the presence of micronuclei. The following data were recorded:

- Total red blood cells /erythrocytes scored
- Number of PCEs differentiated
- Number and percentage of PCE with micronuclei
- Number of NCE differentiated
- Number and percentage of NCE with micronuclei
- Number and percentage of total red blood cells with micronuclei
- Ratio of PCE/NCE

5. Statistics:

The data was analysed group-wise and sex-wise using one way Anova and t-test for unequal number of observations for the percentage of micronucleated cells in the treated and control groups. The t-test was further used for dose-effect relationship.

6. Acceptance criteria:
Acceptance criteria were not specified in the study report.

7. Evaluation criteria:
Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in this study, as not compulsory by the test guideline.

B. MICRONUCLEUS TEST
Systemic toxicity:
Mortality:
No mortality occurred.

Clinical signs of toxicity:
There were no compound- and dose-related signs of systemic toxicity observed.

Body weight:
At sacrifice, marginal body weight loss was noted in the animals of the mid (500 mg/kg bw/day, -1.9 % in males and -2.0 % in females) and high dose group (5000 mg/kg bw/day, -4.3 % in males and -1.0 % in females), respectively.

Evaluation of bone marrow slides:
There was no difference in the ratio of polychromatic (PCE) to normochromatic erythrocytes (NCE) for any of the glyphosate treated groups when compared to solvent control animals, indicating that no bone marrow toxicity had occurred.

In female mice, there was a slight but statistically significant increase in the frequency of micronucleated polychromatic erythrocytes (PCEs) at the highest dose level of 5000 mg/kg bw/day when compared to control animals. A dose effect relationship was evident in those animals.

There was no increase in the frequency of micronucleated PCEs at the low, mid and high dose level in males or as combined sex data.

The toxicological significance of the glyphosate-related increase of micronucleated PCEs in one sex was considered doubtful, as the variation in the percentage of micronucleated PCEs was considerably high among female dose groups as compared to the control.

The frequency of micronucleated PCE, NCE and total erythrocytes in the solvent control animals were comparably low for all animals. The positive control cyclophosphamide showed the expected statistically significant increase in the incidence of micronucleated PCE and NCE in both sexes and a high degree of bone marrow cytotoxicity evident as markedly affected PCE/NCE ratio, demonstrating the sensitivity of the test system.

III. CONCLUSION:

Based on the experimental findings glyphosate technical induced micronuclei in female mice at a dose level of 5000 mg/kg bw/day. No increase in micronuclei formation was observed at lower dose levels in females or in males at any dose level. In conclusion, the test substance was considered weakly positive for clastogenic/aneugenic effects in female mice and negative in male mice *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Based on the experimental findings the test item was considered weakly positive for clastogenic/aneugenic effects in the bone marrow of female mice *in vivo*. The study was performed according to OECD guideline 474 (1983) and under GLP conditions. The number of evaluated polychromatic erythrocytes was far below the recommendation of the current OECD guideline (2016), which resulted in rather high standard deviations. Due to missing historical control data, the biological significance of the weak positive result observed in females is unclear. Besides this, only minor deviations to the currently valid OECD guideline are present. Therefore, the study is considered to provide supporting information. Further deviations were considered to not compromise the outcome of the study.

Assessment and conclusion by RMS:

GLP	Yes
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate technical (batch: 0190A, purity: not reported) was tested for its genotoxic potential in BKW mice in a micronucleus test. Based on the results of a preliminary toxicity study, in which no mortality was observed up to an oral dose level of 5000 mg/kg bw, a dose of 4000 mg/kg bw was selected for the main mutagenicity test. The test item was dissolved in water and administered by oral gavage to three groups of mice for 3 sampling time points (24, 48 and 72 h after administration). Similar constituted groups received the solvent (distilled water) or the positive control (50 mg/kg bw cyclophosphamide). The animals were observed for clinical signs of toxicity and death one hour after dosing and once daily thereafter. Sampling of the vehicle control occurred at 24, 48 and 72 hours after treatment. For the positive control, bone marrow was sampled 24 hours following treatment. Smears were prepared from the femoral bone marrow of each animal and 1000 polychromatic erythrocytes (PCE) per animal were scored for the presence of micronuclei. In addition, the number of micronucleated normochromatic erythrocytes (NCE) associated with 1000 PCE were counted and scored for the incidence of micronuclei.
Short description of results:	Upon treatment with glyphosate technical, 4/10, 2/10 and 1/10 animals died prematurely of the 24 hour, 48 hour and 72 hour sampling group, respectively. Substitute animals were included for the respective dose groups. Except one substitute animal of the 48 hour sampling group, all animals survived until scheduled sacrifice. Thus, the toxicological relevance of the observed mortality is unclear taking into consideration the survival rate of the substitute animals and the test animals in the preliminary study. Clinical signs of toxicity were observed in one animal and comprised hunched posture, lethargy, piloerection, decreased respiratory rate, ptosis and ataxia. The majority of substitute animals showed minor clinical signs of toxicity. When compared to solvent controls, the ratio of PCE/NCE was not affected by treatment, indicating that glyphosate did not induce bone marrow toxicity. There was no statistically significant increase in the incidence of micronucleated PCE or NCE for any sampling time point when compared to their concurrent vehicle controls. However, the respective standard deviations indicate a rather high heterogeneity in results. The positive control cyclophosphamide showed a marked increase in the incidence of micronucleated PCE and a small elevation of the PCE/NCE ratio, hence confirming the sensitivity of the test. Under the conditions of the test, the results indicate that glyphosate technical is negative for cytogenetic effects in bone marrow in mice *in vivo*.

Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable due to a large number of guideline deviations. According to the current guideline OECD 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study only 1000 polychromatic erythrocytes were evaluated. No data on proficiency and/or historical control data were provided and the purity of the test material was not reported. The highest tested dose level of 4000 mg/kg bw exceeds the currently defined maximum dose of 2000 mg/kg bw for administration periods < 14 days. Strong mortality was noted in the main mutagenicity study among various test groups, although a dose-response relationship was not evident and the deaths were not clearly attributable to treatment. The mortality observed was inconsistent with observations in other studies. In addition, evaluation criteria were inconsistent with those specified in the current guideline (2016).
Reasons why the study report is not available for submission	Not applicable

1. Information on the study

Data point	CA 5.4.2/012
Report author	[redacted]
Report year	1991
Report title	Mutagenicity test: Micronucleus test with Glyphosate, batch 206-JaK-25-1
Report No	12324
Document No	Not reported
Guidelines followed in study	OECD 474 (1983), US EPA FIFRA 84-2
Deviations from current test guideline OECD 474 (2016)	The currently defined highest dose for an administration of less than 14 days is exceeded (5000 mg/kg bw/day instead of 2000 mg/kg bw/day), however, no signs indicative of severe toxicity are reported. According to the current guideline OECD 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study 2000 polychromatic erythrocytes were evaluated (requirement of previous OECD guideline (1983)). In addition, the percentage of polychromatic erythrocytes among total erythrocytes was determined for 200 erythrocytes instead of 500 erythrocytes. Bone marrow exposure, indicated by a reduced polychromatic to normochromatic erythrocyte ratio or systemic toxicity were not observed. In addition, no 24-hour control animals were included (first sampling time point). No data on proficiency and/or historical control data were provided. Acceptance and evaluation criteria were not specified in the study report.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate technical (batch: 206-JaK-25-1, purity: 98.6 %) was tested for its clastogenic/aneugenic potential in NMRI mice in a micronucleus test. Based on the results of an initial toxicity study in which no signs of toxicity became evident, the main micronucleus test was performed at a single dose level of 5000 mg/kg bw.

Three groups of 5 animals/sex received a single dose of the test item, dissolved in 0.5 % carboxymethyl cellulose and administered at a constant dosage volume of 10 mL/kg bw. Similar constituted groups of 5 mice/sex received the positive (cyclophosphamide, 30 mg/kg bw) or vehicle control (0.5 % carboxymethyl cellulose in distilled water).

Bone marrow sampling of the test item treated groups was performed 24, 48 and 72 hours after treatment. Positive and vehicle control animals were sacrificed 24 and 48 hours after dosing, respectively. Smears were prepared from the femoral bone marrow of each animal and 2000 immature erythrocytes (PCE) per animal were scored for the presence of micronuclei. The percentage of PCE in 200 erythrocytes was calculated. In addition, the number of micronucleated normochromatic erythrocytes (NCEs) was determined.

Oral administration of glyphosate technical did not induce any clinical signs of systemic toxicity. In addition, the ratio of PCE to NCEs indicates that no bone marrow toxicity was evident in any of the tested conditions.

The incidence of micronucleated polychromatic erythrocytes after treatment with glyphosate was comparable between control and treatment groups for any sampling time point. The frequency of micronuclei in the solvent and positive control groups were in accordance with the laboratory's historical control data, confirming validity and sensitivity of the test. Based on the experimental findings, glyphosate technical is negative for cytogenetic effects in bone marrow in mice *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

Identification:	Glyphosate Technical
Description:	White powder
Lot/Batch #:	206-JaK-25-1
Purity:	98.6 %
Stability of test compound:	The stability of the test item, storage conditions or expiry date were not reported. The stability of the test item in solvent was not specified.
Solvent (vehicle) used:	0.5 % carboxymethyl cellulose in distilled water

2. Control materials

Solvent (vehicle) control:	0.5 % carboxymethyl cellulose in distilled water
Positive control:	Cyclophosphamide, 30 mg/kg bw

3. Test animals:

Species:	Mouse

Strain:	Bom:NMRI (NMRI SPF mice)
Sex:	Male and female
Source:	[redacted]
Age at study initiation:	7 - 10 weeks
Weight at dosing:	26 - 31 g
Acclimation period:	5 days
Diet/Food:	Altromin 1314 (Chr. Petersen Ltd., Ringsted, Denmark), *ad libitum*
Water:	Tap water acidified with hydrochloric acid to pH 2.5, *ad libitum*
Housing:	In groups of 5/sex in Macrolon type III cages measuring 420 x 260 x 150 mm with softwood sawdust bedding.

4. Environmental conditions:

Temperature:	21 ± 3 °C
Humidity:	55 ± 15 %
Air changes:	Approximately 10/hour
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels:	5000 mg/kg bw
Concentrations:	Not specified
Dose volume:	10 mL/kg bw
Number of animals:	5/sex/group
Route of administration:	Oral gavage

b) Main micronucleus test

Dose levels:	5000 mg/kg bw
Concentrations:	500 mg/mL
Dose volume:	10 mL/kg bw
Number of animals:	5/sex/group
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 24 Jan – 01 Feb 1991
Finalisation date: 12 Sep 1991

2. Animal assignment and treatment:

Preliminary toxicity study:
Glyphosate was expected to be of low toxicity. To determine the maximum tolerated dose, a single dose of 5000 mg/kg bw was administered by oral gavage to 4 male and 5 female mice. A group of 3 mice further received the vehicle and served as control. The test substance or the vehicle was applied at a constant dosage volume of 10 mL/kg bw. Bone marrow samples were prepared 24, 48 and 72 hours after dosing from 3 mice per sampling time point and 48 hours after dosing for the control group. To assess bone marrow toxicity upon treatment with the test item, the percentage of polychromatic erythrocytes among the total of erythrocytes was determined for 200 erythrocytes for each animal. The

amount of PCE was comparable between the control and test group.

Based on these results, 5000 mg/kg bw was selected as dose level for the main micronucleus test.

Main micronucleus test:
Groups of five mice per sex were administered a single dose of 5000 mg/kg bw by oral gavage at a constant dosage volume of 10 mL/kg bw. Similar constituted groups of 5 mice/sex received the vehicle (0.5 % carboxymethyl cellulose) or the positive control (30 mg/kg bw cyclophosphamide).
Animals of the test group were sacrificed by cervical dislocation at 24, 48 and 72 hours after treatment and bone marrow smears were prepared. Positive control animals were sacrificed 24 hours after treatment, the vehicle control group was sacrificed 48 hours after dosing.

3. Slide preparation:
Immediately after sacrifice, the right femoral bone was dissected, the proximal end of the femur was cut and marrow cells were flushed out with foetal calf serum. After whirl-mixing, the bone marrow suspensions were centrifuged and smears were prepared. The specimens were fixed in methanol and stained with May-Grünwald/Giemsa

4. Slide evaluation:
Slides were randomly coded and examined by microscopical analysis. About 2000 polychromatic erythrocytes (PCE) per animal were scored for the presence of micronuclei. The percentage of PCE in 200 erythrocytes was calculated. In addition, the number of micronucleated normochromatic erythrocytes (NCE) was determined during the counting of 2000 PCE.

5. Statistics:
The number of micronucleated PCE in the test group were compared to the number found in the vehicle group. Statistical analysis was performed using the one-way analysis of variance performed on the values transformed to normal scores according to Blom's method[18].

6. Acceptance criteria:
Acceptance criteria were not specified in the study report.

7. Evaluation criteria:
Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY
Clinical signs of systemic toxicity have not been described in the study report. Bone marrow toxicity, evident as a shifted ratio of polychromatic erythrocytes has not been observed. The percentage of PCE was between 34 and 43 % for both, test and control group. Based on the results of the preliminary toxicity study, 5000 mg/kg bw was selected as dose level for the main micronucleus test.

C. MAIN MICRONUCLEUS TEST
Systemic toxicity:
Mortality:
No mortality reported.

Clinical signs of toxicity:

[18] Blom (1958): Statistical Estimates and Transformed Beta Variables, New York: John Wiley and Sons, Inc

Clinical signs of toxicity were not described in the study report.

Evaluation of bone marrow slides:
There was no difference in the ratio of polychromatic to normochromatic erythrocytes when compared to vehicle controls for any sampling time point, demonstrating that there was no bone marrow toxicity evident. Values were in the range of 37.7 – 42.2 % and fell into the normal range of the laboratory (data not shown).

There was no statistically significant increase in the incidence of micronucleated PCE in test item-treated animals at any sampling time point when compared to vehicle control. The frequency of micronuclei in the solvent and positive control groups were in accordance with the laboratory's historical control data, confirming the sensitivity of the test and demonstrating the capability of the test animals to respond to mutagenic substances.

Table 5.4.2-14: Mutagenicity test: Micronucleus test with Glyphosate ([redacted] 1991b), summary of genotoxicity data

Treatment	Dose (mg/kg bw)	Sampling time	Males		Females	
			mPCE ± SD /2000 PCE	mean% PCE ± SD /200 erythrocytes	mPCE ± SD /2000 PCE	mean% PCE ± SD /200 erythrocytes
CMC	0.5 %	48 h	3.00 ± 1.41	36.00 ± 5.15#	2.40 ± 0.55	39.80 ± 1.30#
Test item	5000	24 h	3.40 ± 1.14	35.60 ± 2.97	3.00 ± 1.41	40.00 ± 3.32#
	5000	48 h	2.20 ± 0.84	37.00 ± 2.24	3.40 ± 1.67	40.40 ± 1.95
	5000	72 h	1.80 ± 1.30	37.40 ± 3.44	1.60 ± 1.14	37.80 ± 3.63
CPA	30	24 h	48.60 ± 4.98	41.20 ± 3.03	47.80 ± 9.96	43.00 ± 5.70

Mean values and standard deviations (SD) were calculated based on the raw data given in the study report.
mPCE: number of micronuclei observed in 2000 PCE
%PCE: PCE in percent of total erythrocytes
Calculations were performed with raw data values of poor legibility.
CMC: carboxymethyl cellulose, solvent control; CPA: cyclophosphamide, positive control

III. CONCLUSION

Based on the experimental findings glyphosate technical is negative for cytogenetic effects in bone marrow in mice *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of male and female mice i*n vivo*.

The study was performed under GLP conditions and in accordance with OECD guideline 474 (1983). When compared to the currently valid OECD guideline 474 (2016), a number of deviations became evident. The number of polychromatic erythrocytes investigated was 2000/animal, corresponding to the number required by the previous guideline (1997). In addition, the percentage of polychromatic erythrocytes among total erythrocytes was determined for 200 erythrocytes instead of 500 erythrocytes. The deviations were considered to be of minor degree and to not compromise the validity of the study. Bone marrow toxicity, indicated by a reduced polychromatic to normochromatic erythrocyte ratio or

signs of systemic toxicity, was not evident, but the test was performed at dose levels exceeding the limit concentrations specified in the current guideline. The study is therefore considered valid and acceptable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.4.1/013
Report author	[redacted]
Report year	1989
Report title	Mutagenicity study of glyphosate in NMRI mice using the micronucleus test
Report No	Not reported
Document No	Not reported
Guidelines followed in study	No guideline followed. The study was conducted according to the main criteria of OECD 474 (1983).
GLP	No, not conducted under GLP/ Officially recognised testing facilities. When the study was conducted, GLP was not compulsory.
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Glyphosate active ingredient (batch and purity not reported) was tested for induction of micronuclei in the bone marrow of NMRI mice. Based on the results of a preliminary toxicity study (data not shown), three groups of 7 mice/sex were treated with 2000 mg/kg bw glyphosate. The test substance was dissolved in water plus Tween 80 and administered as a single oral dose by gavage. In addition, groups of 5 mice/sex were included as control animals and received either the solvent (water plus Tween 80) by oral gavage or the positive control cyclophosphamide (100 mg/kg bw) by intraperitoneal injection. Glyphosate-treated animals were sacrificed 24, 48 and 72 hours after treatment and bone marrow slides were prepared. Sampling of the solvent control group was performed 48 hours after dosing and sampling of the positive control group was conducted 24 hours after treatment. Smears were prepared from the femoral bone marrow of each animal. About 1000 polychromatic erythrocytes (PCE) per animal were scored for the presence of micronuclei. In addition, the amount of normochromatic erythrocytes (NCE) among 1000 PCE was determined.
Short description of results:	Mortality and clinical signs of toxicity were not reported. However, from the result tables it became obvious that 1/7 glyphosate-treated males of the 48-hour sampling group died during the course of the study. In addition, no results were scored for 1/7 glyphosate-treated males of the 72 hour sampling group. It was not specified why no scoring was performed for the animal, therefore it cannot be excluded that mortality has occurred. Without a dose-response relationship it can be assumed that if mortality occurred, it was not related to treatment.

	There was no significant increase in the number of NCE among 1000 PCE when compared to solvent controls for any sampling time point, indicating that no bone marrow toxicity was evident. In addition, there was no statistically significant increase in the frequency of micronucleated PCE (mPCE) or NCE at any sampling time point. A marked increase in the incidence of mPCE was observed for the positive control. Based on the experimental findings and under the conditions of the test, glyphosate active ingredient did not induce micronuclei in the bone marrow of male and female NMRI mice *in vivo*.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was considered not acceptable, due to a large number of guideline deviations and reporting deficiencies. The test material purity and batch no. were not indicated. According to the current guideline OECD 474 (2016), at least 4000 polychromatic erythrocytes per animal should be evaluated for the presence of micronuclei. In the present study only 1000 polychromatic erythrocytes were evaluated. The guideline further recommends to include a negative/ vehicle control for every sampling time point or at least at the first sampling time point. In the present study the sampling of the solvent control animals was performed 48 hours after treatment, which represents the second sampling time point. Bone marrow exposure, indicated by a reduced polychromatic to normochromatic erythrocyte ratio, was not observed and systemic toxicity was not reported. In addition, mortality was not reported, however, from the result tables it became obvious that 1/7 glyphosate-treated males of the 48-hour sampling group died during the course of the study. In addition, no results were scored for 1/7 glyphosate-treated males of the 72 hour sampling group. It was not specified why no scoring was performed for the animal, therefore it cannot be excluded that mortality has occurred. In addition, evaluation criteria were not specified in the study report and no data on proficiency and/or historical control data were provided. The deviations were considered to compromise the validity of the study.

Category study in AIR 5 dossier (L docs)	Category 2a

#: Following the feedback from the Assessment Group Glyphosate in March 2020, the Notifier is aware of concerns regarding work conducted at this specific contract laboratory ([redacted]). For the sake of completeness, this study is included in the dossier submission since it was part of the data package of previous EU evaluation processes.

2. Full summary

Glyphosate technical (batch: 20080801, purity: 98.8 %) was tested for genotoxicity in CD rats using the micronucleus test. Based on the results of a preliminary toxicity study in which no signs of toxicity nor mortality were observed up to a dose level of 2000 mg/kg bw, 2000 mg/kg bw were selected as top dose for the main micronucleus study. Groups of 5 rats per sex were administered a single oral dose of 500, 1000 and 2000 mg glyphosate technical/kg bw dissolved in 0.8 % aqueous hydroxypropylmethyl cellulose at a constant dosage volume of 20 mL/kg bw. Vehicle control animals treated with 0.8 % aqueous hydroxypropylmethyl cellulose in an identical manner and positive control group animals receiving an intraperitoneal injection of 27 mg/kg bw cyclophosphamide were included in the experiment. All animals were observed for clinical signs of toxicity. Bone marrow sampling was performed 24 hours after treatment for all dose groups including the vehicle and positive controls and additionally after 48 hours for the control and high dose group. 2000 polychromatic erythrocytes (PCE) per animal were scored for the incidence of micronucleated PCE. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was determined for each animal by counting a total of 1000 erythrocytes.

Oral administration of glyphosate technical up to 2000 mg/kg bw did not induce any signs of systemic toxicity in the animals.

There was no difference in the ratio of PCE to NCE observed in test item treated rats when compared to the vehicle controls, indicating that no relevant cytotoxicity in bone marrow occurred. No increase in micronucleated PCE was observed in the treated groups when compared to the corresponding vehicle control group for any dose level and sampling time points. The positive reference item group exhibited a statistically significant increase in the number of micronucleated PCE, demonstrating the functionality of the test system.

Based on the results of the test and under the experimental conditions chosen, there is no evidence for the test item to induce clastogenicity/aneugenicity in rats *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate Technical

Identification:	37/064/08
Description:	White solid
Lot/Batch #:	20080801
Purity:	98.8 % (w/w)
Stability of test compound:	The stability of the test item at storage conditions (at room temperature, in the dark) was guaranteed until the expiry date 01 Aug 2010. The stability of the test item in vehicle was not specified.
Solvent (vehicle) used:	0.8 % aqueous hydroxypropylmethyl cellulose

2. Control materials

Solvent (vehicle) control:	0.8 % aqueous hydroxypropylmethyl cellulose, 20 mL/kg bw administered by oral gavage
Positive control:	Cyclophosphamide, 27 mg/kg bw in 0.9 % NaCl, 20 mL/kg bw administered by intraperitoneal injection

3. Test animals:

Species:	Rat
Strain:	CD
Sex:	Males and females
Source:	[redacted]
Age at dosing:	32-33 days (males) and 33 - 34 days (females)
Weight at dosing:	106-132 g (males) and 88 – 111 g (females)
Acclimation period:	At least 5 days
Diet/Food:	Commercial ssniff® R/M-H V1534 diet (ssniff Spezialdiäten GmbH, Soest, Germany), *ad libitum*, feeding was discontinued approx. 16 hours before administration
Water:	Tap water, *ad libitum*
Housing:	In groups of 2 - 3/sex in Makrolon type III plus cages with granulated textured wood bedding

4. Environmental conditions:

Temperature:	22 ± 3 °C
Humidity:	55 ± 15 %
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels:	500, 1000 and 2000 mg/kg bw
Dose volume:	20 mL/kg bw
Number of animals:	1/sex
Route of administration:	Oral gavage

b) Main micronucleus test

Dose levels:	500, 1000 and 2000 mg/kg bw
Dose volume:	20 mL/kg bw
Number of animals:	500 and 1000 mg/kg bw: 5/sex 2000 mg/kg bw: 10/sex
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 04 Feb – 06 Mar 2009
Finalisation date: 18 May 2009

2. Animal assignment and treatment:

Preliminary toxicity study:
A preliminary study on acute oral toxicity was performed in male and female rats. One animal per sex received a single dose of 500, 1000 or 2000 mg/kg bw by oral gavage at a constant dosage volume of 20 mL/kg bw. The animals were observed for clinical signs of toxicity and mortality for a period of 3 days.

Main micronucleus test:
Based on the results of the preliminary toxicity study, the dose levels for the main micronucleus test were chosen. The top dose was defined as the dose producing signs of toxicity such that higher dose levels based on the same dosing regimen would be expected to produce lethality or as the dose which produces indications of bone marrow toxicity.

Groups of five rats each received a single oral dose of 500, 1000 and 2000 mg/kg bw glyphosate technical, which was administered at a constant dosage volume of 20 mL/kg bw. Similar constituted groups of control animals received the vehicle (0.8 % aqueous hydroxypropylmethyl cellulose) by oral gavage or the positive control (27 mg/kg bw in 0.9 % NaCl) by intraperitoneal injection. All animals were observed for clinical signs of toxicity before sacrifice.

Bone marrow sampling was performed 24 hours after treatment for all dose groups including the vehicle and positive control and additionally after 48 hours for the control and high dose group only.

3. Slide preparation:

After sacrifice, the femurs of the rats were excised and the bone marrow was flushed out with calf serum. The cells were centrifuged, re-suspended in a drop of calf serum and smears of 30 – 60 mm length were prepared. The smears were air-dried, fixed in methanol and stained with Mayers Haemaleum. Afterwards, the slides were rinsed with cold tap water and further stained with 0.5 % (w/v) ethanolic eosin. The slides were again left to air-dry, cleared in xylene and mounted.

4. Slide evaluation:

The slides were coded and randomized before microscopical analysis. 2000 polychromatic erythrocytes (PCE) per animal were scored for the incidence of micronuclei. In addition, the ratio of PCE to normochromatic erythrocytes (NCE) was determined for each animal by counting a total of 1000 erythrocytes.

5. Statistics:

The frequency of micronuclei and the ratio of PCE/NCE was analysed by comparing glyphosate treated samples to those of the positive and the solvent control. Statistical assessment was carried out using the chi-square test corrected for continuity. For each group, interindividual variation in the numbers of micronucleated PCE was estimated by means of a heterogeneity chi-square test. The numbers of micronucleated PCE in each treated group (males and females, separately and combined) were then compared with the numbers in the vehicle control groups by using a 2 x 2 contingency table to determine chi-square. Probability values of $p \leq 0.05$ were accepted as significant.

6. Acceptance criteria:

The micronucleus test was considered valid when the following criteria were met:

- The heterogeneity chi-square test provided evidence of acceptable variability between animals within a group.
- The incidence of micronucleated PCE in the vehicle control groups fell within or close to the historical vehicle control range of the laboratory.
- At least 7 animals (males and females together) out of each group at each kill were available for analysis.
- The positive reference chemical (CPA) induced clear and statistically significant increases in the frequencies of micronucleated PCE.

7. Evaluation criteria:

The test substance was considered as clearly positive if the following criteria were met:

- A statistically significant increase in the frequency of micronucleated PCE occurred for at least one dose at one sampling time.
- The frequency of micronucleated PCE at such a point exceeded the laboratory's historical control range.
- Corroborating evidence was obtained, for example, increased but statistically insignificant frequencies or micronucleated PCE at other doses or kill times, or dose response profiles.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in this study, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

No signs of systemic toxicity or mortality were observed up to the limit dose of 2000 mg/kg bw. Based on the results of the preliminary toxicity study, the dose levels for the main study were selected to be 500, 1000 and 2000 mg/kg bw.

C. MAIN MICRONUCLEUS TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

There were no clinical signs of toxicity observed after administration of glyphosate technical up to the highest reasonable dose level of 2000 mg/kg bw until 48 hours after dosing.

Evaluation of bone marrow slides:

No difference in the ratio of PCE/NCE compared to the vehicle controls was observed in male and female rats treated with glyphosate technical, indicating that no relevant cytotoxicity in bone marrow occurred.

No test item-related increase in micronucleated PCE was observed in any treated group as compared to the corresponding vehicle control group at any of the two sampling time points.
The positive reference item group exhibited a statistically significant increase in the number of micronucleated PCE, demonstrating validity and sensitivity of the test system.

Table 5.4.2-15: Micronucleus test of Glyphosate TC in Bone Marrow Cells of the CD Rat by oral administration ([redacted] 2009), summary of genotoxicity data

Treatment	Dose (mg/kg bw)	Sampling time	Males		Females

III. CONCLUSION

Under the conditions of the test and based on the experimental results of the present study, glyphosate technical tested up to the limit dose of 2000 mg/kg bw did not show mutagenic properties in the rat bone marrow micronucleus test. Therefore, the test item was considered to be negative for clastogenicity/aneugenicity in rats.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for clastogenic/aneugenic effects in the bone marrow of CD rats *in vivo*.

The study was performed in compliance with GLP and in accordance with OECD guideline 474 (1997). There were only minor deviations when compared to the current OECD guideline 474 (2016). The number of polychromatic erythrocytes investigated per animal was 2000 (instead of 4000), which was the number recommended by the previous OECD guideline (1997). Bone marrow exposure, indicated by a reduced ratio of polychromatic to normochromatic erythrocytes, was not shown and no systemic toxicity was observed. However, test item doses included the limit dose of 2000 mg/kg bw. Therefore,

the study was considered valid and acceptable.

Assessment and conclusion by RMS:

Chromosomal aberration tests in the bone marrow of mice *in vivo*:

1. Information on the study

Data point	CA 5.4.2/015
Report author	[redacted]
Report year	1994
Report title	Genetic toxicology: *In vivo* mammalian bone marrow cytogenetic test – Chromosomal analysis
Report No	890-MUT-CH.AB
Document No	Not reported
Guidelines followed in study	OECD 475 (1984)
Deviations from current test guideline OECD 475 (2016)	Only 50 metaphase cells/ mouse were investigated for chromosomal aberrations, whereas the currently valid OECD guideline 475 (2016) suggests a total of 200 metaphase cells to be analysed for each animal. The mitotic index was determined for 100 cells instead of 1000 cells. Analysis of metaphase cells was only performed for control group animals and for animals of the high dose group, were toxicity was observed. There was no scoring for chromosome aberrations for lower dose levels where no toxicity occurred. The animals were treated twice, but the use of the second dose was not justified. The cell cycle arrest time was insufficient and the sampling time after the second dose was later (24 hours plus additional 1.5 hours cell cycle arrest) than specified in the current guideline (24 hours after 2nd dose including cell cycle arrest). Acceptance and evaluation criteria were not specified in the study report. Historical control data were not provided.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate (batch: 046, purity: 96.8 %) was investigated for its potential to induce chromosomal aberrations in bone marrow in male and female Swiss albino mice. The test item was dissolved in refined groundnut oil and administered by oral gavage. Based on the results of a preliminary toxicity study, in which no signs of systemic toxicity were noted at 5000 mg/kg bw/day, the same dose level was also chosen for the *in vivo* bone marrow chromosomal aberration study. Groups of 5 mice/sex received 50, 500 or 5000 mg/kg bw/day for two consecutive days at a constant dosage volume of 10 mL/kg bw. Similar constituted groups of mice received the solvent or the positive control (50 mg/kg bw/day cyclophosphamide).

The animals were observed for clinical signs of toxicity and mortality twice a day and individual body weights were recorded on study Days 1, 2 and at sacrifice.

24 hours after the second treatment, the animals received an intraperitoneal injection of 0.4 % colchicine. 90 minutes following the injection of colchicine, the animals were sacrificed and bone marrow slides were prepared.
A total of 50 metaphases per mouse (250 per sex per condition) were scored for the presence of chromosomal aberrations and the number of dividing cells (mitotic index) was determined for 1000 cells per animal.

Upon treatment with glyphosate, 2/5 males of the high dose group were dull and had soft stool, which was considered to be incidental. In addition, there was a statistically significant reduction of body weight in females of the high dose group (26.8 ± 0.98 g instead of 32.2 ± 2.13 g in control animals). In animals of both sex, there was a statistically significant reduction in the mitotic index at 5000 mg/kg bw/day, indicating that bone marrow toxicity was evident.

There was no statistically significant and biologically relevant increase in the number of aberrant metaphases or in the incidence of individual chromosomal aberrations observed at the highest dose level of 5000 mg/kg bw/day when compared to solvent control animals. A statistically significant increase in the incidence of gaps in females was observed at 5000 mg/kg bw/day, however, the observations were considered to be without toxicological relevance. As the frequency of aberrant metaphase cells upon treatment with glyphosate was not increased at the highest dose level tested, the slides of the low and the mid dose groups were not investigated.

The frequency of aberrant metaphase cells in solvent control animals was as expected and the number of aberrant metaphases and incidences of aberration types was significantly high in cyclophosphamide treated animals. In line with significant toxicity in the bone marrow of cyclophosphamide treated animals, the results confirm the sensitivity of the animals to respond to chromosomal damaging agents.

Under the conditions of the test and based on the experimental findings, glyphosate did not increase the frequency of chromosomal aberrant metaphases in the bone marrow of male and female mice and was therefore considered negative for cytogenicity *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material: Glyphosate (N-(Phosphonomethyl) glycine)

Identification:	Not specified
Description:	Odorless white crystals
Lot/Batch #:	046
Purity:	96.8 %
Stability of test compound:	The stability of the test item at storage conditions (at ambient temperature) was guaranteed until the expiry date July 1994. The stability of the test item in solvent was not specified. Dosing formulations were prepared fresh prior to treatment. Homogeneity of the test compound suspension was maintained by constant stirring/mixing in mortar during treatment.
Solvent (vehicle) used:	Refined groundnut (peanut) oil

2. Control materials

Solvent (vehicle) control:	Refined groundnut (peanut) oil
Positive control:	Cyclophosphamide (Endoxan-ASTA), 50 mg/kg bw/day

3. Test animals:

Species:	Mouse
Strain:	Swiss albino
Sex:	Male and female
Source:	[redacted]
Age at dosing:	8 - 12 weeks
Weight at dosing:	32 – 38 g (males) and 28 – 32 g (females)
Acclimation period:	At least one week
Fasting period prior administration:	Gold Mohur pelleted mice feed (Lipton India Ltd., Bangalore, India), *ad libitum*
Diet/Food:	Protected, deep borewell water, passed through activated charcoal filter and exposed to UV rays in Aquaguard on-line water filter-cum-purifier, *ad libitum*
Water:	In groups of 5/sex in sterilised standard polypropylene cages measuring 290 x 220 x 140 mm with paddy husk bedding
Housing:	Mouse

4. Environmental conditions:

Temperature:	22 ± 3 °C
Humidity:	40 - 70 %
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

a) Preliminary toxicity study

Dose levels:	2000 and 3000 mg/kg bw/day
Concentrations:	Not specified
Dose volume:	Not specified
Number of animals:	2/sex/group
Route of administration:	Oral gavage

b) Main cytogenicity test

Dose levels:	50, 500 and 5000 mg/kg bw/day
Concentrations:	5.1, 51.5 and 334.0 mg/mL
Dose volume:	10 mL/kg bw (low and mid dose), 15 mL/kg bw (high dose)
Number of animals:	5/sex/group
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 11 Jan – 09 Feb 1993
Finalisation date: 22 Jan 1994

2. Animal assignment and treatment:

Preliminary toxicity study:
In a range-finding study two male and two female mice were administered dose levels of 2000 and 3000 mg/kg bw/day for two consecutive days to determine the maximum tolerated dose (MTD). Based on the results of the preliminary toxicity study, dose levels for the bone marrow chromosomal aberration study were chosen.

Main micronucleus test:
Groups of five mice per sex were administered for two consecutive days at doses of 50, 500 and 5000 mg/kg bw/day. The test item was dissolved in refined groundnut (peanut) oil and administered via oral gavage at a constant dosage volume of 10 mL/kg bw. Similar constituted groups of 5 mice/sex were treated with the solvent or positive control (50 mg/kg bw/day cyclophosphamide).
The animals were observed for clinical signs of toxicity and mortality twice a day and individual body weights were recorded on study Days 1, 2 and at sacrifice.

24 hours after the second treatment, the animals received an intraperitoneal injection of 0.4 % colchicine at a dosage volume of 10 mL/kg bw. 90 minutes later, the animals were sacrificed by cervical dislocation and bone marrow slides were prepared.

3. Slide preparation:
After sacrifice, the femur bones from both sides were removed, dissected and bone marrow cells were flushed out with 0.56 % potassium chloride solution. The cell suspensions underwent hypotonic treatment at 37 °C for 15 minutes, followed by centrifugation and drop-wise re-suspension in freshly prepared methanol and glacial acetic acid (3:1) fixative. The cells were fixed two times for 10 minutes, followed by 1 hour fixation in the refrigerator. The cell suspension was dropped onto a clean chilled slide and flame dried. Staining was performed with 2 % Giemsa for 10 minutes, afterwards the slides were rinsed with distilled water, blow dried, immersed in xylene and coverslip mounted with DPX.

4. Metaphase analysis:
Slides were coded and 50 metaphase cells per animal (250 per condition) were scored for chromosomal aberrations. Number and frequency of metaphase cells were recorded and evaluated for aberrations such chromatid or chromosome gaps, breaks, acentric fragments, ring chromosomes, multiple chromatid breaks, pulverization, polyploidy and exchange figures.

In addition, toxicity was evaluated based on the mitotic index, representing the frequency of metaphase cells in 100 cells per slide.

5. Statistics:
Intra-group body weight changes during the treatment period were compared by paired t-test. Chromosomal aberrations in treated and positive control animals versus solvent control animals were statistically analysed by Z-test.

6. Acceptance criteria:
Acceptance criteria were not specified in the study report.

7. Evaluation criteria:
Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS
Analytical determinations were not performed in the study, as not compulsory by the test guideline.

B. PRELIMINARY TOXICITY STUDY

There were no clinical signs of toxicity and no changes in body weight observed. The maximum tolerated dose (MTD) was determined to be > 3000 mg/kg bw/day. Based on the results of the dose-range finding study, the dose levels for the bone marrow cytogenicity study were selected.

C. BONE MARROW CHROMOSOMAL ABERRATION TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

There were no treatment-related signs of systemic toxicity at 50 and 500 mg/kg bw/day. In the high dose group, 2/5 males were dull and had soft stool. The findings were considered toxicologically not relevant.

Body weight:

At sacrifice, there was a statistically significant reduction in body weight development of females of the high dose group. The observation was attributed to treatment and considered toxicologically relevant.

Table 5.4.2-16: Genetic toxicology: *In vivo* mammalian bone marrow cytogenetic test – Chromosomal analysis ([redacted] 1994), body weight changes

Group	Dose [mg/kg bw/day]	Males			Females		
		Day 1	Day 2	Day 3	Day 1	Day 2	Day 3
Solvent		35.2 ± 2.04	35.6 ± 1.49	36.0 ± 1.79	28.8 ± 0.98	29.2 ± 0.98	26.8 ± 1.60
Test item	50	36.0 ± 1.26	35.6 ± 0.80	35.2 ± 1.60	28.4 ± 1.60	34.0 ± 1.79	32.3 ± 2.13
	500	34.8 ± 1.60	34.0 ± 1.79	32.3 ± 2.13	29.6 ± 0.80	28.8 ± 0.98	29.2 ± 0.98
	5000	34.8 ± 1.60	36.0 ± 1.26	35.2 ± 1.60	30.8 ± 0.98	28.8 ± 1.60	26.8 ± 0.98*
CPA	50	36.8 ± 1.60	36.8 ± 1.60	35.4 ± 2.30	29.6 ± 1.49	29.6 ± 1.49	29.2 ± 1.60

CPA: Cyclophosphamide, positive control

* Statistically significantly decreased compared to control by paired t-test.

Evaluation of bone marrow slides:

There was no statistically significant and biologically relevant increase in the number of aberrant metaphases or in the incidence of individual chromosomal aberrations observed at the highest dose level of 5000 mg/kg bw/day when compared to solvent control animals.

A statistically significant increase in the incidence of gaps in females was observed at 5000 mg/kg bw/day; in both, males and females of the 5000 mg/kg bw/day group there was once incidence of each chromosome exchange figure (statistically not significant). The observations were both considered to be without toxicological relevance.

In addition, there was a statistically significant reduction in the mitotic index at 5000 mg/kg bw/day, indicating that bone marrow toxicity was evident.

As the frequency of aberrant metaphase cells upon treatment with glyphosate was not increased at the highest dose level tested, the slides of the low and the mid dose groups were not investigated.

The frequency of aberrant metaphase cells in solvent control animals was as expected and the number of aberrant metaphases and incidences of aberration types was significantly high in cyclophosphamide

treated animals. In line with significant toxicity in the bone marrow of cyclophosphamide treated animals, the results confirm the sensitivity of the animals to respond to chromosomal damaging agents.

Table 5.4.2-17: Genetic toxicology: *In vivo* mammalian bone marrow cytogenetic test – Chromosomal analysis ([redacted] 1994), summary of genotoxicity data in rats

Compound	Dose [mg/kg bw/day]	Sampling time point	Number of animals (♂ + ♀)	No. of metaphases scored	Genotoxicity					Judge	Mitotic index [%]

CPA: Cyclophosphamide

*: Statistically significantly when compared to control by "Z" test

PI: polyploid cells

III. CONCLUSION:

Based on the results of the present study, glyphosate did not increase the frequency of chromosomal aberrant metaphases in the bone marrow of male and female mice. Thus, the test item was considered negative for cytogenicity *in vivo* under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for chromosome aberrations in the bone marrow of male and female Swiss albino mice *in vivo*.

The study was performed in compliance with GLP and according to OECD guideline 475 (1984). When compared to the current OECD guideline 475 (2016), a number of deviations became evident. The number of metaphase cells scored for chromosome aberrations was 50, whereas 200 metaphases should be evaluated according to the current guideline. Likewise, the mitotic index was determined for 100 cells instead of 1000 cells. The animals were treated twice, but the use of the second dose was not justified.

Bone marrow exposure was indicated by a reduction in the mitotic index and clinical signs of toxicity and impaired body weight analysis were observed in animals of the high dose group. Analysis of metaphase cells was only performed for control group animals and for animals of the high dose group, were toxicity was observed. There was no scoring for chromosome aberrations for lower dose levels where no toxicity occurred. However, as no induction of chromosomal aberrations was observed at this concentration, it can be assumed that the number of chromosome aberrations was comparatively low at lower test item doses. Further deviations to the current guideline were considered to be of minor degree. Due to the large number of deviations and because only a very low number of metaphase cells was investigated per animal, the study was considered to provide supporting information.

Evidence of bone marrow exposure was used to read across to micronucleus assays in mice of the same strain reported by the same study authors.

Assessment and conclusion by RMS:

Chromosomal aberration tests in the bone marrow of rats *in vivo*:

1. Information on the study

Data point	CA 5.4.2/016
Report author	[redacted]
Report year	1983
Report title	*In Vivo* Bone Marrow Cytogenetics Study of Glyphosate in Sprague-Dawley Rats
Report No	830083
Document No	M-645019-01-1
Guidelines followed in study	No guideline followed, study was conducted similar to OECD 475 (2016)
Deviations from current test guideline OECD 475 (2016)	The test item was administered by intraperitoneal injection, which does not represent an intended route for human exposure. In addition, the test was conducted as limit test with a dose level of 1000 mg/kg bw, whereas the current OECD TG 475 suggests a dose level of 2000 mg/kg bw. There was no evidence that the test item was administered at a dose level which induces toxicity, as no clinical signs of systemic toxicity were observed and no bone marrow toxicity became evident. Furthermore, no body weight data or individual toxicity data were reported. In addition, the mitotic index as an indicator for cytotoxicity was not calculated and the number of polyploid

	cells was not determined. A total of 50 metaphase cells/rat were investigated for chromosomal aberrations, whereas the currently valid OECD guideline 475 (2016) suggests that at least 200 metaphases should be analysed for each animal. In addition, sampling time points for bone marrow cells was 6, 12 and 24 hours, but a latter sampling time point (24 hours after the first sampling time point) was not included. The test was conducted with 3 rats per sex (6 rats per dose level), whereas the current OECD TG 475 recommends to conduct the test in 5 rats/sex or in 5 rats of one sex. The weight of the animals was not reported. In addition, acceptance and evaluation criteria were not specified in the study report. Historical control data were not provided.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, not conducted under GLP /Officially recognised testing facilities. When the study was performed, GLP was not compulsory.
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

A mammalian bone marrow chromosomal aberration test was performed in male and female Sprague-Dawley rats in order to investigate clastogenic effects of glyphosate (batch: T830044, purity: 98.7 %) *in vivo*.

The test substance was dissolved in Hank's Buffered Salt Solution (HBSS) and administered to 3 groups of fasted animals via intraperitoneal injection. All three groups of 3 rats per sex received a test item dose of 1000 mg/kg bw. Similarly constituted groups of rats received the vehicle (HBSS) or the positive control cyclophosphamide and served as controls. About 4, 10 and 22 hours following treatment, each one group of test item and solvent control animals was injected with 2 mg/kg bw colchicine. Two hours after colchicine administration (6, 12 and 24 hours after treatment), the animals were sacrificed and bone marrow slides were prepared for each animal. Bone marrow samples for the positive control group animals were prepared from the 24 hour sampling time only.

A total of 50 metaphases per animal (300 per sex per condition) were scored for the presence of chromosomal aberrations.

Clinical signs of systemic toxicity were not reported for either control or glyphosate treated animals and no signs of bone marrow toxicity became evident.

A significant increase in the number of aberrant metaphases was not observed for any of the three sampling time points upon treatment with glyphosate. The type and frequency of any chromosomal aberrations in glyphosate-treated rats was comparable to those of solvent control animals.

In contrast, rats treated with the positive control cyclophosphamide showed a strong increase in the frequency of structural chromosome aberrations about 24 hours after treatment. In addition, a reduction in metaphase cells was observed for these animals, indicating that bone marrow toxicity was evident. As solvent and positive control animals showed the expected results, the sensitivity of the test system and the capability of the animals to respond to clastogenic substances was demonstrated.

Based on the results of the experiment and under the tested conditions, glyphosate was considered negative for clastogenicity in male and female rats *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

Identification:	Glyphosate
Description:	White powder
Lot/Batch #:	T830044
Purity:	98.7 %
Stability of test compound:	The stability of the test item was not reported. Storage at room temperature was recommended. The stability of the test item in solvent was not specified.
Solvent (vehicle) used:	Hank's Buffered Salt Solution (HBSS)

2. Control materials

Solvent (vehicle) control:	Hank's Buffered Salt Solution (HBSS)
Positive control:	Cyclophosphamide, 25 mg/kg bw in HBSS

3. Test animals:

Species:	Rat
Strain:	Sprague-Dawley (Crl: CD®(SD)BR)
Sex:	Male and female
Source:	[redacted]
Age at dosing:	Approx. 9 weeks
Weight at dosing:	Not specified
Acclimation period:	Approx. 7 days
Fasting period prior administration:	14 – 24 hours
Diet/Food:	Purina Laboratory Rodent Chow® No. 5002 (Ralston-Purina Company, St. Louis, Missouri, USA), *ad libitum*
Water:	Tap water supplied by the public water system, *ad libitum*
Housing:	In stainless steel mesh cages suspended over absorbent paper bedding

4. Environmental conditions:

Temperature:	21 - 23°C
Humidity:	35 -60 %
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

Dose levels:	1000 mg/kg bw
Concentrations:	100 mg/mL
Dose volume:	10 mL/kg bw
Number of animals:	6 males and 6 females
Route of administration:	Intraperitoneal injection

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 08 – 12 Aug 1983
Finalisation date: 20 Oct 1983

2. Animal assignment and treatment:

Three groups of 3 rats per sex (6 rats/ group in total) received an intraperitoneal injection of 1000 mg/kg bw glyphosate, which was administered at a constant dosage volume of 10 mL/kg bw. Prior to treatment, the animals were fasted for 14-24 hours. Similar constituted groups of control animals received the vehicle (HBSS) or the positive control (25 mg/kg bw cyclophosphamide in HBSS).

About 4, 10 and 22 hours following treatment, each one group of test item and solvent control animals was injected with 2 mg/kg bw colchicine. Two hours after colchicine administration (6, 12 and 24 hours after treatment), the animals of the test item and the solvent control group were sacrificed by CO_2 asphyxiation and severance of the spinal cord. Bone marrow slides from the positive control group were sampled 24 hours after treatment only.

3. Slide preparation:

Immediately after sacrifice, both femurs of the animals were dissected and marrow was aspirated from each femur and mixed with HBSS. The cells were pelleted by centrifugation and re-suspended in 0.075 M potassium chloride. After removal of gross debris, the cells were incubated in a water bath at 37 °C for 30 minutes, and subsequently fixed with Cornoy's fixative (methanol/glacial acetic acid 3:1 v/v). The cells were centrifuged again, re-suspended in fixative, dropped onto clean wet slides and flamed to facilitate spreading of chromosomes. The slides were air-dried and stained with 2 % Giemsa solution for 15-20 minutes, rinsed with water, air-dried again and covered with cover slips.

4. Metaphase analysis:

Slides were randomly coded and approximately 50 mitotic cells per animal (300 per condition) were scored for chromosomal aberrations. Number and frequency of metaphase cells were recorded and evaluated for structural chromosomal aberrations such as dicentric chromosomes, ring chromosomes, chromosome deletions, gaps. In addition, chromatid aberrations and the number of aneuploidy cells were recorded.

5. Statistics:

The student's t-test was used for data analysis.

6. Acceptance criteria:

Acceptance criteria were not specified in the study report.

7. Evaluation criteria:

Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed.

B. BONE MARROW CHROMOSOMAL ABERRATION TEST

Systemic toxicity:

Mortality:

No mortality occurred.

Clinical signs of toxicity:

No clinical signs of systemic toxicity were reported.

Evaluation of bone marrow slides:

A significant increase in the number of aberrant metaphases was not observed for any of the three sampling time points upon treatment with glyphosate. Although a small number of chromatid aberrations was noted 6, 12 and 24 hours after treatment, the frequency was comparable for glyphosate-treated and solvent control animals. In addition, there was no evidence for bone marrow toxicity in any of the test item treated groups.

A huge increase in the frequency of chromosomal aberrant cells, accompanied with strong evidence for bone marrow toxicity was observed for the positive control cyclophosphamide 24 hours after treatment, demonstrating the animal's capability to respond to clastogenic substances and confirming the sensitivity of the test.

§: in 100 metaphases, calculated as follows: = (100/number of metaphases scored) x number of aberrations

III. CONCLUSION

Based on the results of the present study, glyphosate did not increase the frequency of chromosomal aberrant metaphases in the bone marrow of male and female rats. Thus, the test item was considered negative for clastogenicity in vivo under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for chromosome aberrations in the bone marrow of male and female Sprague-Dawley rats *in vivo*.

The study was conducted not compliant with GLP but similar to OECD guideline 475 (2016). However, a number of deviations became evident. The test item was administered by intraperitoneal injection, which does not represent an intended route for human exposure. In addition, the test was conducted as limit test with a dose level of 1000 mg/kg bw, whereas the current OECD TG 475 suggests a higher dose level of 2000 mg/kg bw. There was no evidence that the test item was administered at a dose level which induced toxicity, as no clinical signs of systemic toxicity were observed and no bone marrow toxicity became evident. However, due to the route of exposure selected (intraperitoneal injection) it can be assumed that the bone marrow was exposed. In addition, the mitotic index as an indicator for cytotoxicity was not calculated and the number of polyploid cells was not determined. A total of 50 metaphase cells/rat were investigated for chromosomal aberrations, whereas the currently valid OECD guideline 475 (2016) suggests that at least 200 metaphases should be analysed for each animal.

Further deviations were considered to be of minor degree. Due to the large number of guideline deviations, the study was considered to provide supporting information.

Assessment and conclusion by RMS:

CA 5.4.3 *In vivo* studies in germ cells

In the previous 2001 EU glyphosate evaluation genotoxic effects on germ cells were examined in dominant

lethal assays in rats and mice. In both species no genotoxic effect of glyphosate on germinal tissues was found. No new studies were performed since the last review.

Table 5.4.3-1: Summary of *in vivo* genotoxicity testing with glyphosate acid in germ cells

1. Information on the study

Data point	CA 5.4.3/001, CA 5.4.3/002 and CA 5.4.3/003
Report author	[redacted]
Report year	1992
Report title	Dominant lethal test in Wistar rats
Report No	TOXI: 888-DLT
Document No	Not reported
Guidelines followed in study	OECD 478 (1984)
Deviations from current test guideline OECD 478 (2016)	Dose levels were spaced with a factor of 5, which is above the factors (2 – 4) specified in the current OECD guideline 478 (2016). Necropsy was performed on Day 16 after pairing rather than on gestation Day 16. The number of implantations per group for each mating period was below the recommended number of 400 implants per group as required according to OECD 478 (2016). Fetal body weights were not recorded. No information on historical control data was provided. There was no raw data on individual animals treated with the positive control provided. The mean pre- and post-implantation losses per dam were not calculated, but percentages of pre-implantation losses, as well as percentages of post-implantation losses (corresponding to the dominant lethal factor) were reported. Acceptance and evaluation criteria were not specified in the study report. Statistical assessment of under- and overdispersion was not performed.
Previous evaluation	Yes, accepted in RAR (2015)

GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Glyphosate (batch: 1071-83-6, purity: 96.8 %) was investigated in a dominant lethal study in Wistar rats. The test item was dissolved in refined groundnut oil and administered by oral gavage to groups of 30 males at dose levels of 200, 1000 and 5000 mg/kg bw (single dose) and a constant dosage volume of 10 mL/kg bw. A similar constituted group of males received the solvent control. Two positive control groups of 5 males received ethylmethanesulphonate either administered at a treatment regime of 100 mg/kg bw/day for 5 consecutive days or as single dose of 500 mg/kg bw.

Immediately after dosing, the males were paired with untreated virgin females (mating ratio 1:1) for 6 days. On the 8th day after treatment, the males were again paired with a new batch of virgin females. The procedure was repeated for 10 consecutive weeks. All animals were observed twice daily for clinical signs. Body weights were recorded for males prior to treatment, on Days 1, 2, 4 and 6 and weekly thereafter. Females were weighed prior to mating and at terminal sacrifice. The females from each mating interval were sacrificed on gestation Day 16. The uterus and ovaries were dissected and investigated for the number of *corpora lutea*, implantations, early resorptions, fetal and embryonic resorptions and the number of live implants. All males were subjected to gross necropsy following the last pairing.

Oral treatment with glyphosate did not induce mortality in any animal. Clinical signs of toxicity were observed predominantly for animals of the high dose group throughout the whole study period and comprised nasal discharge, rough hair coat, snuffling, soft stool/diarrhea and urine incontinence. In addition, the body weight of sires was decreased in the 1000 and 5000 mg/kg bw dose group during the first four days of treatment. Both observations were attributed to treatment and considered toxicologically relevant.

At terminal necropsy, unilateral testicular atrophy was observed in 3/30 males of the high dose group. Male fertility was not impaired upon treatment with glyphosate.

Investigation of the female uteri contents revealed an acute toxic effect of glyphosate at a dose level of 5000 mg/kg bw after the first mating. The number and percentage of pregnant females and the number of implantations per dam were significantly lower than for control animals. In line with these findings, there was an increased incidence of early resorptions and of pre- and post-implantation losses in the animals of this group. In the first mating group, there were no adverse effects on the number of *corpora lutea*, the number of fetal and embryonic resorptions and the number of live implants per dam.

Fertility indices during the remaining 9 study weeks were not considered to be affected by treatment. Although changes of statistical significance were observed for the number of implantations, the number of early, fetal and embryonic resorptions, the number of live implants and the number of pre- and post-implantation losses, these fluctuations and highly variable values for dominant lethality were observed among all dose groups and without any relation to dose or duration of treatment.

Treatment with the positive control ethylmethanesulphonate had statistically significant dominant lethal effects for both treatment regimes. A significant decrease in the incidence of pregnancy to 0 % was observed in the third mating interval and a gradual recovery back to normal by 9 to 10 weeks. In addition, there was an increased incidence of small moles /fetal resorptions during the first week, which

gradually recovered to normal by week 9.

Based on the experimental findings and under the conditions of the test, treatment of males with glyphosate was considered to induce acute toxic effects at 5000 mg/kg bw in male and female animals during the first mating period. Under the conditions of the test, glyphosate did not induce dominant lethal effects in Wistar rats and was therefore considered non-genotoxic to germ cells *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

Identification:	Glyphosate
Description:	Odourless, white crystals
Lot/Batch #:	1071-83-6
Purity:	96.8 %
Stability of test compound:	Under storage conditions (at ambient temperature) stability was guaranteed for more than two years. Dosing formulations were prepared fresh prior to treatment.
Solvent (vehicle) used:	Refined groundnut (peanut) oil

2. Control materials

Solvent (vehicle) control:	Refined groundnut (peanut) oil
Positive control:	Ethylmethanesulphonate, 100 mg/kg bw/day for 5 days in distilled water or 500 mg/kg bw as single dose in distilled water

3. Test animals:

Species:	Rat
Strain:	Wistar
Sex:	Males and females
Source:	Bred at [redacted]
Age at study initiation:	20 – 24 weeks
Weight at study initiation:	> 250 g (males) and > 150 g (females)
Acclimation period:	At least 10 days
Diet/Food:	Pelleted rat feed (M/S Lipton India Ltd., Bangalore, India), *ad libitum*
Water:	Deep borewell water, passed through activated charcoal filter and exposed to UV rays in Aquaguard on-line water filter-cum-purifier, *ad libitum*

Housing:	Before treatment: In groups of 15-20/sex in suspended stainless steel wire mesh cages with clean paddy husk bedding. During mating: On a 1:1 basis (male:female) in a standard polypropylene cages measuring 290 x 220 x 140 mm) with sterilized paddy husk bedding. Post mating: Females were housed in groups of 5 in serial order from the same group in standard polypropylene cages measuring 430 x 270 x 150 mm) with sterilized paddy husk bedding.

4. Environmental conditions:

Temperature:	22 ± 3 °C
Humidity:	52 - 70 %
Air changes:	Approximately 10 - 15/hour
Photoperiod:	12-hour light and dark cycle

5. Test concentrations and treatment groups:

Dose levels:	200, 1000 and 5000 mg/kg bw
Dose volume:	10 mL/kg bw
Number of animals:	30 males and 300 females per group (30 females per mating interval)
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 03 Sep 1991 – 31 Jan 1992
Finalisation date: 04 Nov 1992

2. Animal assignment and treatment:

Groups of 30 males per dose received a single administration of glyphosate by oral gavage at dose levels of 200, 1000 and 5000 mg/kg bw at a constant dosage volume of 10 mL/kg bw. Similar constituted groups received the solvent (refined groundnut oil) or the positive control ethylmethane sulfonate. The positive control substance was dissolved in distilled water and administered to two groups of 5 males at a treatment regimen of 100 mg/kg bw/day for 5 consecutive days and as single dose of 500 mg/kg bw.

Immediately after dosing, the males were paired with untreated virgin females (mating ratio 1:1) for 6 days. On Day 8 after treatment, the males were again paired with a new batch of virgin females. The procedure was repeated for 10 consecutive weeks. The females from each mating interval were sacrificed on gestation Day 16.

3. Observations

All animals were observed twice daily during the first week and once daily during the remaining period for signs of toxicity and mortality. The time of onset, degree and duration of clinical signs was recorded.

4. Body weight

The body weight of male animals was recorded prior to treatment, on Days 1, 2, 4 and 6 and weekly thereafter. For females, the initial body weight and the body weight at terminal sacrifice were noted.

5. Sacrifice

All animals were sacrificed under ether anaesthesia.
Males were sacrificed after 10 mating intervals and investigated for gross necropsy changes in the visceral organs. From all sires the following organs were collected and preserved in 10 % neutral buffered formalin: testes, epididymides, seminal vesicles and prostate.

Females from each mating interval were sacrificed on gestation Day 16. The uterus along with the ovaries was dissected and the following parameters were recorded prior to preservation in 10 % neutral buffered formalin:

- Number of *corpora lutea* in each ovary
- Number of implantations
- Number of early resorptions
- Number and percentage of small moles/embryonic resorptions
- Number and percentage of large moles/fetal resorptions
- Number and percentage of live implants

Furthermore, the percentage of pre- and post-implantation losses were determined according to the following formulas:

$$\text{Pre} - \text{implantation loss [\%]} = \frac{\text{Total number of corpora lutea} - \text{Number of implantations}}{\text{Total number of corpora lutea}} \times 100$$

$$\text{Post} - \text{implantation loss [\%]} = \frac{\text{Number of early} + \text{late embryonic deaths}}{\text{Total number of implantations}} \times 100$$

The percentage of post-implantation losses corresponds to the dominant lethal factor.

6. Statistics:

The weekly male body weight, the number of *corpora lutea*, the number of implantations, the number of early resorptions, the number and percentage of small and large moles, the number and percentage of live implants and the percentage of pre- and post-implantation losses were statistically analysed using the Bartlett's test for homogeneity, analysis of variance and Dunnett's multiple pairwise comparison. The number of early resorptions were compared by Mann Whitney test; pregnancy indices were analysed by "Z"-test. Results of the statistical analysis were designated in comparison to the solvent control group.

7. Acceptance criteria:

Acceptance criteria were not specified in the study report.

8. Evaluation criteria:

Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in this study, as not required by the test guideline.

B. OBSERVATIONS

Systemic toxicity:

Mortality:

One sire of the positive control group in the second dose regime (single treatment with 500 mg/kg bw)

died during study week 4. There were no deaths in the dose groups treated with glyphosate.

Clinical signs of toxicity:
Clinical signs of toxicity were observed among all treatment and control groups. Commonly and frequently observed symptoms included nasal discharge, rough hair coat, snuffling, soft stool/diarrhea and urine incontinence. The incidence was increased at 5000 mg/kg bw, which was attributed to treatment and considered toxicologically relevant. In animals of the high dose group, the clinical signs were observed throughout the entire study period.

Table 5.4.3-2: Dominant lethal test in Wistar rats ([redacted] 1992), clinical signs of toxicity observed in sires

Clinical sign of toxicity	Dose group [mg/kg bw]			
	0	200	1000	5000
Nasal discharge	1/30	0/30	2/30	9/30
Rough hair coat	0/30	0/30	0/30	4/30
Snuffling	3/30	0/30	0/30	10/30
Soft stool / diarrhea	1/30	0/30	1/30	5/30
Urine incontinence	0/30	0/30	5/30	1/30

C. BODY WEIGHT AND BODY WEIGHT DEVELOPMENT OF SIRES

Starting body weights of all glyphosate treated groups were statistically significantly higher than those of the solvent control group. The difference continued during the entire study period until final sacrifice. Upon treatment with the test item, body weight of sires was decreased in the 1000 and 5000 mg/kg bw group during the first four days of treatment, but was comparable to those of solvent control treated animals thereafter. The observation was considered treatment-related.

Table 5.4.3-3: Dominant lethal test in Wistar rats ([redacted] 1992), body weights in sires

* Statistically significant difference from control group by Dunnett's test

D. NECROPSY OF SIRES

At terminal sacrifice, unilateral testicular atrophy was noted in 3/30 sires of the high dose group. The effect was considered treatment-related. There were no further gross lesions in visceral organs and the reproductive system observed.

E. FERTILITY INDICES

In the first mating interval (study week 1), the number and percentage of pregnant females was reduced in the high dose group (statistically not significant, refer to 5.4.3-4). The effect was explained by acute toxicity of the test item and in line with increased incidences of early resorptions (refer to Table 5.4.3-7), pre- and post-implantation losses (refer to Table 5.4.3-11 and Table 5.4.3-12). Pregnancy status at 200 and 1000 mg/kg bw was not affected by treatment. Within the remaining 9 mating intervals, there were no changes in the number and percentage of pregnant females.

The number of *corpora lutea* per dam was not affected by treatment (refer to Table 5.4.3-5). A decreased number of *corpora lutea* at 1000 mg/kg bw among the females of the first mating interval and a significant

increase in the number of *corpora lutea* at 5000 mg/kg bw in the females of the third mating interval were considered incidental.

Upon treatment with glyphosate, the number of implantations per dam showed fluctuations among all dose groups over the entire study period (refer to Table 5.4.3-6). The statistically significant decrease at 5000 mg/kg bw in females of the first mating interval was attributed to the acute toxic effects caused by the test item and of toxicological relevance. Further, there was a significant increase in the number of implantations per dam during study week 4 at 200 mg/kg bw, a significant decrease in all test item treated groups in study weeks 7 and 8 and in the mid dose group (1000 mg/kg bw) during study week 9. The statistically significant observations in test item-treated groups during mating intervals 4, 7, 8 and 9 were attributed to the high variability of implantation sites among solvent control animals rather than to treatment with glyphosate and therefore considered to be incidental.

PC: positive control EMS: Ethylmethanesulphonate, positive control, [x]combined data for both treatment regimens (100 mg/kg bw/day for 5 days in distilled water or 500 mg/kg bw as single dose in distilled water)
*: $p < 0.05$ and ** $p < 0.01$ statistical significance when compared to controls, ↓ decrease, ↑ increase

A statistically significant increase in the number of early resorptions was noted during study week 1 (first mating) at 5000 mg/kg bw, during study week 3 (third mating) at ≥ 1000 mg/kg bw and during study week 4 (fourth mating) at 1000 mg/kg bw. The effect was not reproducible in the next mating interval. Due to a lack of a dose-dependency, the observation was not attributed to treatment.

[#]: reported as mean number of early resorptions per dam in study report

There was a statistically significant increase in the incidence of small moles / fetal resorptions at ≥ 1000

mg/kg bw during weeks 1 and 7, at 1000 mg/kg bw during week 5, at 5000 mg/kg bw during weeks 6 and 8 and in all glyphosate treated groups during week 9 (refer to Table 5.4.3-8). In addition, strong fluctuations in the percentages of fetal resorptions were noted over the entire study period. The observations were not dose-related and inconsistent throughout the study period and therefore not attributed to treatment.

A statistically significant increase in the mean number of embryonic resorptions per dam was observed in the low and mid dose group only for mating intervals 3, 4 and 10 (refer to Table 5.4.3-9 Table below). In addition, the percentage of embryonic resorptions was statistically significantly increased at 5000 mg/kg bw after the first mating, at 200 mg/kg bw after the 2nd, 3rd and 8[th] mating and at 200 and 1000 mg/kg bw during weeks 4 and 10. Without any dose-response relationship, the observations were considered to be incidental and not related to treatment.

Increases and decreases in the incidence and percentage of live implants were observed in test item-treated and solvent control-treated animals and occurred without any dose-relation and without consistency over the 10 mating intervals. Thus, the changes were as well considered unrelated to treatment (refer to Table 5.4.3-10).

*: $p < 0.05$ and ** $p < 0.01$ statistical significance when compared to controls, ↓ decrease, ↑ increase

Statistically significant increases in the percentages of pre-implantation losses were noted at 5000 mg/kg bw for the first mating interval, for all or most treatment groups during weeks 3, 4, 5 and 7 and statistically significantly decreased in all or in the majority of glyphosate treated groups during weeks 2, 8, 9 and 10. There was no dose-response relationship evident at any mating interval. Thus, the effects on the percentage of pre-implantation losses were not considered to be related to treatment with glyphosate.

The percentage of post-implantation loss, corresponding to the dominant lethal factor, was statistically significantly increased in the high dose group of the first mating interval, which was attributed to acute toxicity in the animals. The dominant lethal factor was further statistically significantly increased in the mid and high dose group after the 6th mating and for all glyphosate treated groups after the 7th mating. For the females of the remaining mating intervals, the dominant lethal factor was either not affected or lower than in solvent control animals. None of the observations was dose-related or consistent over the ten mating periods.

[#]: Corresponds to the dominant lethal factor

*: $p < 0.05$ and ** $p < 0.01$ statistical significance when compared to controls, ↓ decrease, ↑ increase

Treatment with the positive control ethylmethane sulphonate induced statistically significant dominant lethal effects and demonstrated the validity of the test. There was a statistically significant decrease in the incidence of pregnancy to 0 % observed in the third mating interval and a gradual recovery back to normal by 9 to 10 weeks (refer to Table 5.4.3-4). In addition, there was an increased incidence of small moles / fetal resorptions during the first week (mating period 1), which gradually recovered to normal by week 9 (mating period 9, refer to Table 5.4.3-8).

III. CONCLUSION

Under the conditions of the test, glyphosate did not induce dominant lethal effects in Wistar rats up to a dose level of 5000 mg/kg bw. Treatment of males with 5000 mg/kg bw was associated with clinical signs of toxicity and reduced body weight in males, as well as with acute toxicity after the first mating in females. Toxicity in female rats became evident as a reduction in the incidence of pregnancy and an increase in the incidences of early resorption and pre- and post-implantation losses. Based on the experimental findings, glyphosate was considered non-genotoxic to germ cells *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for genotoxicity to germ cells *in vivo*. The test item did not induce any dominant lethal effects.

At 5000 mg/kg bw, treatment with glyphosate caused acute toxic effects in females of the first mating group, which affected the fertility indices pregnancy, early resorption, pre- and post-implantation losses.

The study was performed under GLP and in accordance with OECD guideline 478 (1984). When compared to the current OECD guideline (2016), a number of deviations became evident. The spacing factor between dose levels was too high (5 instead of 2 – 4) and the number of implantations per group for each mating period was below the recommended number of 400 implants per group as required

according to OECD 478 (2016). Fetal body weights were not recorded and no information on historical control data was provided. Further, there was no raw data on individual animals treated with the positive control provided. The mean pre- and post-implantation losses per dam were not calculated, but percentages of pre-implantation losses, as well as percentages of post-implantation losses (corresponding to the dominant lethal factor) were reported. Further deviations were considered to be of minor degree. Due to the large number of deviations to the current OECD guideline, the study was considered to provide supporting information.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.3/004
Report author	[redacted]
Report year	1982
Report title	Mutagenic testing of glyphosate in rat by dominant lethal test
Report No	Not reported
Document No	Not reported
Guidelines followed in study	No guideline followed, study was conducted similarly to OECD 478 (2016)
Deviations from current test guideline OECD 478 (2016)	When compared to OECD 478 (2016), clinical signs of toxicity and mortality were not reported and no body weights were recorded. The selected dose levels were comparably low, but a scientific justification for the selection of dose levels was not given. For some mating intervals, the number of implantations per group for each mating period was below the recommended number of 400 implants per group. Therefore, the number of animals mated was presumably not sufficient. Fetal body weights were not recorded and no historical control data were provided. Necropsy of sires was not performed and resorptions, termed as "dead implants" in study report were not distinguished as early or late resorptions. In addition, pregnant females were sacrificed on gestation Day 18, whereas OECD 478 (2016) recommends to sacrifice the females between gestation Days 14 – 15 for rats. Raw data on individual animals were not provided, therefore standard deviations were not calculated. In addition, analytical determinations on the test items stability, homogeneity or concentration in the diet were not performed. Acceptance and evaluation criteria were not specified in the study report.
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, not conducted under GLP /Officially recognised testing facilities. When the study was performed, GLP was not compulsory.
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (I docs)	Category 3a

2. Full summary

The mutagenic potential of glyphosate active principle (batch: 00260481, purity: not reported) was investigated in a dominant lethal study in CFY rats.

The test item was incorporated into the ground diet and administered via the feed to male animals for a period of 8 weeks. Dose levels of 10, 30 and 100 mg glyphosate/kg food were applied, corresponding to a mean actual achieved test substance intake of 6.8, 20.5 and 70.4 mg/kg bw/day. A group of control males received the normal diet without test item and a group of positive control animals was administered 5 mg cyclophosphamide/kg food, corresponding to a mean actual achieved intake of 3.7 mg/kg bw/day.

After dosing, each male was paired with untreated females (mating ratio 1 : 2) for one week. After separation, the males were paired with two new females for a second week. Females were continually replaced after one week until 4 mating intervals were completed.

Information on clinical signs of toxicity, mortality or individual and group mean body weights were not included in the study. Food consumption and mean achieved compound intake was recorded on a weekly base. Analytical determinations on stability, homogeneity and concentration of the test item in the diet were not conducted.

Females were sacrificed on Day 18 of gestation. The uterus and ovaries were dissected and investigated for the number of *corpora lutea*, the number of implantations, the number of dead implants (resorptions) and the number of viable fetuses.

Investigations of the female uterine contents revealed no treatment-related findings. The number of pregnant females, the number of *corpora lutea* and implantation sites and the number of resorptions were not affected for any mating interval upon treatment with glyphosate. The number of viable fetuses was comparable for females mated with glyphosate-treated and solvent control-treated males. In addition, the number of females having one or more dead fetus did not increase. The percentage of pre-implantation loss was considered not to be affected by treatment. Fluctuations were noted in females of all dose groups, but most groups showed a decrease in pre-implantation losses. However, the findings were not consistent during the 4-week mating period and a dose-response relationship was not observed. The percentage of post-implantation loss, corresponding to the dominant lethal factor, was comparable for all glyphosate and control groups.

Treatment with cyclophosphamide resulted in a strong increase in the number of dead implants / resorptions in the females of all mating intervals and a reduction in the number of viable fetuses, especially in the females of the first mating interval. Cyclophosphamide proved to be highly mutagenic and induced clear dominant lethal effects, demonstrating the sensitivity and validity of the test.

Based on the experimental findings, glyphosate active principle has no mutagenic potential in germ cells *in vivo*.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test material: N-phosphonomethyl-glycine

Identification: Glyphosate active principle

Description: Not specified

Lot/Batch #:	00260481
Purity:	Not specified
Stability of test compound:	The stability of the test item at storage conditions or in vehicle (feed) was not specified.
Solvent (vehicle) used:	The test item was incorporated into the diet (LATI laboratory rodent food)

2. Control materials

Solvent (vehicle) control:	LATI laboratory rodent food
Positive control:	Cyclophosphamide, 5 mg/kg food (nominal concentration), corresponding to 3.7 mg/kg bw/day (actual dose received)

3. Test animals:

Species:	Rat
Strain:	CFY
Sex:	Males and females
Source:	[redacted]
Age at study initiation:	12 months
Weight at study initiation:	Not specified
Acclimation period:	Not specified
Diet/Food:	Standard LATI rat and mouse food (Lati, Gödöllö, Hungary)
Water:	Not specified
Housing:	In groups of 5/sex in shoebox type plastic cages with wood shaving bedding. During mating: Each male was cohabitated with 2 females.

4. Environmental conditions:

Environmental conditions were not specified.

5. Test concentrations and treatment groups:

Dose levels:	10, 30 and 100 mg/kg food (nominal dose), corresponding to 6.8, 20.5 and 70.4 mg/kg bw/day (actual dose, calculated based on average food intake)
Treatment duration:	8 weeks
Number of animals:	The total number of animals used was 100 males and 900 females. The number of animals used per mating interval was not explicitly specified in the study report. As the animals were divided into 5 groups, it can be assumed that 20 males per group were used. There is a discrepancy in the mentioned number of 900 females used and the information that each male was mated during the 4 week mating period with 2 females per week, leading to a total number of 800 females used in the study.
Route of administration:	Oral, feed

B: STUDY DESIGN AND METHODS

1. Finalisation date: 1982

2. Animal assignment and treatment:

The test item was incorporated into the ground diet and administered via the feed to male animals for a period of 8 weeks. Dose levels of 10, 30 and 100 mg/kg food were applied, corresponding to an actual mean daily intake of 6.8, 20.5 and 70.4 mg/kg bw/day, as calculated based on the average weekly food intake per group. A group of control males received the normal diet without test item and a group of positive control animals was administered 5 mg/kg food cyclophosphamide, corresponding to 3.7 mg/kg bw/day (actual dose received).
After dosing, each male was paired during 4 weeks with two females per week (mating ratio 1 : 2).

3. Observations

Information on observations regarding mortality or clinical signs of toxicity were not included in the study report.

4. Body weight

Information on individual or group mean body weights of animals in the respective groups were not included in the study report.

5. Food consumption and compound intake

Food consumption and test substance intake were recorded for each dose group in mg/kg bw/week.

6. Sacrifice

Female rats were sacrificed on the 18th day of gestation. The uteri and ovaries of the animals were dissected and investigated for the following parameters:

- Number of *corpora lutea*
- Number of implantations
- Number of resorptions
- Number of viable and nonviable fetuses

Furthermore, the percentage of pre- and post-implantation loss was determined as follows:

$$\text{Pre} - \text{implantation loss [\%]} = \frac{\text{Total number of corpora lutea} - \text{Number of implantations}}{\text{Total number of corpora lutea}} \times 100$$

$$\text{Post} - \text{implantation loss [\%]} = \frac{\text{Number of implantations} - \text{Number of live fetuses} *}{\text{Total number of implantations}} \times 100$$

* fetuses (gestation day 18) were termed embryos in study report

The percentage of post-implantation losses corresponds to the dominant lethal factor.

Macroscopical examination of male rats was not included in the study report.

7. Statistics:

Statistical analysis was not described in the study report.

8. Acceptance criteria:

Acceptance criteria were not specified in the study report.

9. Evaluation criteria:

Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations on the stability, concentration and homogeneity of the test substance in the diet were not performed in the study.

B. OBSERVATIONS

Systemic toxicity:

Mortality:

Information on mortality was not provided in the study report.

Clinical signs of toxicity:

Clinical signs of toxicity were not reported.

C. FOOD CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food consumption of males during the 8-week treatment period. The average intake of test substance per group was 47.3 ± 2.9, 143.3 ± 11.9 and 492.9 ± 35.4 mg/kg bw/week, calculated based on the average food intake (g/kg bw/week) over all treatment weeks. Based on this, the corresponding mean daily doses of 6.8, 20.5 and 70.4 mg/kg bw/day were calculated.

D. BODY WEIGHT AND BODY WEIGHT DEVELOPMENT OF SIRES

Body weights were not recorded during the course of the study.

E. NECROPSY OF SIRES

Information on macroscopical or microscopical analysis of sacrificed males was not included.

F. FERTILITY INDICES

Treatment with glyphosate did not affect the number of mated males and females (refer to Table 5.4.3-13 and Table 5.4.3-14). The number of pregnant females was comparable for all groups.

Table 5.4.3-13: Mutagenic testing of glyphosate in rat by dominant lethal test ([redacted], 1982), number of males mated

PC: positive control Cyclophosphamide

The amount of resorptions (termed "dead implants" in study report) was comparable to those of control animals for all mating intervals (refer to Table 5.4.3-17). The number of females having one or more dead fetus of early death did not increase either.

Table 5.4.3-17: Mutagenic testing of glyphosate in rat by dominant lethal test ([redacted], 1982), number of dead implants / resorptions

3	11.9	12.2	13.4	12.0	9.9
4	11.9	12.8	13.6	12.5	11.2

PC: positive control Cyclophosphamide

Further, the percentage of pre -implantation losses (refer to Table 5.4.3-19) was not considered to be affected upon treatment with glyphosate. Fluctuations were noted in females of all dose groups, but most groups showed a decrease in pre-implantation losses. However, the findings were not consistent during the 4-weeks mating period and a dose-response relationship was not observed.

Table 5.4.3-19: Mutagenic testing of glyphosate in rat by dominant lethal test ([redacted], 1982), percentage of pre-implantation losses

	Group				
	1	2	3	4	PC

4	14.4	9.2 ↓	12.5 ↓	11.7 ↓	8.4

PC: positive control Cyclophosphamide

The percentage of post-implantation losses, corresponding to the dominant lethal factor, was not affected by treatment (refer to Table 5.4.3-20).

Treatment with the positive control cyclophosphamide markedly increased the number of dead implants / resorptions in the females of all mating intervals (refer to Table 5.4.3-17) and markedly reduced the number of viable fetuses, especially in the females of the first mating interval (refer to Table 5.4.3-18). Treatment with cyclophosphamide induced clear dominant lethal effects, demonstrating the sensitivity and validity of the test.

[#]: Corresponds to the dominant lethal factor

III. CONCLUSION

Based on the experimental findings and under the conditions of the test, glyphosate active principle did not cause dominant lethal effects in CFY rats after 8-week dietary administration. Therefore, glyphosate active principle is considered non-genotoxic to germ cells *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for mutagenic effects in the dominant lethal assay in rats.

The study is not compliant with GLP but was performed according to the main criteria of OECD guideline 478 (2016). The study is considered supplementary due to serious reporting deficiencies, e.g. the purity of the test compound was not given and it is not unequivocally clear how many males and females were allocated to the individual test groups. Further methodology deficiencies are the number of implants (< 400/group) indicating the number of animals mated was not sufficient. In addition, the dose levels appear to be too low for definitive assessment. It is known from other studies that much higher doses can be applied. However, it is the only dominant lethal test with repeated dietary administration, and, therefore, the study may provide some additional information.

Assessment and conclusion by RMS:

1. Information on the study

Data point	CA 5.4.3/005
Report author	[redacted]
Report year	1980
Report title	Dominant lethal mutagenicity assay with technical Glyphosate in mice
Report No	401-064

Document No	M-643921-01-1
Guidelines followed in study	No guideline followed, study was conducted similarly to OECD 478 (2016)
Deviations from current test guideline OECD 478 (2016)	The number of implantations per group for each mating period was below the recommended number of 400 implants per group. It can be assumed that the number of males and females used for mating was too low. Fetal body weights were not recorded. No historical control data were provided. No dominant lethal frequency was calculated in the study report. Acceptance and evaluation criteria were not specified. Statistical analysis did not include the assessment of under- and overdispersion.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, not conducted under GLP /Officially recognised testing facilities. When the study was performed, GLP was not compulsory.
Acceptability/Reliability	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The mutagenic potential of glyphosate (batch: XHJ-64, purity: 98.7 %) was investigated in a dominant lethal study in CD-1 mice. The test item was dissolved in aqueous 0.5 % Methocel® and administered by oral gavage to groups of 10 males at dose levels of 200, 800 and 2000 mg/kg bw (single dose) at a constant dosage volume of 10 mL/kg bw. A similar constituted group of males received the solvent control (vehicle) or the positive control Cytoxan®. The positive control substance was administered via intraperitoneal injection as single dose of 240 mg/kg bw at a constant dosage volume of 12 mL/kg bw.

Immediately after dosing, each male was paired with untreated virgin females (mating ratio 1:2) for 7 days. After separation, each male was then paired with two new females for a second week. Females continued to be replaced in this manner for eight weeks so that each male was mated with a total of 16 females. All animals were observed twice daily for mortality and overt changes in appearance and behaviour. Body weights were recorded for males prior to treatment and weekly thereafter. Females were sacrificed 13 days after mid-week of their caging and presumptive mating. The uterus and ovaries were dissected and investigated for the number of *corpora lutea*, the number of implantations, the number of early and late resorptions and the number and localisation of viable and non-viable fetuses.

Four unscheduled deaths were observed during the course of the study. One female mated with a male of the 200 mg/kg bw group died in study week 3, one male of the 800 mg/kg bw group died in study week 5, one male of the 2000 mg/kg bw group died in week 6 and one female mated with a male of the 2000 mg/kg bw dose group died in study week 2. Necropsy of the decedent animals revealed no treatment-related findings, therefore the observations were not attributed to treatment but considered to be incidental. There were no treatment-related clinical signs of toxicity and no differences in body weight development in males over the entire study period.

Investigations of the female uterine contents revealed no treatment-related findings. The number of pregnant females, the number of *corpora lutea* and implantation sites and the number of early and late resorptions were not affected for any mating interval upon treatment with glyphosate. There was a slight but statistically significant decrease in the number of viable fetuses in females of the 800 mg/kg bw group mated during study week 1 and in females of the 2000 mg/kg bw group mated during study week 3. As no increase in early fetal deaths were observed in these groups, the findings were not attributed to glyphosate treatment and considered to be incidental. Pre- and post-implantation losses and calculated dominant lethal factors were comparable for treated and control groups.

Treatment with the positive control Cytoxan® induced a statistically significant decrease in the number of viable fetuses and an increase in the proportion of early fetal deaths, indicated by a statistically significant increase in the mean number of early resorptions and post-implantation loss observed during the first 3 weeks of mating. These results indicated a dominant lethal effect and an effect at the postmeiotic stage of spermatogenesis, thereby demonstrating the validity of the test system.

Under the conditions of the test, there was no mutagenic potential identified for glyphosate in the dominant lethal assay and is therefore considered non-genotoxic to germ cells *in vivo*.

I. MATERIALS AND METHODS

A: MATERIALS

1. Test material:

Identification:	Technical Glyphosate
Description:	White powder
Lot/Batch #:	XHJ-64
Purity:	98.7 %
Stability of test compound:	The stability of the test item at storage conditions or in vehicle was not specified.
Solvent (vehicle) used:	Aqueous 0.5 % Methocel®

2. Control materials

Solvent (vehicle) control:	Aqueous 0.5 % Methocel®
Positive control:	Cytoxan®, 240 mg/kg bw dissolved in sterile water

3. Test animals:

Species:	Mouse
Strain:	CD-1
Sex:	Males and females
Source:	[redacted]
Age at study initiation:	70 - 110 days
Weight at study initiation:	36 – 45 g (males) (weight of females not specified)
Acclimation period:	At least 10 days
Diet/Food:	Purina® Certified Rodent Chow® 5002, *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	Individually (except during mating) in suspended wire mesh cages. During mating: Each male was cohabitated with 2 females.

4. Environmental conditions:

The animals were maintained in a temperature-, humidity- and light controlled room

5. Test concentrations and treatment groups:

Dose levels:	200, 800 and 2000 mg/kg bw
Dose volume:	10 mL/kg bw
Number of animals:	10 males and 160 females per group (2 females per mating interval)
Route of administration:	Oral gavage

B: STUDY DESIGN AND METHODS

1. Dates of experimental work: 04 Jun – 09 Aug 1979
Finalisation date: 16 Apr 1980

2. Animal assignment and treatment:

Groups of 10 males per dose received a single administration of glyphosate by oral gavage at dose levels of 200, 800 and 2000 mg/kg bw at a constant dosage volume of 10 mL/kg bw. Similar constituted groups received the solvent (0.5 % aqueous Methocel®). The positive control Cytoxan® was administered via intraperitoneal injection as single dose of 240 mg/kg bw at a constant dosage volume of 12 mL/kg bw.

Immediately after dosing, each male was paired with untreated virgin females (mating ratio 1: 2) for 7 days. After separation, each male was then paired with two new females for a second week. Females continued to be replaced in this manner for eight weeks so that each male was mated with a total of 16 females.

3. Observations

All animals were observed twice daily for mortality and overt changes in appearance and behaviour. All males were given a detailed observation to determine if any clinical signs of toxicity were present.

4. Body weight

The body weight of male animals was recorded prior to treatment and weekly thereafter for 9 weeks.

5. Sacrifice

All mice not surviving to the scheduled sacrifice were necropsied. Males were sacrificed on the last day of mating.

Females were sacrificed by carbon dioxide inhalation thirteen days after mid-week of their caging and presumptive mating. The uterus and ovaries were removed by an abdominal incision and investigated for the following parameters:

- Number of *corpora lutea* per dam
- Number of implantations
- Number of early and late resorptions
- Number and location of viable and nonviable fetuses

The thoracic and abdominal cavities and organs of the dams were examined for grossly evident morphological changes.

Furthermore, the number of post-implantation losses was determined. The number of pre-implantation losses was determined based on the raw data provided in the study report.

Mutagenic effects in the dominant lethal assay were assessed by comparing the number of early fetal

deaths in the treated groups versus the control groups. For all groups, the dominant lethal factor was calculated as follows:

$$\text{Dominant lethal factor [\%]} = \frac{\text{Number of post} - \text{implantation losses}}{\text{Total number of implantations}} \times 100$$

6. Statistics:

All statistical analysis compared the treatment groups (test article and positive control) with the vehicle control group.

Fetal deaths per dam and post-implantation losses were compared by the Mann-Whitney U-test. The number of dams with fetal deaths was compared using the chi-square test with Yates' correction for 2 x 2 contingency tables and/or Fisher's exact probability test. The mean number of live fetuses and corpora lutea were compared by analysis of variance (one-way classification) Bartlett's test for homogeneity of variances and the appropriate t-test (for equal or unequal variances) using Dunnett's multiple comparison tables to judge significance of differences.

7. Acceptance criteria:

Acceptance criteria were not specified in the study report.

8. Evaluation criteria:

Evaluation criteria were not specified in the study report.

II. RESULTS AND DISCUSSION

A. ANALYTICAL DETERMINATIONS

Analytical determinations were not performed in the study, as not required by the test guideline.

B. OBSERVATIONS

Systemic toxicity:

Mortality:

Four unscheduled deaths occurred during the course of the study. One female mated with a male of the 200 mg/kg bw group died in study week 3, one male of the 800 mg/kg bw group died in study week 5, one male of the 2000 mg/kg bw group died in week 6 and one female mated with a male of the 2000 mg/kg bw dose group died in study week 2. The cause of death could not be determined at necropsy. The observations on mortality were not attributed to treatment and considered to be incidental.

Clinical signs of toxicity:

There were no test item-related signs of systemic toxicity observed. Incidental findings included alopecia, matting of the hair coat and enlargement of the genital area. These findings were observed randomly throughout various weeks of the study among all treatment groups. Due to the random occurrence and small number of total animals affected, the findings were not related to treatment.

C. BODY WEIGHT AND BODY WEIGHT DEVELOPMENT OF SIRES

There were no biologically meaningful differences in body weight and body weight gain in any of the treatment groups when compared to control animals over the entire study period.

D. NECROPSY OF SIRES

Necropsy of unscheduled sires revealed no abnormal findings which were related to treatment.

E. FERTILITY INDICES

Treatment with glyphosate did not affect the number and percentage of pregnant females throughout the course of the study (refer to Table 5.4.3-21). In addition, the number of *corpora lutea* (refer to Table

5.4.3-22) and the number of implantations (refer to) were not affected by treatment.

The amount of early and late resorptions was comparable to those of control animals for all mating intervals (refer to Tables below). There were no non-viable fetuses in any dose group of any mating interval. However, there was a slight but statistically significant decrease in the number of viable fetuses in females of the 800 mg/kg bw group mated during study week 1 and in females of the 2000 mg/kg bw group mated during study week 3 (refer to Table 5.4.3-26). As no increase in early fetal deaths were observed in these groups, the findings were not attributed to glyphosate treatment and considered to be incidental.

Further, the incidence of pre- and post-implantation losses (refer to Tables below) was not considered to be affected upon treatment with glyphosate and the retrospectively calculated dominant lethal factors (refer to Table 5.4.3-29) were comparable for glyphosate treated and control animals.

PC: positive control Cytoxan

** $p < 0.01$ statistical significance when compared to controls

Treatment with the positive control Cytoxan® induced statistically significant dominant lethal effects and effect at the postmeiotic stage of spermatogenesis and demonstrated the validity of the test. When compared to the vehicle control group, there was a statistically significant decrease in the number of viable fetuses and an increase in the proportion of early fetal deaths, indicated by a statistically significant increase in the mean number of early resorptions and post-implantation loss observed during the first 3 weeks of mating.

PC: positive control Cytoxan

[#]: Calculated as follows: (total post implantation loss per female / total implantations per female) x 100

In addition, there was a lower number of implantations observed during the first three weeks of mating after treatment with Cytoxan® (refer to
), with a statistically significant decrease at mating weeks 2 and 3 when compared to control animals (refer to Table 5.4.3-21). The observations were attributed to a decreased ovulation rate, as seen by a lower number of corpora lutea during these weeks (refer to Table 5.4.3-22).

III. CONCLUSION

Under the conditions of the test, glyphosate had no mutagenic potential in CD-1 mice in the dominant lethal assay up to a dose level of 2000 mg/kg bw. Based on the experimental findings, glyphosate was considered non-genotoxic to germ cells *in vivo*.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Negative for mutagenic effects in the dominant lethal assay in mice.

The experimental performance of the study was not conducted under GLP criteria, but matched the descriptions of OECD guideline 478 (2016). However, there was a large number of deviations when compared to the current guideline. The number of implantations per group for each mating period was below the recommended number of 400 implants per group. It can be assumed that the number of males and females used for mating was too low. Fetal body weights were not recorded and no historical control data were provided. No dominant lethal frequency was calculated in the study report, but as the raw data were provided in the study report, dominant lethal factors could be calculated retrospectively for this evaluation. Further deviations were of minor degree and considered to not compromise the outcome of the study. Due to the large number of deviations, the study was considered to provide supporting information.

Assessment and conclusion by RMS:

Literature evaluation

A literature search for the active substance glyphosate was performed in accordance to the provisions of the EFSA Guidance "Submission of scientific peer-reviewed open literature for the approval of pesticide active substances under Regulation (EC) 1107/2009" and updated Appendix to this Guidance document. The following publications were found relevant and reliable for this section and the summaries are thus presented below and are part of the general discussion at the beginning of the section.

Table 5.4-1: Overview on literature found relevant for evaluation of glyphosate in section 5.4

4. Full summary of the study according to OECD format

In this study PPPs were analyzed for the correlation of GHS classifications resulting mainly from in vivo LD50-values with classifications obtained from calculated LD50-values using the CLP calculation method (CM). Accordingly, the CM predicted 80 % of the PPPs correctly. However 31 % of classified products were not identified revealing a considerable inaccuracy of this method. Based on these results ten PPPs and corresponding ASs were further tested in a cytotoxicity assay employing 3T3 and hFF cells (one PPP and corresponding AS were tested in HepaRG cells).

Materials and methods

Chemicals - Glyphosate isopropylamine salt (MON 0138) and RoundUP LB Plus (360 g/L A.I., MON 52276) was purchased from Monsanto Agrar Deutschland GmbH, Düsseldorf, Germany. Glyphosate was received dissolved in water at a concentration of 620 g/L.

Culture of Balb/3T3 cells, hFF cells and HepaRG cells - Mouse fibroblast cells (Balb/3T3) and human foreskin fibroblast cells (hFF) were cultured in Dulbecco's modified eagle medium (DMEM) supplemented with 10 % (v/v) foetal bovine serum (FBS) and 50 U/mL penicillin/streptomycin, and passaged every 3 to 4 days at a split-ratio of approximately 1:20 for 3T3 cells and 1:8 for hFF cells after enzymatic dissociation with trypsin-EDTA. Differentiated HepaRG cells were received in 96-well plates and were grown for 2 weeks in Williams's medium containing 10 % foetal calf serum (FCS), 100 U/mL penicillin/streptomycin, 0.05 % human insulin and 50 µM hydrocortisone hemisuccinate. For differentiation, cells were incubated for a another 2 weeks in differentiation medium containing in addition to the above components 1.7 % DMSO.

Proliferation test - To determine the optimal seeding density for the 48-hour toxicity assay, proliferation tests were performed in 2 independent runs. 3T3 and hFF cells were seeded in test medium (DMEM) supplemented with 10 % (v/v) Panexin NTA serum substitute and 50 U/mL penicillin/streptomycin, into 96-well plates, in a 2-fold dilution series, with the highest cell density being 1.6×10^4 cells/well. After 48 hours the viability of the cells was assessed by measuring the reduction of resazurin to the fluorescent resorufin. The fluorescence signal was measured at 530 nm (excitation) and at 590 nm (emission) using a multimode plate reader.

Cytotoxicity test - 3T3 and hFF cells were dissociated into single cells and seeded into 96-well plates in 100 µL per well of DMEM supplemented with 10 % (v/v) Panexin NTA serum substitute and 50 U/mL penicillin/streptomycin, at a density of 2,000 cells per well for 3T3 cells and 4,000 cells per well for hFF cells. Differentiated HepaRG cells were received in 96-well plates already seeded in a density of 9,000 cells per well. The test medium for HepaRG cells was based on phenol-red-free Williams's medium containing 2 % foetal calf serum (FCS), 100 U/mL penicillin/streptomycin, 0.05 % human insulin and 50 µM hydrocortisone hemisuccinate. After 24 hours, 100 µL of test medium (containing the double required final concentration of the test substance) were added to each well (day 0). After 48 hours cell viability was assessed by measuring the reduction of resazurin to the fluorescent resorufin. The fluorescence signal was measured at 530 nm (excitation) and at 590 nm (emission) using a multimode plate reader.

Testing of glyphosate and MON 52276 - At least two independent runs of each experiment were performed.

The highest tested concentration for glyphosate isopropylamine salt was 1000 µg/mL.

Results
Proliferation assay - Proliferation tests were performed to determine the optimal seeding density for the 48-hour toxicity assay. The cells were seeded in a 2-fold dilution series into 96-well plates, and reduction of resazurin into the fluorescent resorufin was measured after 48 hours. The proliferation assay revealed an optimal seeding concentration for the cytotoxicity test of 2,000 cells per well for 3T3 cells and 4,000 cells per well for hFF cells.

Testing of glyphosate and MON 52276 - Two controls, saccharin as the negative control and 5-FU as the positive control, were tested for 48 hours on 3T3 and hFF cells. The treatment of both cell types with saccharin did not significantly reduce cell viability up to a concentration of 1,000 µg/mL. In contrast, the treatment with 5-FU resulted in a noticeable reduction of viability, with different IC_{50} values for the two cell types, i.e. 0.06 ± 0.01 µg/mL for 3T3 cells and 0.14 ± 0.05 µg/mL for hFF cells. The IC_{50} for glyphosate isopropylamine salt was 954.8 ± 117.1 µg/mL for 3T3 cells and 1211 ± 885.7 µg/mL for hFF cells. The IC_{50} for MON 52276 was 313.2 ± 29.3 µg/mL for 3T3 cells and 361.6 ± 612 µg/mL for hFF cells. The ratio of the AUC under the % viability vs concentration curve of glyphosate isopropylamine salt over MON 52276 is 1.7 for 3T3 cells and 1.3 for hFF cells. This indicates that the treatment of hFF cells with glyphosate and its formulation Roundup did not result in significant differences between cytotoxicity curves. The ratio of the AUCs of glyphosate over MON 52276 for both cell types was below a factor 2 and could thus be regarded as minor.

Conclusion
In this study, glyphosate isopropylamine salt, amongst other pesticides, and its corresponding formulation MON 52276 were tested for cytotoxicity in 3T3 cells and hFF cells. The IC_{50} for glyphosate isopropylamine salt was 954.8 ± 117.1 µg/mL for 3T3 cells and 1211 ± 885.7 µg/mL for hFF cells and the IC_{50} for MON 52276 was 313.2 ± 29.3 µg/mL for 3T3 cells and 361.6 ± 612 µg/mL for hFF cells. The ratio of the AUCs of glyphosate over MON 52276 for both cell types was below a factor 2 and could thus be regarded as minor.

4. Assessment and conclusion

Assessment and conclusion by applicant:
It was the intention of this study to evaluate the GHS classification of pesticide formulations for acute toxicity based on calculated LD_{50} values using the CLP calculation method (CM). Because of the considerable inaccuracy of this method the *in vitro* cytotoxicity of 10 pesticide formulations was compared against that of the active ingredient using mouse (3T3) and human (hFF) fibroblasts. In this exercise the IC_{50} for glyphosate isopropylamine salt was found to be 954.8 ± 117.1 µg/mL for 3T3 cells and 1211 ± 885.7 µg/mL for hFF cells and the IC_{50} for MON 52276 was 313.2 ± 29.3 µg/mL for 3T3 cells and 361.6 ± 612 µg/mL for hFF cells. The difference in cytotoxicity (expressed as the AUC of the % viability vs concentration curve) between glyphosate and MON 52276 could be regarded as minor.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate isopropylamine salt used was not sufficiently characterized and the standard deviation of the IC_{50} of glyphosate (1211 ± 885.7 µg/mL) and MON 52276 (361.6 ± 612 µg/mL) for human fibroblasts is too large.

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

Effects of technical materials of pesticide active ingredients, belonging to various chemical classes, on erythropoiesis in mouse bone marrow were studied as part of the research on the pesticide mutagenic activity in micronucleus test. The purpose of the present study was to estimate the toxic action of the test substances on the target organ and the validity of the results of the micronucleus assay under conditions of erythropoiesis suppression.

Materials and methods

Chemicals - Four glyphosate batches were tested with a purity of respectively 95.7, 98.3, 95.1, and 95.8 %.

Animals – CD-1 mice were purchased from "Andreevka" Branch of the Federal Government Budgetary Establishment of Science "Scientific Center of Biomedical Technologies" of the Federal Bio-Medical Agency of the Russian Federation. The acclimation period was 7 days. Mice had access to drinking water and feed ad libitum, and were maintained under a 12:12-hour light/dark photoperiod at 22 – 22.5 °C and 36 - 40 % humidity.

Mammalian Erythrocyte Micronucleus Test (OECD TG 474) - At least 5 groups of minimum 5 mice per sex were used. Each assay included a positive control group (40 mg/kg bw cyclophosphamide), a negative control group (1 % potato starch in water), and 3 treatment groups. Glyphosate was administered orally by gavage once a day for 2 subsequent days (24 hours apart) at a volume of 10 mL/kg bw. The maximum dose in the main experiment was either 2,000 mg/kg bw or the MTD as determined in a preliminary dose-finding experiment. Mice were sacrificed 22 hours after the second administration by cervical dislocation, then femurs were removed and bone marrow was harvested. To assess the effect of glyphosate on erythropoiesis, the ratio of polychromatic erythrocytes (PCEs) to the sum of PCEs and normochromatic erythrocytes (NCEs) was determined by counting at least 500 cells (PCEs + NCEs) per animal (at least 250 cells for each slide) under a Nikon Eclipse Ci-L microscope. At least 4,000 PCEs were counted per animal by two different researchers.

Statistical analysis - Statistical analysis was performed using SPSS Statistics v. 22.0 software. The statistical significance of the difference in the proportion of PCEs/(PCEs + NCEs) between the highest dose group and the concurrent negative control group was evaluated using the independent samples t-test for each study.

Results
It should be noted that the negative control values slightly varied from experiment to experiment, and that the historical negative controls of the laboratory were 0,50 ± 0,06 and 0,52 ± 0,06 PCEs/(PCEs+NCEs) females and males, respectively. Cyclophosphamide did not cause a significant decrease in the proportion PCEs/(PCEs+NCEs) in comparison with the negative control. The 4 glyphosate batches tested at the limit dose of 2,000 mg/kg bw in CD-1 mice according to the protocol of the *in vivo* micronucleus assay compliant with OECD test guideline 474 did not reveal any effect on erythropoiesis in the bone marrow.

Conclusion
Glyphosate tested at the limit dose of 2,000 mg/kg bw in mice in the *in vivo* micronucleus assay did not show any effect on erythropoiesis in the bone marrow.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Along with 51 other pesticides 4 batches of glyphosate with purities ranging from 95.1 to 98.3 % were investigated for their effect on erythropoiesis in mice. To assess the toxicity of glyphosate on the bone marrow the *in vivo* micronucleus test in the mouse according to OECD test guideline 474 was conducted at the limit dose of 2,000 mg/kg bw. No effect of glyphosate on erythropoiesis was found.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the source of the glyphosate batches used was not reported and no suitable positive control was used in the micronucleus test. The test conducted was in compliance with OECD test guideline 474.

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

This study investigates the cyto- and genotoxic potential of the active ingredient glyphosate and GBHs in human mononuclear white blood (HMWB) cells. HMWB cells were treated for 4 h at 37 °C with increasing concentrations (1–1000 µM) of glyphosate alone and in three GBHs (Roundup Mega, Fozat 480 and Glyfos) to test cytotoxic effect with fluorescent colabelling and genotoxic effect with comet assay. In addition, each concentration was tested with and without metabolic activation using human liver S9 fraction.

Materials and methods
Chemicals; Analytical-grade glyphosate (N-(phosphonomethyl) glycine, CAS No: 1071-83-6) was purchased from VWR International Kft (Debrecen, Hungary) and samples of three GBHs, i.e.
• Roundup Mega containing 551 g/L or 42 % (w/w) potassium salt of glyphosate (CAS No: 70901-12-1; equivalent to 450 g/L glyphosate) and 7 % (w/w) ethoxylated etheralkylamine (CAS No: 68478-96-6);
• Fozat 480 containing 480 g/L or 41 % (w/w) isopropylammonium salt of glyphosate (CAS No: 38641-94-0; equivalent to 360 g/L glyphosate) and < 5 % (w/w) hygroscopic substances;

• Glyfos containing 480 g/L or 42 % (w/w) isopropylammonium salt of glyphosate (equivalent to 360 g/L glyphosate) and 9 % (w/w) polyethoxylated tallow amine (CAS No: 61791-26-2);

were kindly provided by pesticide applicators. Composition data for each formulation were retrieved from the material safety data sheets (MSDS). Chemicals used for the assays and human liver-derived metabolic activation system (S9 fraction) were obtained from Sigma-Aldrich Chemie GmbH (Heidelberg, Germany). Cell culture medium and its supplements were obtained from Biowest (Nuaillè, France). The acetomethoxy derivative of calcein (Calcein AM) and propodium iodide (PI) fluorescent dyes were purchased from Biotium (Hayward, CA, USA). Heparin-containing vacutainers were purchased from BD Vacutainer Systems (Plymouth, UK).

Cell cultures; Human peripheral whole blood samples were obtained by venipuncture and collected into heparin-containing vacutainer tubes from four non-smoking, healthy volunteers (three males and one female, aged 20–40 years) without known previous contact with pesticides, mutagens or carcinogens. Cultures were prepared within 1 h of phlebotomy. Human mononuclear white blood (HMWB) cells were prepared from erythrocytes by density-gradient centrifugation over Histopaque-1077 gradient. The buffy coat was aspirated and re-suspended in RPMI 1640 medium containing 10 % foetal calf serum (FCS).

Cell treatment; HMWB cells were treated in the cell-culture medium with increasing concentrations (1 µM, 10 µM, 100 µM, 250 µM, 500 µM, 750 µM and 1 mM) of glyphosate alone and in three GBHs in a way that the concentrations of glyphosate in GBHs were equivalent. Concentrations were chosen based on the results from previous in vitro studies performed on human lymphocytes. The stock solutions and the dilution series were made in phosphate-buffered saline (PBS) and adjusted with 1 M NaOH to pH 7.2. Aliquots of different concentrations of glyphosate and GBH solutions, as well as PBS as negative control, were added to the cell cultures and incubated for 4 h at 37 °C. The PBS content was always < 10 % (v/v) in the cell culture medium. The experiments were conducted in the presence and absence of S9 fraction. 100 µL of the working S9 mix containing 10 % (v/v) of S9 fraction was composed of 8 mM MgCl2, 33 mM KCl, 100 mM sodium phosphate buffer pH 7.4, 5 mM glucose-6-phosphate, and 4 mM NADP was added to the S9+ samples. 100 µM hydrogen peroxide was used as a positive control.

Cytotoxicity assay; After treatment, aliquots of samples were immediately subjected to cytotoxicity test. Calcein AM and propidium iodide (PI) fluorescent dyes were used to colabel the cells. Calcein AM is a non-polar compound that passively crosses the plasma membrane of living cells, where it is cleaved by

intracellular esterases to reveal a very polar derivative of fluorescein (calcein) that remains trapped in the cytoplasm. PI is a DNA intercalating dye, which is able to permeate membranes of dead and dying cells but cannot penetrate plasma membranes of live healthy cells. Both fluorescent dyes were dissolved in PBS (pH 7.2) to a final concentration of 2 µM each. 200 µL of this working solution added to the cell pellets (1 × 105 cells), and incubated for 30 min at 4 °C, protected from light. The labelled cells were washed and re-suspended in ice-cold PBS buffer. 40 µL of the cell suspension was put on a microscope slide for immediate microscopic examination at 100x magnification using a Zeiss Axioplan epifluorescent microscope. FITC filter for Calcein AM and TRITC filter for PI was applied to excite the colabelled cells. Survival rate was determined by visual examination of 10 randomly selected non-overlapping fields per slide. Each field contained 10 to 30 images. Cell viability was expressed as the mean of the percentages of living cells from repeated experiments. The proportions of living cells observed in technical replicates were subjected to statistical analysis.

Genotoxicity assay; The alkaline version of the comet assay was performed according to the methodology of Collins (2004). Following treatment, samples were centrifuged and HMWB cells were resuspended in serum-free medium at a cell density of 2000 cells/µL. Degreased frosted slides were coated with two layers: 1 % normal melting point agarose (NMA) covered with 0.75 %, low melting point agarose (LMA) containing the cells (~2 × 105 per slide). After solidification, the embedded cells were lysed (2.5 M NaCl, 100 mM Na2EDTA, 10 mM Tris base, pH 10, 1 % sodium N-lauroyl sarcosinate and 1 % Triton X-100 added fresh) at 4 °C for 18–20 h, shielded from light. After lysis, the DNA was allowed to unwind for 20 min in alkaline electrophoresis buffer (300 mM NaOH, 1 mM Na2EDTA, pH 13) and subjected to electrophoresis in the same buffer for 20 min at 0.8 V/cm and 300 mA in a horizontal electrophoresis tank (Cleaver Scientific, Rugby, UK). Finally, the slides were rinsed gently three times with neutralization buffer (0.4 M Tris base-HCl, pH 7.5) to remove excess alkali and detergent. After drying, each slide was stained with ethidium bromide (20 µg/ml) and stored in a humidified container at 4 °C until analysis. The fluorescence signal was detected at 400x magnification using a Zeiss Axioplan epifluorescent microscope equipped with a CCD camera connected to an image analysis system. The Comet Imager v.2.2.1. Software (MetaSystems GmbH, Germany) was used to analyse 2 × 50 randomly captured comets from duplicate slides and compute the DNA damage parameters. Percentage of DNA in the tail (tail DNA%) and tail length in µm (TL) were measured to quantify DNA damage. The results are presented as mean of the median values of DNA damage parameters from repeated experiments. The medians of technical replicates were subjected to statistical analysis.

Data analysis; Experiments were independently performed three times from three different donors. The rate of cell viability and the central values of DNA damage parameters in the comet assay induced by various concentrations of the xenobiotics in repeated experiments were statistically compared to that of untreated cells using ANOVA with Dunnett's post hoc test. To statistically analyse the effect of metabolic activation, DNA damage values were pooled from three repeated experiments to compare results from S9-treated and S9-untreated samples at each exposure concentration by using Mann-Whitney test because pooled data sets followed non-normal distribution. Statistically significant difference was accepted at 5 % significance level.

Results

Cytotoxicity; The viability of HMWB cells treated with glyphosate alone was found to be over 86 % in the absence and presence of S9 over the entire concentration range (please refer to Figure below). Regardless of metabolic activation, GBHs induced a significant decrease in the proportion of living cells from 250 µM of Round Mega and Glyfos whereas from 500 µM of Fozat 480.

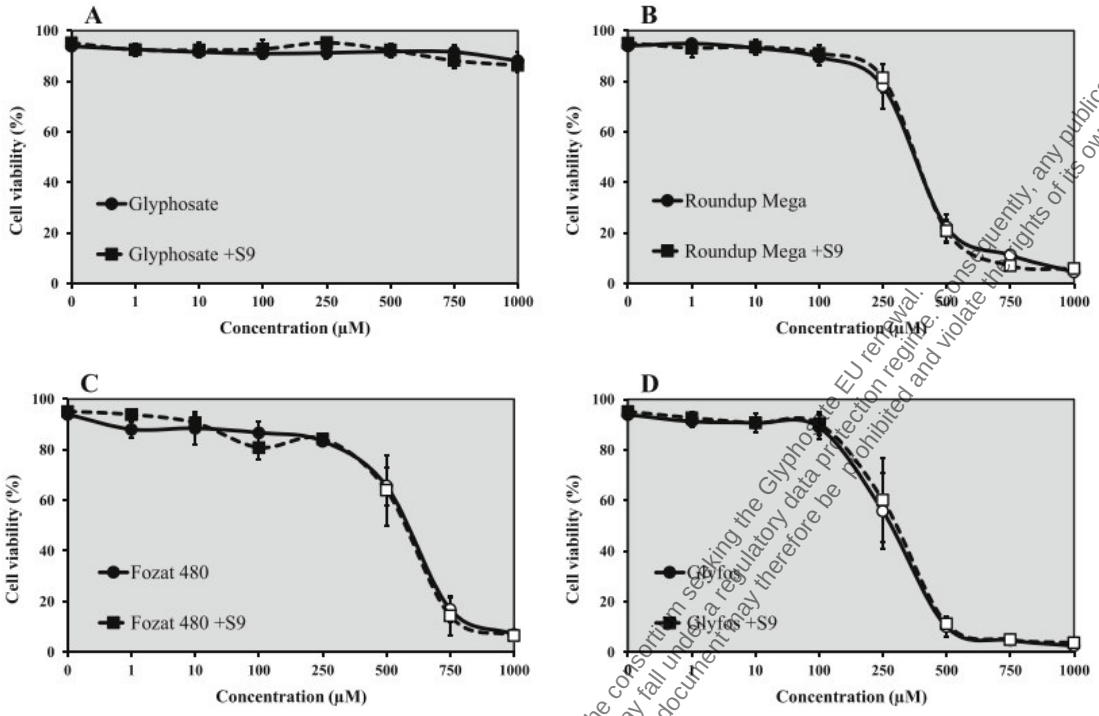

Figure 5.4.3-1: Effect of 4-h exposure to increasing concentrations of glyphosate (A), Roundup Mega (B), Foza 480 (C) and Glyfos (D) on cell viability in the absence and presence (+S9) of metabolic activation system. The data points indicate the means ± standard error of the mean (SEM) and three repeated experiments. Statistically significant decrease of cell viability, indicated by empty data points, was determined by comparing the values induced by various doses of glyphosate or GBHs to the background level of untreated cells by ANOVA with Dunnett's post hoc test. (from: Nagy *et al*., 2019)

DNA damage; Exposure of HMWB cells to glyphosate in the 0–1000 µM concentration range did not result in dose-dependent increase of DNA damage measured by the comet assay parameters. Unlike the active principle, GBHs induced statistically significant increase of both DNA damage parameters from 500 µM (Roundup Mega and Glyfos) and 750 µM (Fozat 480) compared to untreated cells. S9 treatment did not influence the effect of active ingredient glyphosate over the whole concentration range. On the contrary, addition of S9 to the assay modified the effects of GBHs in a non-consistent manner. The presence of metabolic enzymes significantly decreased the DNA damage induced by Roundup Mega and Fozat 480 at 1000 µM and from 10 µM, respectively. Metabolic activation could be observed only in samples exposed to 250 µM or higher concentrations of Glyfos indicated by the statistically significant differences in the tail DNA% and TL values between the S9-treated and S9-untreated cells (Tables 1 and 2).

Table 5.4.3-30: DNA damage induced by 4-hour exposure to glyphosate and GBHs with and without metabolic activation system (S9) in HMWB cells measured as tail DNA% (from: Nagy *et al*., 2019)

Discussion

The use of glyphosate containing products both for agricultural and residential purposes continues to rise since their first introduction to the market in 1974. Today, uncountable GBHs are registered in more than 130 countries worldwide. The unrestricted application of GBHs in the past few decades has resulted in the accumulation of glyphosate residues in environmental media exposing – and also impairing the health of – aquatic and terrestrial animals, as well as humans. In this study, we measured potential differences in the cyto- and genotoxicity between the declared active ingredient glyphosate and three marketed GBHs in HMWB cells in vitro with the use of the comet assay. To examine the toxicity of potential metabolites of the selected herbicides, human liver-derived metabolic enzyme system (S9) was also applied. The cytogenetic side effects of glyphosate and GBHs in humans have received pronounced scientific coverage in the last decade, resulting in numerous in vivo and in vitro human studies, which demonstrated that glyphosate alone or GBHs have detectable genotoxic potential, while others have reached opposite conclusions. Our results indicate that glyphosate alone could not induce DNA strand breaks in HMWB cells up to 1000 μM measured with the comet assay even in the presence of metabolic activation. This finding contrasts with previous studies employing isolated human blood mononuclear cells treated with glyphosate concentrations corresponding to ours, but using different experimental settings. A study showed with comet assay that glyphosate at 0.7 μM (in vitro) caused a statistically significant increase of DNA damage in human peripheral blood lymphocytes; however, they applied longer (20 h) exposure time than used in this study, and, unlike in our experiment, cells were incubated on microscope slides embedded in agarose gel at 25 °C. A further study also observed DNA damage in the above cell type from 20.7 μM (3.5 μg/ml) and from 250 μM, respectively. Although they incubated the cell cultures under the same conditions as used in our study (for 4 h at 37 °C), they applied LMA at lower concentration (0.5 %), as well as lower electrophoretic voltage (0.7 V/cm) and time (15 min). The execution of comet assay by them applying 24 h exposure time and lower electrophoretic voltage was also different from the method we used. These discrepancies in the experimental design along with the possible inter individual variability in response to genotoxic insults may explain the contradictory findings. The cytotoxic potential of the active ingredient glyphosate in the 0–1000 μM concentration range was found to be minimal, whereas formulations showed to have pronounced cell-killing activity to HMWB cells in our study. All the three GBHs resulted in substantially decreased cell viability (< 23 %) from 500 μM (Roundup Mega and Glyfos) and from 750 μM (Fozat 480) concentrations. Exposure to GBHs also caused statistically significant ($p < 0.05$) increase of DNA damage from 500 μM (Roundup Mega and Glyfos) and 750 μM (Fozat 480). However, this observation cannot be explained by the direct genotoxic potential of GBHs, rather due to the high level of cytotoxic activity of the formulations, because cell death mechanisms, both apoptosis and necrosis, can produce spontaneous DNA fragmentation that can act as a confounder in the assessment of primary DNA damage in the comet assay. The high cytotoxic potential of GBHs may be attributed to the presence of other ingredients in the formulations, which has been reported in previous publications. POEA, the declared co-formulant in Glyfos, is more than 1000 times more cytotoxic than glyphosate alone, and concerns were also raised for its genotoxic potential at concentrations not causing cytotoxicity. Thus, EFSA concluded that POEA is clearly more toxic than glyphosate when tested in GBHs, and in response to this, Glyfos was withdraw from the Hungarian market in 2017. The ethoxylated etheralkylamine added to Roundup Mega has very similar toxicological properties as POEA, which is supported by the identical dose-response relationships of Roundup Mega and Glyfos, both of them containing surfactants at roughly the same concentration. The adjuvant content of Fozat 480 (< 5 % hygroscopic substances) could not be determined exactly from the MSDS; however, we can suspect from the path of the cell viability dose-response that it may also contain ethoxylated surfactants similarly to the other two GBHs. It is proven that ethoxylated adjuvants can be embedded into the cell membrane disrupting its integrity and permeability and therefore increasing the bioavailability of glyphosate. In this sense, surfactants in GBHs have an indirect synergistic effect with glyphosate. Researchers concluded that DNA damage observed in HMWB cells after exposure to glyphosate, Roundup 360 PLUS or the metabolite of glyphosate (aminomethylphosphonic acid, AMPA) was not due to direct interaction of these compounds with DNA as no DNA adducts formation has been observed, but rather ROS-mediated effects induced by the chemicals leading to cell death and indirect DNA damage. Previous studies have not been able to clearly demonstrate the oxidative DNA damaging potential of glyphosate; however, GBHs produced an increase in reactive oxygen species in both in vitro and in vivo test systems highlighting the role of adjuvants in the cytotoxic effects observed in our experiments. Despite

the definite cytotoxic effect, Roundup Mega and Fozat 480 are still commercially available not only in Hungary, but also in many other European countries under various brand names. In our study, the presence of metabolic activation did not alter the cytotoxic potential of either the active ingredient glyphosate or the GBHs. By contrast, we noted decreased DNA damages in the comet assay with Roundup Mega and Fozat 480, but increased damage with Glyfos as a result of S9 treatment. In humans, the only metabolite of glyphosate is the AMPA. It has been shown that AMPA is not able to induce DNA damage below a relatively high (4.5 mM) concentration, which is in agreement with our data. The diverse response of GBHs to metabolic activation observed in the comet assay may be explained by the presence of variable adjuvants in the formulations that underwent different metabolic modifications. Our results may indicate that the metabolite(s) of POEA in Glyfos can be more toxic than the parent compound in the comet assay, but not in the cell viability assay. There is no evidence in the published literature that POEA or other surfactants, or even products which contain these adjuvants, might undergo metabolic activation, and afterwards, become able to cause cytogenetic effects. The potential metabolic transformation of adjuvants can be hypothesized only from animal experiments; however, these studies have provided contradictory findings so far. This can still be considered as a critical knowledge gap to clarify the genotoxic potential of adjuvants in common commercial formulations of glyphosate under in vivo circumstances. A complex long-term experimental animal study has recently been initiated to assess possible risks resulting from the ubiquitous exposure to GBHs, and has already provided preliminary data on Roundup-induced endocrine effects and altered reproductive developmental parameters in male and female Sprague Dawley rats at a dose level considered as “safe”.

Conclusion

This is the first study that compared toxic effects of various glyphosate-based herbicide formulations to each other and with the declared active ingredient glyphosate in isolated human mononuclear white blood cells. GBHs caused much stronger cytotoxic effect on HMWB cells in comparison to glyphosate that may be attributed to the effect of various surfactants added to the formulations or their interaction with the active ingredient glyphosate and/or with other components of GBHs. Therefore, the GBHs-induced DNA damage observed in the comet assay could be most likely explained by non-genotoxic mechanisms and cannot indicate direct DNA damaging effects of glyphosate-based herbicide formulations. Nevertheless, by applying extended exposure durations and/or other test systems, such as the cytokinesis-block micronucleus cytome assay would allow for the discrimination between the cyto- and genotoxic effects and for the determination of the possible permanent genotoxic effect of these herbicides. Furthermore, this study, for the first time, pointed out the possibility that POEA containing formulation can undergo metabolic activation which draws attention to the need for comprehensive investigation of the toxicity of formulations to confirm our results and to assess the true health risks of environmental and occupational exposures.

3. Assessment and conclusion

Assessment and conclusion by applicant:

This paper describes a well conducted comet assay using human lymphocytes as the test system to examine the genotoxicity and cytotoxicity of glyphosate and 3 commercial products containing glyphosate. No DNA damage was induced by analytical grade glyphosate. The 3 glyphosate products induced an increase in tail intensity in the comet assay only at highly cytotoxic concentrations, non-toxic concentrations induced no DNA damage.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate tested was not sufficiently characterized and no positive control was used.

Assessment and conclusion by RMS:

5. Full summary of the study according to OECD format

In vitro studies were conducted to determine the short-term cytotoxic and genotoxic effects of pure glyphosate and two glyphosate formulations (Roundup® and Wipeout®) at concentrations relevant to human exposure using whole blood (cytotoxicity) and various cancer cell lines (cytotoxicity and genotoxicity). Pure glyphosate (pure glyph) and Roundup® (Ro) showed similar non-monotonic toxicological profiles at low dose exposure (from 10 µg/ml), whereas Wipeout® (Wo) demonstrated a monotonic reduction in cell viability from a threshold concentration of 50 µg/ml, when tested in whole blood. We evaluated whether using various cancer cells (the estrogen-E2-responsive HEC1A, MCF7 and the estrogen-insensitive MDA-MB-231) exposed to moderate doses (75–500 µg/ml) would indicate varied toxicity and results indicated significant effects in the HEC1A cancer cells. A non-monotonic reduction in cell viability was observed in HEC1A exposed to pure glyph (75–500 µg/ml) and proliferative effects were observed after exposure to Wo (75, 125 and 250 µg/ml). Genotoxicity assessment (test concentration 500 µg/ml) demonstrated DNA damage in the HEC1A and MDA-MB-231 cells.

Materials and methods

Chemicals - Glyphosate (99.5 % purity) was purchased from Supelco Analytical (USA).

Whole blood cell culture and exposure - Blood from 5 healthy volunteers was collected by venipuncture in heparin-containing tubes. Blood samples were diluted 1:10 in RPMI 1640 media supplemented with 50 µg/ml streptomycin and 50 U/ml penicillin. The 1 mL whole blood samples were exposed to glyphosate at various concentrations up to 500 µg/mL for 18 hours at 37 °C. Lipopolysaccharide (LPS, 5 µg/mL) was used as the positive control and pyrogen-free water as the negative control.

Breast cancer (MCF7 and MDA-MB-231) and endometrial cancer (HEC1A) cell line culture - MCF7 (hormone responsive) and MDA-MB-231 (hormone independent) cell lines were obtained from the American Type Culture Collection (ATCC), USA and HEC1A cells were obtained from Nelson Mandela Metropolitan University, Eastern Cape, South Africa. All cell lines were grown in DMEM supplemented with 5 % heat-inactivated fetal calf serum, 50 U/mL penicillin and 50 µg/mL streptomycin. To maintain a stable estrogen-sensitive phenotype, cells were cultured in phenol-free medium after the removal of phenol red. All data were normalized against untreated controls. Cell lines were routinely maintained under standard cell culture conditions at 37 °C, 5 % CO2 and 90 % humidity. The different cell lines were exposed to glyphosate at varying concentrations up to 500 µg/mL for 24 hours at 37 °C. Camptothecin (100 µM), a DNA topoisomerase inhibitor, was used as the positive control in this study.

Cytotoxicity assay (MTT assay) - Following exposure to glyphosate, samples were incubated in 0.5 mg/mL MTT reagent for 3 hours for the cancer cell lines and for 30 minutes for whole blood at 37 °C. After incubation, the MTT reagent was aspirated and 1 mL of DMSO was added to solubilize the formazan

product formed. Purple color formation was determined spectrophotometrically at 560 nm using a Biotek Powerwave XS microplate reader.

Single-cell gel electrophoresis (comet assay) - The exposure concentrations used for this study were chosen based on results obtained in the cell viability assay and the positive control reference concentration was chosen based on cytotoxicity results reported in the HepG2 human liver cell line. The MCF7, MDA-MB-231 and HEC1A cancer cell lines (100,000 cells/well) were incubated in 24-well plates for 4 hours at 37 °C, in the presence of 500 and 1000 µg/mL glyphosate. Camptothecin was used as a positive control in this study (100 µM). The preparation of the samples and the method used for the comet assay were conducted according to the instructions described in the OxiSelect™ Comet Assay Kit (Cell Biolabs, Inc).
Preparation of cell samples for the comet assay - Trypsinized cells were pooled (three sample wells) and centrifuged at 700×g for 2 minutes. The supernatant was discarded and the pellet washed with ice cold PBS and centrifuged at 700×g. The cells (1×10^5 cells/mL) were then resuspended in ice cold PBS before the assay was conducted.

Comet assay sample slide preparation and cell lysis - Resuspended cells (10 µL) were combined with 100 µL molten comet agarose and the mixture (75 µL/well) was immediately placed onto an OxiSelect™ comet slide. Slides with the cell agarose mixture were incubated at 4 °C in the dark for 15 minutes to allow the agarose to set. Slides were treated in pre-chilled lysis buffer (pH 10) for 60 minutes at 4 °C in the dark followed by treatment in alkaline solution (pH 13) for 30 minutes at 4 °C in the dark.

Alkaline electrophoresis - Slides were subjected to alkaline electrophoresis for 18 minutes at 300 mA, neutralized in pre-chilled deionised water and washed in 70 % cold ethanol for 5 minutes. The slides were then air-dried and incubated with 100 µL of 1 × Vista Green dye prepared in TE buffer (10 mM Tris, pH 7.5, 1 mM EDTA) for 15 minutes at room temperature in the dark.

Comet assay sample visualization and data analysis - Slides were visualized with fluorescence microscopy (5×) using a FITC filter (7 %). Images were obtained using an AxioCam MR3 Camera and stored in the Axio vision Rel.4.8 program. Image J Macro was used to calculate the tail length, % tail moment and % tail DNA. 50 cells were analyzed per slide (replicates of 3) from pooled cell cultures, per experimental treatment (n = 3).

Statistical analysis - All data were presented as mean ± standard error of the mean (SEM). ANOVA single-factor analysis (Microsoft Excel) was used to determine significant differences ($P \leq 0.05$, $P \leq 0.01$). Non-linear least square regression models were applied to cytotoxicity data in human whole blood using the Graphpad Prism 6 software package. Goodness of fit was assessed using R2, R2 adjusted values and by the assessment of upper and lower 95 % confidence limits associated with the model fit. The Wald–Wolfowitz (runs) test was used to determine the deviation of the nonlinear regression model from the experimental data. The models were used to estimate the concentration of glyphosate required to illicit a half maximal response (half maximal effective concentration, EC50). Based on the observed biphasic nature of the curves obtained for glyphosate and Roundup, a model describing a seven-parameter bell-shaped dose (combines two sigmoidal responses)-response curve was selected.

Results

Cell viability in human whole blood – Glyphosate cytotoxicity in human whole blood at concentrations from 0.1 to 500 µg/mL was determined using the MTT reduction assay. A statistically significant reduction in cell viability of whole blood was observed for glyphosate at 10, 50 and 250 µg/mL but not at 500 µg/mL. LPS was a suitable positive control for this study.

Cell viability (MTT assay) in human cancer cell lines - A statistically significant reduction in cell viability was noted for glyphosate in the HEC1A cell line at 75, 125, 250 and 500 µg/mL. No change in viability was seen with the MCF7 and MDA-MB-231 cell lines. The positive control, camptothecin, reduced significantly cell viability in all three cell lines.

Single cell gel electrophoresis (comet assay) - The test concentrations selected for genotoxicity studies were based on the results of the cell viability study and reference concentrations were chosen based on glyphosate concentrations reported in the literature to incur genotoxic damage in human cell lines. Glyphosate was tested in the comet assay at 500 and 1000 µg/mL where a statistically significant increase in tail length and tail moment was observed at both concentrations in the HEC1A and MDA-MB-231 cell lines. The positive control, camptothecin, increased tail length significantly in the HEC1A and MDA-MB-231 cell lines but not in the MCF-7 cell line. The positive control increased tail moment significantly in all 3 cell lines.

Discussion and conclusions

When tested at concentrations ranging from 0.1 to 500 µg/mL, a statistically significant reduction in cell viability was observed in whole blood at glyphosate concentrations of 10, 50 and 250 µg/mL but not at 500 µg/mL. When tested for cytotoxicity glyphosate showed a statistically significant reduction in cell viability in the endometrial cancer cell line HEC1A at 75, 125, 250 and 500 µg/mL. No effect on cell viability was seen on hormone responsive (MCF7) and hormone independent (MDA-MB-231) breast cancer cell lines at concentrations up to 500 µg/mL. When glyphosate was tested for DNA damage in the single cell gel electrophoresis assay (comet assay) a statistically significant increase in tail length and tail moment was observed at 500 and 1000 µg/mL in the endometrial cancer cell line HEC1A and the hormone independent breast cancer cell line MDA-MB-231. No DNA damage was observed in the hormone responsive breast cancer cell line MCF7 up to concentrations of 1000 µg/mL. Cytotoxicity results at concentrations relevant to occupational and residential exposure to glyphosate observed in the three cancer cell lines suggest that toxicity varies depending on cell type, with the most significant results observed in the HEC1A cancer cell line exposed to glyphosate. Moderate concentrations of glyphosate (500 µg/mL) induced genotoxic effects in the HEC1A and MDA-MB-231 cancer cell lines, which suggests that glyphosate may display various mechanisms of toxicity.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The cytotoxicity of glyphosate has been investigated in whole blood, in hormone independent (MDA-MB-231) and in hormone responsive (MCF7) cell lines and in a an endometrial cancer cell line (HEC1A). The capacity of glyphosate to produce DNA damage was investigated in MCF7, MDA-MB-231 and HEC1A cells in the Comet assay. Glyphosate was found to reduce cell viability in whole blood at the intermediate concentrations (10-250 µg/mL) but not at the highest concentration tested (500 µg/L). A significant concentration related reduction in cell viability was seen with glyphosate in HEC1A cells (> 75 µg/mL) but not in the two other cell lines. When glyphosate was tested at 500 and 1000 µg/mL an increase in tail length and tail moment was observed in HEC1A and MDA-MB-231cells but not in the hormone responsive breast cancer cell line MCF7. The *in vitro* concentrations of glyphosate at which DNA damage was observed were 500 and 1,000 µg/mL which are systemic concentrations that cannot be reached in *in vivo* toxicology studies.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the Comet assay was only conducted at concentrations that are physiologically not feasible in *in vivo* toxicology studies (> 1mM).

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

In this study, the induction of micronucleus formation in vivo in polychromatophilic erythrocytes of bone marrow of CD-1 mice was assessed by the action of three different technical glyphosate products on the market in the Russian Federation. It was found that the tested samples of technical products showed different cytogenetic activity, while only one of them caused a statistically significant, dose-dependent increase in the frequency of induction of micronuclei compared to the negative control.

The analysis of the composition of the studied product samples showed that the cytogenetic activity may depend on the content of potentially mutagenic impurities, formaldehyde in particular.

The acquired data provides some additional grounds for lowering the upper limit of formaldehyde content in technical glyphosate products and also indicates the need to assess the genotoxic activity of analogue pesticides entering the market of plant protection products.

Materials and methods

Three glyphosate technical products were used that were manufactured at different factories and that contained the active substance (glyphosate acid) in amounts of 96.6 %, 95.8 % and 95.7 % in technical products I, II and III, respectively.

Chromosomal disturbances were revealed through the use of in vivo micronucleus analysis [OECD Test No. 474: Mammalian Erythrocyte Micronucleus Test. 2016] of the bone marrow erythrocytes in CD-I laboratory mice obtained from the husbandry center at the Andreyevka Branch of the Federal State Budget Research Institution "Biomedical Technology Science Center" of the Russian Federal Medicobiological Agency.

Five mice per group were used. Technical glyphosate was administered intragastrically in 1 % starch in doses of 500, 1,000 and 2,000 mg/kg of body weight (the maximum dose according to OECD Test No. 474) twice, twenty-four hours apart, and the animals were euthanized 22 hours following the second administration. At the same time, an excipient (1 % starch) was given as a negative control following the same pattern as was used for the technical glyphosate. Cyclophosphamide was used as a positive control, given intragastrically in the amount of 40 mg/kg once, at the same time as the second dose of glyphosate. Bone marrow preparations from each specimen were studied microscopically (on a Japan-made Nikon Eclipse Ci-L), counting 4,000 polychromatophilic erythrocytes (PCEs) for measuring micronucleus frequency), and the portion among the erythrocytes as a whole made up by PCEs, counting no fewer than 500 erythrocytes for each animal.

A statistical analysis of the study results was carried out using SPSS Statistics v. 22.0 (IBM, New York, USA). Frequencies of micronuclei in the PCEs were compared by building a generalized log-linear model

of the Poisson Regression ($\alpha = 0.05$). The data were also checked for dependencies between micronucleus frequency and the dose of the technical product being tested using the Mantel-Haenszel method.

Results

All the research was carried out in accordance with OECD Manual No. 474 and Methodological Instructions MU-1.2.3365-16. Each experiment used positive and negative controls simultaneously. The frequency of PCEs containing micronuclei in the case of the positive control was in a range from 1.58 to 2.95 %, while in the case of the negative control it was from 0.06 to 0.12 %. All the values were within the range of the distribution boundaries of historical laboratory controls.

The quantification of the portion of total erythrocytes made up by polychromatophilic erythrocytes show that in none of the analyses was erythropoiesis suppressed, i.e. there were no toxic effects on mouse bone marrow.

Varying effects were revealed during the study of the mutagenic activity of the glyphosate technical products through micronucleus analysis. Technical products II and III did not significantly increase the PCE frequency in mouse bone marrow compared to the simultaneous negative controls (please refer to Table and Figure below).

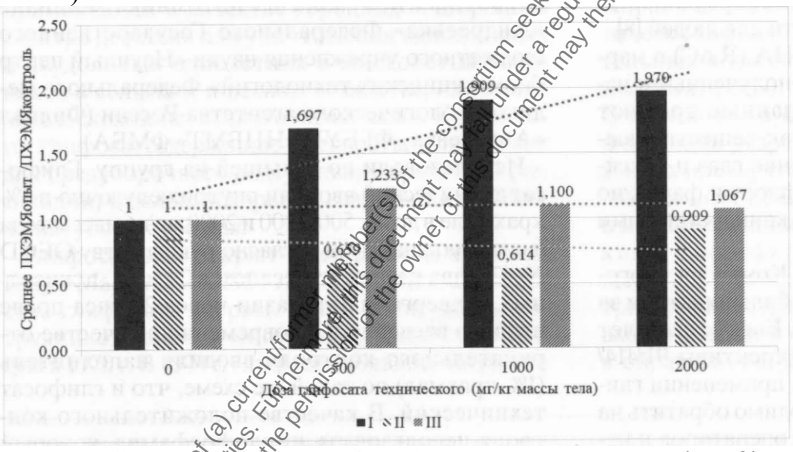

Figure 5.4.3-2: Technical Glyphosate Dose (mg/kg of body weight) Frequencies of increased occurrence of PCEs compared to the negative control depending on the dose of glyphosate technical products. I, II, III – Reference numbers for different technical products. $PCEMN_{exp}$ denotes the frequency of PCEs with micronuclei in groups of mice that received different glyphosate doses. $PCEMN_{control}$ denotes the frequency of PCEs with micronuclei in groups of mice that received an excipient with 1 % starch (negative control) (from: Ilyushina *et al*., 2018)

When administering technical Product I, a low, but statistically significant genotoxic effect was observed at all doses (Table 2). Moreover, a statistically significant linear dependency was observed of the frequency of PCEs with micronuclei upon the dose of the compounds under study (p= 0.002) (please refer to Table below).

A comparison was made between the content of ingredients in the study samples based on the available batch analysis certificates for the technical products. Two ingredients were of special interest from the point of view of genotoxicity: nitroso-glyphosate and formaldehyde. According to the provided certificates, Nitrosoglysophate, was not present in any of the batches of technical products (its content, in accordance with FAO specifications, must not exceed 1 mg/kg). Formaldehyde content in products I, II and III amounted to 0.13 %, 0.024 % and 0.06 %, respectively. A formaldehyde level in the glyphosate product of 0.13 % is the maximum permissible concentration in glyphosate technical products in accordance with the FAO specifications[14]. However, it should be noted that, according to Annex I of Directive 91/414/EEC, as amended in 2017, the partial content of formaldehyde in glyphosate must not exceed 1 mg/kg [10].
A comparison of the results we have obtained on the mutagenic activity and formaldehyde concentrations

in glyphosate technical samples showed that statistically significant genotoxic effects and a linear dependence of the frequency of PCEs with micronuclei upon the dose of the compound under study were only observed in the case of the product with 0.13 % formaldehyde. Lower concentrations of this ingredient did not induce the statistically significant formation of PCEs with micronuclei in bone marrow cells.

Thus, the observed mutagenic effects were most likely not related to the active ingredient, but rather to the formaldehyde contained as an ingredient in the products.

	9.791	0.002	0.28	0.597	0.06	0.938

The results obtained are in agreement with data from the literature. In the majority of studies conducted using the Ames test, glyphosate did not induce gene mutations in bacteria [Li A.P., Long T.J., 1988]. In both *in vivo* and *in vitro* micronucleus analyses carried out on different subjects, contradictory data were obtained. An increased frequency of the appearance of micronuclei was noted in several studies on cultivated human buccal epithelial cells [Koller V.J. et al, 2012], in mouse bone marrow [Manas F., 2009], and in human lymphocytes having undergone been affected by glyphosate-containing preparations during crop spraying [Bolognesi C. eta la, 2009]. However, the majority of the studies gave negative results in terms of micronucleus analyses [Kier L.D., 2013]. However, none of the studies analyzed the content of possible mutagenic ingredients in technical products and glyphosate-containing preparations and their contribution to the observed effects.

Conclusion

The comparative investigation of the genotoxic activity of various glyphosate technical products through the analysis of micronuclei in mouse bone marrow erythrocytes showed that cytogenetic activity may depend on the content in the product of potentially mutagenic ingredients, and in particular of formaldehyde. The contradictory results obtained in different studies of the mutagenic activity of glyphosate and preparations containing it may be connected to the different concentrations of ingredients that may exhibit effects of intracellular genetic structures.

The obtained data comprise additional substantiation for reducing the upper limit for formaldehyde content in glyphosate technical products, and also provide evidence of the need to assess the genotoxic activity of analogous pesticides entering the Russian Federation's market.

3. Assessment and conclusion

4.

Assessment and conclusion by applicant:

This paper describes the results of three different technical batches of glyphosate tested in a mouse micronucleus test. The study followings the recommendations of OECD 474, with some deficiencies, mostly regarding the reporting of data rather than test methodology. However, the reliability of the reported conclusions are unknown due to a lack of clarity and accuracy of the reported data. Individual animal data and group mean±SD frequency of micronucleated (MN) PCE have not been reported. Instead the results per group appear to be presented as the total number of MN PCE found per 40,000 PCE, together with the frequency of MN PCE values, expressed as relative to control, for the group with calculated 95 % upper and lower limits (no explanation for how these data awere derived is provided). The text describes the vehicle control MN PCE frequencies as ranging between 0.06 % and 0.12 % (within HCD) but similar detail is not provided for the treated groups. Consequently, there is no indication of animal variability within the groups and it is unknown if any of the treated animals fall outside of HCD. Furthermore, the total number of MN PCE is described as being per 40,000 PCE, however, only 4000 PCE were scored per animal and with 5 animals per group this would result in total of 20,000 PCE per group.

The authors postulate that the positive results observed for technical batch I are likely to be due to the presence of 0.13 % formaldehyde in the material, although they provide no data to support their hypothesis.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the source of the 3 glyphosate batches was not revealed although the concentrations of the most important impurities were given for each batch. Although reference was made to OECD test guideline 474 too little detail was given on the conduct of the MN assay to conclude to reliability without restrictions and the data are inadequately reported.

Assessment and conclusion by RMS:

Reliability criteria for *in vivo* toxicology studies

1. Information on the study

Data point:	CA 5.4/006
Report author	Santovito, A. *et al.*
Report year	2018
Report title	In vitro evaluation of genomic damage induced by glyphosate on human lymphocytes
Document No	doi.org/10.1007/s11356-018-3417-9 E-ISSN: 1614-7499
Guidelines followed in study	Some compliance with OECD 473 and OECD 487
Deviations from current test guideline	Only continuous treatments in the absence of S9 were performed and these exceeded the 1.5 cell cycles recommended by both guidelines. No historical control data are reported. Treatment commenced within 24 hours of PHA stimulation rather than 44-48 hours.
Previous evaluation	No

GLP/Officially recognised testing facilities	Not applicable
Acceptability/Reliability:	Yes/Reliable with restrictions

2. Full summary of the study according to OECD format

In this study, the *in vitro* clastogenic and/or aneugenic effects of glyphosate was analysed by chromosomal aberrations and micronucleus assays. Human lymphocytes were exposed to five glyphosate concentrations: 0.500, 0.100, 0.050, 0.025, and 0.0125 µg/mL, where 0.500 µg/mL represents the established acceptable daily intake value, and the other concentrations were tested in order to establish the genotoxicity threshold for this compound.

Materials and Methods
Study population; Peripheral venous blood was collected from six healthy Italian subjects (two males and four females, mean age ± SD, 27.50 ± 12.55), non-smoking, not alcoholics, not under drug therapy, and with no recent history of exposure to mutagens. All subjects signed the informed consent. The study was approved by the University of Turin ethics committee and was performed in accordance with the ethical standards laid down in the 2013 Declaration of Helsinki.

Blood sample collection and lymphocyte cultures; Blood samples were obtained by venipuncture, collected in heparinized tubes, cooled (4 °C), and processed within 2 h after collection. Lymphocyte cultures, fixation, and staining procedures were performed as previously described. Total time of lymphocyte cultures was 52 and 72 h for CA and MNi assays, respectively. After 24 h of incubation, 8.6 µL of glyphosate stock solution (Sigma-Aldrich, Saint Louis, MO, USA, CAS n. 1071-83-6) at the final concentration of 0.5 mg/mL in dimethyl sulfoxide (DMSO) was added to the lymphocyte culture in order to reach a final glyphosate concentration of 0.500 µg/mL. Similarly, 8.6 µL of glyphosate stock solution diluted 5, 10, 20, and 40 times with DMSO were added to the lymphocyte cultures in order to reach the final glyphosate concentrations of 0.100 µg/mL, 0.050 µg/mL, 0.025 µg/mL, and 0.0125 µg/mL, respectively. In particular, 0.500 µg/mL represents the ADI concentration established by EFSA for this compound, whereas 0.100, 0.050, 0.025, and 0.0125 µg/mL concentrations were tested in order to evaluate the genotoxicity threshold. Three control cultures were assessed: (1) positive control, by adding only MMC (final concentration 0.1 µg/mL culture); (2) 0.1 % DMSO solvent control, obtained by adding 8.6 µL of DMSO to the lymphocyte culture; and (3) negative control culture without both glyphosate and DMSO, obtained adding 8.6 µL of RPMI medium to the lymphocyte culture. Only for MNi assay, after 44 h of incubation, cytochalasin-B was added to the cultures at a concentration of 6 µg/mL to block cytokinesis. Similarly, only for CA assay, to arrest cells in mitosis, colchicine was added at the concentration of 0.06 µg/mL during the last 2 h of culture. After 52 h (for CAs assay) and 72 h (for MNi assay) of incubation at 37°C, the cells were collected by centrifugation, treated for 10 min with a pre-warmed hypotonic solution (75 mM KCl). After centrifugation and removal of the supernatant, the cells were fixed with a solution of methanol/acetic acid (3:1 v/v). The treatment with the fixative was repeated three times. Finally, the supernatant was discarded, and the pellet, dissolved in a minimal volume of fixative, was seeded on the slides to detect CAs and MNi by conventional staining with 5 % Giemsa (pH 6.8) prepared in Sörensen buffer.

Cytokinesis-block micronucleus assays; Microscope analysis was performed at ×400 magnification on a light microscope (Dialux 20, Leica, Germany). MNi, nucleoplasmic bridges (NPB), and nuclear buds (NBUD) were scored in 2000 binucleated lymphocytes with well-preserved cytoplasm per subject (total 12,000 binucleated cells per concentration). Cells containing one of more MNi were scored as "micronucleated cell" (MNC). A total of 2000 lymphocytes per donor per concentration were scored to evaluate the cytokinesis-block proliferation index (CBPI), according to the following formula: [1 × N1] + [2 × N2] + [3 × (N3 + N4)] / N, where N1–N4 represents the number of cells with 1–4 nuclei, respectively, and N is the total number of cells scored.

Chromosomal aberration assay; Microscope analysis was performed at ×1000 magnification on a light

microscope (Dialux 20, Leica, Germany). For each subject and glyphosate concentration, 200 complete complete metaphases (for a total of 1200 metaphases for each dose) were analyzed. Cells containing one of more types of CAs were scored as "aberrant cell" (Ab.C). In order to determine cytotoxicity, the mitotic index (MI) was calculated from the number of metaphases in 1000 cells analyzed per subject per concentration (a total of 6000 cells per concentration).

Statistical analysis; Comparison of mean values of the percentage of cells with MNi, MNC, CBPI, NPBs, NBUDs, CAs, Ab.C, and MI between exposure levels and controls was assessed by the nonparametric Mann-Whitney test. Statistical calculations were carried out using the SPSS software package program (version 24.0, Inc., Chicago, IL, USA). All P values were two-tailed, and P values of 5% or less were considered statistically significant for all tests carried out.

Results

Effect of glyphosate on CA formation; **Error! Reference source not found.** shows values of CAs found in the human peripheral lymphocytes cultured in the presence of different glyphosate concentrations. Glyphosate was found to induce the following structural CAs: gaps, chromatid and chromosome breaks, dicentric chromosomes, rings, tri-tetraradials, and acentric fragments. This last, together to chromatid breaks, represent the most frequent observed aberrations (Table below). Gaps were excluded from statistical analysis. Glyphosate was found to significantly increase the CA and Ab.C frequencies at all tested concentrations when compared with the solvent control, including the concentration of 0.025 µg/mL, but with the exception of 0.0125 µg/mL. A dose effect was also observed, since the regression analysis revealed a significant correlation between glyphosate concentrations and the CA and Ab.C frequencies (refer to **Error! Reference source not found.**). Vice versa, no significant differences were found between the DMSO solvent-control and the negative control, whereas the cultures treated with the MMC showed a significant increase of the cytogenetic damage with respect to all concentrations of glyphosate. Finally, no significant differences were found in the MI values between solvent control and all tested concentrations of glyphosate, although at 0.500 µg/mL, the P value resulted to be borderline.

Effect of glyphosate on MNi formation; **Error! Reference source not found.**shows the frequencies of MNi found in the human peripheral lymphocytes cultured in the presence of different glyphosate concentrations. Glyphosate significantly increased the MNi frequency at all tested concentrations when compared to the solvent control, with exception of 0.0125 µg/mL (Table 3). Vice versa, no effect has been observed on the frequencies of NBUD and NPB, with the only exception of 0.500 µg/mL of glyphosate that was found to increase in a significant manner the frequency of NPBs with respect to the solvent control. Also in this case, a relationship between the frequency of MNi and the concentrations of glyphosate was observed (Table 2), as well as the DMSO solvent-control cultures did not show significant differences with respect to the negative controls. MMC was found to significantly increase the MNi, NPB, and NBUD formation compared with the negative control solvent controls and all tested concentrations of glyphosate, with exception of 0.500 µg/mL. After 48-h exposure, a significant reduction of the CBPI value in cultures treated with glyphosate was not observed, indicating that, at the tested concentrations, glyphosate does not seem to produce effects on the proliferation index. Finally, at 0.500 µg/mL, glyphosate significantly induced the NPB formation, whereas no differences were found in the frequency of NBUD between DMSO solvent control and all glyphosate concentrations.

Table 5.4.3-34: Induction of micronuclei by Glyphosate in human lymphocytes in vitro. Number of scored binucleated cells for each concentration of the test substance = 12,000 (from: Santovino *et al*., 2018)

Discussion

Glyphosate is an active ingredient of most widely used herbicides. Although it is believed to be less toxic than other herbicides, data about its possible genotoxicity are controversial and IARC classified this compound as probably carcinogenic to human (IARC 2015). The genotoxic effects of high concentrations of glyphosate have been documented, although with contradictory results, in a great number of scientific papers, as well as in evaluation reports of different international agencies. On the other hand, the effects of low concentrations of this compound, likely to be encountered in everyday life, were poorly investigated. Results of our study provided information about in vitro clastogenic effects of glyphosate on human lymphocytes at the low ADI concentration of 0.500 µg/mL and its submultiples. Based on the obtained data, it can be concluded that glyphosate significantly increased the CA and MNi levels in human lymphocytes at the ADI concentration of 0.500 µg/mL established by EFSA and at its submultiple concentrations, up to 0.025 µg/mL. The mechanisms underlying genotoxic potential of glyphosate alone or in complex with other compounds are unknown, although the exposure to glyphosate was found to trigger oxidative processes involved in the increase of the genomic damage. NPB frequency was found to increase with increasing glyphosate concentrations, although a statistical significance was found only at the higher glyphosate concentration (Table 3). However, we obtained a significant linear regression (Table 2) due to a steady increase with the dose, indicating a possible effect of the compound inducing this kind of damage, which is consistent with the increased dicentric frequency observed in the chromosomal aberration test. Also, other authors analyzed in vitro the genotoxic potential of glyphosate in lymphocytes, but at exposure levels of higher magnitude orders. For example, in human lymphocytes cultured without S9 and in the presence of glyphosate at concentrations of 3.5, 92.8, and 580 µg/mL, the authors observed a slightly increased frequency of MNi and a significant tail length increase after a comet assay. Other authors evaluated the induction of CAs and MNi in blood cells of other animal models. Positive clastogenic and genotoxic effects of glyphosate on bovine peripheral lymphocytes cultured in vitro with herbicide concentrations ranging from 17 µM (2.874 µg/mL) to 170 µM (28.740 µg/mL) were reported, whereas another study reported no CAs effect of glyphosate at concentrations ranging from 28 (4.734 µg/mL) to 1120 µM (189 µg/mL). Contradictory results were obtained by a further study, in which observed, after 48 h of treatment without S9, a statistically significant increase in MNi frequency at 280 µM (47.34 µg/mL) but not at 560 µM (94.68 µg/mL) of glyphosate in one donor, and the opposite in a second donor (positive at 560 µM but not at 280 µM). Finally, another study in in vitro experiments based on comet assay, showed that 7 mM of glyphosate (1183 µg/mL) caused DNA damage in blood cells of Nile tilapia (Oreochromis niloticus). Concentrations of glyphosate similar to those evaluated in the present paper were tested in HepG2 cells by the MNi assay. Similarly to what we observed in human lymphocytes, these authors found

a significantly higher number of MNi at the ADI value of 0.500 µg/mL, as well as at the residential exposure level of 2.91 µg/mL, after 4 h of treatment. Vice versa, negative results on Hep-2 cells were obtained with CA assay at glyphosate concentrations of 0.20 mM (33.8 µg/mL), 1.20 mM (203 µg/mL), and 6.00 mM (1014 µg/mL). Significant levels of DNA damage were also observed in human buccal epithelial cells exposed to glyphosate concentrations ranging between 10 and 20 mg/L, whereas another study showed that, in peripheral blood mononuclear cells, glyphosate induces DNA damage in the concentration range from 0.5 mM (84.54 µg/mL) to 10 mM (1690 µg/mL), and a significant decrease of global DNA methylation at concentration of 0.25 mM (42.27 µg/mL). Interestingly, the same authors also observed a significantly increased methylation of p53 promoter at concentrations of 0.25 mM and 0.5 mM (42.27 and 84.54 µg/mL). This hypermethylation was found to be able to downregulate the p53 gene expression and to activate proto-oncogenes, with consequent genomic alterations and cancer risk. The possibility of glyphosate causing cancer promotion in skin cells and proliferation in breast cells has been also observed in vivo and in vitro studies by mouse and human models, respectively. In this scenario, the results obtained in the present study require attention. Indeed, increased CA and MNi frequencies in peripheral blood lymphocytes have been positively associated with increased cancer risk and early events in carcinogenesis, respectively. Moreover, it should be emphasized that, beyond the cases of intoxication where glyphosate content in blood was found to range from 0.6 to 150 µg/mL, in subjects who were indirectly exposed to this substance, glyphosate was found in blood at concentrations of 0.074 ± 0.028 µg/mL, a value about seven times lower with respect to the established ADI value, but in the range of concentrations we tested (from 0.5 to 0.0125 µg/mL). At the same time, the genotoxicity of a compound should not be evaluated only after single administrations in in vitro or in vivo systems, but also, and especially, after chronic administration of the same compound, even at lower quantities than those established by the competent agencies. In this sense, the clastogenicity we observed at concentrations of 0.100, 0.050, and 0.025 µg/mL represents an important signal, especially in view of a chronic exposure to these glyphosate concentration levels. Finally, no significant differences in CBPI and MI values were found between all tested concentrations and the solvent control, indicating that, at these concentrations, glyphosate does not influence in a significant manner the replicative capacity of the cells. These data differ from a study which observed a reduction of mitotic and proliferation indices in bovine lymphocytes, but at higher glyphosate concentrations (94.68 µg/mL and 189 µg/mL). Similarly, other authors described decreased levels of MI for other herbicides or insecticides, also in this case, at concentrations much higher than those tested in the present work.

Conclusion

In the present work, there was evidence for cytogenetic effects of glyphosate on cultured human lymphocytes. Despite the limitations of an in vitro study due to the reduced sample size, it is our opinion that the increased cytogenetic damage observed by our group at glyphosate concentrations equal and lower than the established ADI value requires further investigations in order to establish the effective genotoxicity threshold of this extensively used compound. Indeed, the glyphosate concentrations tested in the present work represent more realistic concentrations, likely to be encountered in everyday life, with respect to the higher doses evaluated in other published papers. In this scenario, in order to draw conclusions about the effects associated to the chronic exposure to low doses, in vitro studies are useful tools to investigate the dose response effects, the molecular mechanisms of action of different environmental xenobiotics, and their genotoxicity. This last, compared to other types of toxicity, may result in severe consequences that can be also inherited after long periods following exposure. The same DNA damage that occurs in a single cell, caused by low but chronic exposure to genotoxic compounds, can cause unexpected severe consequences in the long run.

5. Assessment and conclusion

Assessment and conclusion by applicant:

This paper describes human lymphocyte chromosome aberration and micronucleus tests with glyphosate. Although broadly compliant with OECD 473 and 487 there are some critical deficiencies which will have adversely influenced the reliability of the findings. Treatment with glyphosate was initiated 24 hours after lymphocyte cultures were stimulated to divide, instead of the recommended 48

hours, consequently the cultures would not have been asynchronous. This could mean cells in some stages of the cell cycle may have been under-represented, whilst others over-represented. Exposure to glyphosate was continuous for 28 hours in the chromosome aberration assay or 48 hours in the micronucleus assay. In contrast OECD test guidelines recommend maximum exposure of 1.5 cell cycles, equivalent to approximately 24 hours for lymphocyte cultures. For both endpoints the paper does not confirm if the slides were coded prior to analysis. The positive control has been compared statistically to the glyphosate treated cultures rather than the solvent controls.

The authors consider that glyphosate induces tri-tetraradial aberrations (amongst other aberration types) but fails to comment that the frequency of these aberrations observed at a single glyphosate concentration is 3-fold lower than the frequency observed in the solvent control cultures. Furthermore, it is unusual that the only multi-aberrant metaphases observed were a small number of positive control metaphases and gaps did not appear to increase with treatment but chromatid and chromosome breaks did.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate tested was not sufficiently characterized and although the genotoxicity tests conducted were in general in accordance with the OECD test guidelines, significant deficiencies were noted.

2. Full summary of the study according to OECD format

The toxic effects of glyphosate in vitro on HepG2 cells exposed for 4 and 24 h to low glyphosate concentrations likely to be encountered in occupational and residential exposures [the acceptable daily intake (ADI; 0.5 μg/mL), residential exposure level (REL; 2.91 μg/mL) and occupational exposure level (OEL; 3.5 μg/mL)] were studied. The assessments were performed using biomarkers of oxidative stress, CCK-8 colorimetric assay for cell proliferation, alkaline comet assay and cytokinesis-block micronucleus (CBMN) cytome assay. The results obtained indicated effects on cell proliferation, both at 4 and 24 h. The levels of primary DNA damage after 4-h exposure were lower in treated vs. control samples, but were not significantly changed after 24 h. Using the CBMN assay, a significantly higher number of MN and nuclear buds at ADI and REL after 4 h and a lower number of MN after 24 h were found. The obtained results revealed significant oxidative damage. Four-hour exposure resulted in significant decrease at ADI [lipid peroxidation and glutathione peroxidase (GSH-Px)] and OEL [lipid peroxidation and level of total antioxidant capacity (TAC)], and 24-h exposure in significant decrease at OEL (TAC and GSH-Px). No significant effects were observed for the level of reactive oxygen species (ROS) and glutathione (GSH) for both treatment, and for 24 h for lipid peroxidation. Taken together, the elevated levels of cytogenetic damage found by the CBMN assay and the mechanisms of primary DNA damage should be further clarified, considering that the comet assay results indicate possible cross-linking or DNA adduct formation.

Materials and Methods

Chemicals - Glyphosate was purchased as analytical standard purity grade (≤100 %) as Pestanal®, a registered trademark of Sigma-Aldrich Laborchemikalien GmbH, Germany.

Cell line - HepG2 cell line (ATCC® HB8065™) was purchased from the American Type Culture Collection (Rockville, MD, USA), cultivated in EMEM supplemented with 10 % foetal bovine serum

(FBS) and 1 % penicillin-streptomycin (10,000 U/mL) and maintained in a humidified atmosphere (95 % relative humidity) with 5 % CO_2 at 37 °C. Testing was performed when the duplication time has been established to be constant, and the passage step was more than 3 but less than 10 cell passages.

Treatment conditions - The cells in culture were exposed to glyphosate concentrations of 0.5 µg/mL, 2.91 µg/mL and 3.5 µg/mL in PBS corresponding with the systemic concentrations at the acceptable daily intake (ADI), the residential exposure level (REL) and the occupational exposure level (OEL). The calculation of the concentrations to be tested was based on the average male human body weight of 60 kg and the total volume of 36 L of extracellular liquid. HepG2 cells were grown until 80 % confluence, trypsinized and transferred in cell culture flasks for the micronucleus and comet assays and in 96 well plates for the cell proliferation assay and the determination of markers of oxidative stress. Prior to treatment, the culture medium was removed, cells were washed with PBS and fresh complete medium with glyphosate was added. Cells were treated for 4 or 24 hours at 37 °C in a humidified atmosphere (95 % relative humidity) with 5 % CO_2. Negative and positive controls were tested in parallel.

Cell proliferation assay - Proliferation of HepG2 cells after 4 and 24 hours of exposure to glyphosate was studied by means of the CCK-8 colorimetric assay, based on the use of Cell Counting Kit-8. This kit uses 2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfophenyl)-2H-tetrazolium, sodium salt (WST-8) that is bioreduced by cellular dehydrogenases to an orange formazan product, soluble in tissue culture medium in the presence of the electron carrier, 1-methoxy PMS. The amount of formazan produced is directly proportional to the number of living cells. At the end of treatment cells were washed with PBS and 10 µL of WST-8 solution added. After 4 and 24 hours of incubation at 37 °C in a CO_2 incubator, the optical density at 450 nm was determined for each well using a Victor3™ Multilabel Plate Reader. Data were expressed as a percentage absorbance compared to relevant negative controls. The positive control was 10 % DMSO in the complete nutrient medium. The experiment was done twice independently with 4 repeated measurements in each.

Alkaline comet assay - After 4 or 24 hours of treatment, cells were washed twice with PBS, detached by trypsinization, centrifuged and resuspended in complete EMEM. 7 µL of single cell suspension at 10^4 cells/mL was mixed with low melting point agarose and layered on slides. Duplicate slides were prepared for each time period and concentration together with negative and positive controls. Hydrogen peroxide was used as the positive control. Following preparation of all microgels, they were immersed in fresh cold lysis solution for 24 hours. Afterwards, slides were washed with bidistilled water and denatured in freshly prepared cold denaturation/electrophoresis buffer. After 20 min at 4 °C, cells were placed in the electrophoretic chamber and subjected to electrophoresis. Afterwards the slides were neutralized, dehydrated and stained with ethidium bromide (20 µg/mL) for image analysis with the fluorescent microscope Olympus BX51 (×200 magnification) using the Comet Assay IV software. A total of 100 nucleoids (50 per slide) were measured per each experimental point. The level of DNA damage was estimated based on tail intensity (TI), indicating %DNA in the comet tail. The experiment was performed once with two replicates that were compared, and if no statistically significant difference was found they were combined.

Cytochalasin B-blocked micronucleus cytome assay (CBMN cytome assay) - Cells were seeded at 10^4 cells/mL in complete EMEM medium. After 4 or 24 hours of treatment with glyphosate, cells were washed twice with PBS and fresh complete medium was added. At the 44th hour, cytochalasin B (3 µg/mL) was added and the cell cultures harvested 24 hours thereafter. The positive control, cyclophosphamide, was incubated simultaneously. After harvesting, the medium was discarded, and cells were washed twice with PBS, detached by trypsinization, rinsed and resuspended in complete EMEM medium. Cell suspensions in complete EMEM were centrifuged and the pellet resuspended in PBS, centrifuged and the pellet fixed and put on slides for staining with 2 % Giemsa stain and air-dried. The experiment was performed once with two replicates. Micronuclei (MNi), nucleoplasmic bridges (NPBs), nuclear buds (NBUDs) and apoptotic and necrotic cells were scored in binucleated (BN) cells. A total of 2000 BN cells per each experimental point were scored to determine the parameters of the CBMN Cytome assay.

Lipid peroxidation - Malondialdehyde (MDA), and endproduct of lipid peroxidation, was measured using the thiobarbituric acid reactive substance (TBARS) assay with some modification. 0.5 mL of sample was added to 0.5 mL of thiobarbituric-trichloroacetic acid (TBA-TCA) reagent and heated at 90 °C for 30 min and then cooled in an ice bath and centrifuged. Absorbances were measured with a microplate spectrophotometric system (Victor3™ Multilabel Plate Reader) at 530 nm. Two independent experiments were performed and each sample was measured in duplicate. The TBARS concentration in unknown samples was calculated using a standard curve constructed with 1,1,3,3- tetrametoxypropane (0.3–6.07 µM) and expressed as µM.

Total antioxidant capacity - Total antioxidant capacity (TAC) was investigated using the ferric-reducing ability of plasma (FRAP) assay, based on the reduction of Fe3+-TPTZ complex under acidic conditions. The FRAP assay used in this study was slightly modified. 100 µL of cell suspension (10^4 cells in total) was added to 1.0 mL of FRAP reagent. Absorbance was measured after 4 minutes of incubation at 593 nm using the FRAP working solution as a blank. Two independent experiments were performed and each sample was measured in duplicate. The results were calculated on a basis of a standard curve using $Fe_2SO_4 \cdot 7H_2O$ (0.05-4.0 mM).

ROS detection - The amount of intercellular reactive oxygen species (ROS) was measured using 2′,7′-dichlorodihydrofluorescein diacetate (DCFH-DA). DCFH-DA is deacetylated by cellular esterases to form a non-fluorescent compound which is then oxidized in the presence of hydroxyl, peroxyl and other ROS to the fluorescent 2′,7′-dichlorodihydrofluorescein (DCF). All measurements were performed in quadruplicate in dark-sided 96-well microplates in which each well was added 100 µL of cell suspension containing 10^4 cells. Cells were grown in the same medium and conditions as for the cell proliferation assay and treated with the same concentrations of glyphosate for 4 and 24 hours. After treatment the cells were washed with PBS and 100 µL of 50 µM DCFH-DA dye diluted in PBS was added and kept in contact with the cells for 30 minutes at 37 °C in a CO_2 incubator. The control for dye autofluorescence was prepared without addition of dye. Negative (non-treated) cell controls in EMEM were included in each experiment. The positive control was a solution of 100 mM H_2O_2. Measurements were made using a Victor3™ Multilabel Plate Reader at an excitation wavelength of 485 nm and an emission wavelength of 535 nm. Data were expressed as fluorescence arbitrary units (AUs) and later transformed into percentages compared to control values.

Quantification of glutathione - The fluorogenic bimane probe, monochlorobimane (MBCl), reacts specifically with glutathione (GSH) and forms a fluorescent product equal to the amount of GSH that can be measured fluorometrically. Cell cultures in 96-well plates were prepared with 100 µL of cell suspension containing 10^4 cells and each well was treated with glyphosate for 4 and 24 hours. After washing with PBS, cells were incubated with 100 µL of 50 µM MBCl in PBS for 20 minutes at 37 °C in a CO_2 incubator. Measurements were made using a Victor3™ Multilabel Plate Reader at an excitation wavelength of 355 nm and an emission wavelength of 460 nm. Negative cell controls were included in each experiment. Data were expressed as fluorescence AUs and later transformed into percentages compared to control values. All of the measurements were performed in quadruplicate.

Glutathione peroxidase activity - Glutathione peroxidase (GSH-Px) activity in HepG2 cells was measured according to the European standardized method. To increase assay sensitivity for the measurement of GSH-Px, samples were prediluted 60 times instead of a recommended 110-fold dilution as used for blood samples. The amount of glutathione oxidized by *t*-butyl hydroperoxide was determined by following the decrease in β-NADPH concentration at 340 nm. Two independent experiments were performed and each sample was measured in duplicate. One unit of GSH-Px was expressed as the amount of enzyme that oxidizes 1 µmol β-NADPH/min at 37 °C. Activity of GSH-Px was expressed in U/g total protein. The protein concentration of cell lysates was measured using a Total Protein Kit, Micro. Samples, standards and blanks were tested in triplicate, and absorbance was measured in 96-well plates at 570 nm**.**

Statistical analysis - Statistical analysis was performed using StatSoft Dell Statistica 13 package program. Descriptive statistics were used to determine the basic statistical parameters (mean, standard error and deviation, median and minimum and maximum values). Data gathered with the Comet Assay IV software

were logarithmically transformed prior to statistical evaluation, with the aim of normalizing distributions and equalizing variances. The intra- and intergroup comparisons between samples were performed using one-way analysis of variance (ANOVA) with post hoc Scheffé's test. Comparisons between values obtained with the CBMN Cytome assay and HepG2 proliferation kinetics measured with CBMN were made by Pearson's $\chi 2$ test for two-by-two contingency tables. For the biochemical and cell proliferation assays descriptive statistics and *t* test for comparisons between independent samples were used. The level of statistical significance was set at $p < 0.05$.

Results

Cell proliferation measured by the CCK-8 assay - Although without statistical significance a slight increase of cell proliferation was observed in HepG2 cells after a 4-hour treatment of about 9 % at the ADI and almost 8 % at the REL. The values recorded for the OEL-treated cells were not different from control. After 24 hours of treatment, HepG2 cells showed a not statistically significant increase in cell proliferation of 3 % at the REL and of 1 % at the OEL when compared to the control. Proliferation of ADI-treated cells did not differ from control.

Primary DNA damage measured by the alkaline comet assay - After 4 hours of exposure, the TI was statistically significantly decreased at all glyphosate concentrations. After 24 hours of exposure, the TI at ADI, OEL and REL were not statistically significantly different from control. Throughout comet measurements, apoptotic and necrotic nucleoids were also counted but there were no significant deviations from control.

Cytogenetic damage measured using CBMN cytome assay - After 4 hours of exposure, a not statistically significant increase in MN was found in HepG2 cells treated with glyphosate at all 3 concentrations. In HepG2 cells treated with glyphosate at ADI and REL, a statistically significant increase in nuclear buds (NBUD) frequency was observed. The incidence of nucleoplasmic bridges (NPB) was highest in cells treated with glyphosate at ADI (6 per 2000 BN cells). Only 2 apoptotic cells per 2000 cells were found in the sample treated with glyphosate at OEL. The nuclear division index (NDI) in glyphosate-treated cells was different from that of the control. In the OEL-treated sample, there were statistically significant changes in the distribution of M1–M4 cells and OEL treatment resulted with more cells in the M2 phase. The same effect was observed when ADI-treated and OEL-treated samples were compared, as well as when REL-treated and OEL-treated samples were compared. After 24 hours of exposure, a lower number of micronucleated BN cells and a lower frequency of BN MN was found at all 3 glyphosate concentrations when compared to the control. Also the frequency of BN NBUDS was statistically significantly lower at all 3 concentrations. Control and glyphosate-treated cells did not significantly differ in the number of NPBs. At ADI 7 and at REL 5 apoptotic cells per 2000 BN cells were found. There was no statistically significant difference in NDI values between glyphosate-treated samples and control. A slightly changed incidence of M2 and M3 cells was found in treated samples as compared to control.

Lipid peroxidation - After 4 hours of exposure, TBARS concentrations in samples treated with glyphosate at ADI and OEL were statistically significantly lower than control values. Treatment of HepG2 cells for 24 hours with glyphosate resulted in lower TBARS concentrations at REL, but the difference was not statistically significant.

GSH level - The level of GSH was not statistically significantly different from the control value for all concentrations and exposure times. After 4 hours of treatment, the ADI-treated sample showed a 4 % higher level of GSH than the control whereas REL and OEL-treated cells showed GSH levels similar to control values. The 24-hour ADI-treated sample had the lowest GSH concentration, which was 5 % lower than the levels measured in the control samples, and REL- and OEL-treated cells showed GSH levels similar to control values.

GSH-Px activity - GSH-Px activity was statistically significantly decreased in HepG2 cells exposed to glyphosate at the ADI concentration after 4 hours. After 24 hours of treatment, a statistically significant decrease in the GSH-Px activity was observed at the OEL concentration.

Discussion

The present study evaluated how low-dose exposure for 4 and 24 hours affected cytotoxic, genotoxic and biochemical parameters in the human hepatoma cell line HepG2. Glyphosate increased not statistically significantly cell proliferation in HepG2 cells after 4 and 24 hours of exposure. The effect was more pronounced after 4 hours (8–9 % as compared to control), than after 24 hours (3 % as compared to control). The results of this study have demonstrated that exposure to glyphosate for 4 hours led to a slightly increased cytogenetic damage in terms of MN. Despite the non-significant increase in MN frequencies at ADI and REL, significant increases in nuclear bud frequency were found after 4 hours of exposure. Since nuclear budding represents a mechanism of MN formation, these results indicate that even a low dose of glyphosate as the ADI influences the level of DNA damage and cell stability. After 24 hours of exposure, all of the treated cells showed a lower frequency of micronuclei, nuclear buds and nucleoplasmic bridges than the control. The results obtained suggest that glyphosate exerts the highest DNA-damaging potential after 48 or even after 72 hours of treatment. Considering that the shorter exposure lasted only 4 hours, while the total cell culture lasted for 72 hours before harvesting, there was an opportunity to better examine the effects of low-dose exposure on DNA damage. On the contrary, in the case of an exposure of 24 hours it seems that this effect only started to be slightly visible. Serum in the cell culture can mask the development of DNA damage observed in micronucleus assay results. This can be the explanation, why the standard time period used in this experiment did not demonstrate an effect, while in the comet assay the primary DNA damage demonstrated higher damage levels.

Conclusion

All cytogenetic, molecular and biochemical methods used in this study indicate that glyphosate applied at low concentrations, possesses a toxic potential towards HepG2 cells, which has to be further explained. It seems that the theory of different effects of low-dose vs. high-dose exposure, and more deleterious effects at low doses, is true. Although at ADI, REL and OEL, no drastically different levels of oxidative damage were seen, the elevated level of permanent DNA damage found with the micronucleus assay calls for concern, especially if leading to adduct formation, as shown by comet assay results. Based on the obtained results, it cannot be said without doubt whether glyphosate acts as an aneugen or a clastogen, but there are indications from previous studies that the aneugenic effect plays an important role in the formation of micronuclei. This study did not evaluate the effects of glyphosate on cytoskeleton and proteins, but this would be a direction for future evaluations of glyphosate toxicity, together with the clarification of its effects on cell membrane level, especially in different phases of the cell cycle.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The objective of this study was to examine the effects of acute exposure (4 and 24 hours) of human hepatoma HepG2 cells to glyphosate at concentrations equivalent to the systemic concentrations at the ADI, REL and OEL. The endpoints investigated in this study are cell proliferation, DNA damage, MN formation and oxidative stress. A non-statistically significant increase in cell proliferation was seen in the CCK-8 test with no dose-effect relationship. The comet assay showed a statistically significant decrease in tail intensity after 4 hours with no difference from control after 24 hours. In the CBMN cytome assay a non-statistically significant increase in BN MN frequency was seen after 4 hours without a dose-effect relationship. After 24 hours, a decrease instead of an increase in BN MN frequency was reported. The nuclear bud frequency was statistically significantly elevated after 4 hours of exposure but was statistically significantly lower than control after 24 hours of exposure. The indicator tests for oxidative stress did not show a substance related effect.

Overall, the results of the study do not indicate a genotoxic potential of glyphosate. The lack of statistical significance, reproducible effects as well as the fact that the control values in the Comet assay and micronucleus assay seem to be highly variable limit the reliability of the study.

This publication is considered relevant but reliable with restrictions because the cytogenetic damage

found *in vitro* at a systemic concentration corresponding with the ADI (0.5 µg/mL which should have been 0.17 µg/mL) was not confirmed in *in vivo* regulatory MN studies with doses up to 2000 mg/kg bw corresponding with a systemic concentration of about 50 µg/mL.

2. Full summary of the study according to OECD format

The purpose of this study was to assess DNA damage (determination of single and double strand-breaks by the comet assay) as well as to evaluate DNA methylation (global DNA methylation and methylation of p16 (CDKN2A) and p53 (TP53) promoter regions) in human peripheral blood mononuclear cells (PBMCs) exposed to glyphosate. PBMCs were incubated with the compound studied at concentrations ranging from 0.1 to 10 mM for 24 h. The study has shown that glyphosate induced DNA lesions, which were effectively repaired. However, PBMCs were unable to repair completely DNA damage induced by glyphosate. A decrease in global DNA methylation level at 0.25 mM of glyphosate was also observed. Glyphosate at 0.25 mM and 0.5 mM increased p53 promoter methylation, while it did not induce statistically significant changes in methylation of p16 promoter. To sum up, it was shown for the first time that glyphosate (at high concentrations from 0.5 to 10 mM) may induce DNA damage in leucocytes such as PBMCs and cause DNA methylation in human cells.

Materials and methods

Chemicals – Glyphosate (95 % purity) commercially obtained from Sigma-Aldrich, USA.

Isolation of PBMCs - PBMCs were isolated from leucocyte-buffy coat from blood collected from 9 healthy volunteers (aged 18-55 years) with no symptoms of infectious disease. For each parameter, 3 leucocyte-buffy coats were taken from 3 blood donors. After dilution with PBS (1:4) PBMCs were isolated from the

buffy coat by centrifugation using lymphocyte separation medium (LSM). The PBMCs were collected, suspended in erythrocyte lysis buffer and incubated. Afterwards PBS was added and the cells centrifuged. The supernatant was decanted and the cells were washed twice with RPMI with L-glutamine and 10 % fetal bovine serum (FBS). The cells were resuspended in RPMI medium with L-glutamine, 10 % FBS and penicillin-streptomycin (0.5 %) and counted in the hemocytometer. The final PBMCs density used in the experiments after addition of glyphosate was $1x10^6$ cells/mL. After incubation, PBMCs were diluted to a density of 5 x 10^4 cells/mL for the comet assay and condensed to a density of 5 x 10^6 cells/mL for the conduct of epigenetic methods. The viability of the cells was over 94 %.

Treatment of PBMCs - Glyphosate was dissolved in PBS and the final concentrations of glyphosate in the comet assay were in the range of 0.25 to 10 mM, while epigenetic changes were assessed after exposure to glyphosate at 0.25 and 0.5 mM. For the determination of DNA damage the cells were incubated with glyphosate for 24 hours and repair of the DNA lesions was assessed after a recovery period of 120 minutes following incubation. In the comet assay, 0.25 mM was chosen as the lowest concentration of glyphosate which produced any statistically significant changes in DNA damage. Epigenetic changes were assessed at 0.25 mM which did not induce DNA damage and at 0.5 mM which induced statistically significant DNA damage. For the assessment of cell viability PBMCs were incubated for 24 hours with different concentrations of glyphosate. Afterwards, the cells were centrifuged and the test solution discarded. The cells were then resuspended in RPMI medium and incubated for an additional 2 hours. Cell viability was 90.0 %, 90.2 %, 90.4 %, 88.5 %, and 87.8 % for control, 0.5, 5, 7.5 and 10 mM of glyphosate, respectively. Each DNA damage experiment included hydrogen peroxide as the positive control.

Alkaline comet assay - The comet assay was performed under alkaline conditions with some modifications. A freshly prepared cell suspension in 0.75 % low melting point agarose dissolved in PBS was layered onto microscope slides pre-coated with 0.5 % normal melting point agarose. The cells were lysed for 1 hour at 4 ºC in an alkaline buffer and DNA was allowed to unwind for 20 minutes in an alkaline solution. Electrophoretic separation was performed in an alkaline solution at 4 ºC for 20 minutes at an electric field strength of 0.73 V/cm (28 mA). Then, the slides were washed in water and stained with 2 mg/mL 4',6-diamidino-2-phenylindole (DAPI) and covered with cover slips. The comets were observed at 200 x magnification in an Eclipse fluorescence microscope. Fifty images (comets) were randomly selected from each sample and the mean value of DNA in the comet tail was taken as an index of DNA damage (expressed in percent). For one blood donor, 3 parallel tests with aliquots of the sample of the cells were performed for a total number of 150 comets. A total number of 450 comets from 3 blood donors was recorded to calculate mean ± SEM.

DNA repair - The control samples and the PBMCs treated with glyphosate at 0.5, 5, 7.5 and 10 mM were washed and resuspended in fresh RPMI 1640 medium with L-glutamine preheated to 37 ^{0}C. Aliquots of the suspension were taken immediately after incubation at time "zero" and 120 minutes later. The samples were placed in an ice bath to stop DNA repair. The repair was assessed as a decrease in the extent of DNA damage measured after 120 minutes of post-incubation using the alkaline version of the comet assay.

Methylation of p16 (CDKN2A) and p53 (TP53) promoter regions - Chemical modification of 500 ng of genomic DNA was performed with the Cells-to-CpG™ Bisulfite Conversion Kit. For methylation analysis, a quantitative methylation-specific real-time PCR assay (qMSP) was conducted in 3 independent experiments including 3 blood donors with FastStart SYBR Green Master. All samples were amplified in triplicate. To determine the methylation status of a particular gene expressed as the methylation index (MI) in percentage, the Ct values of the methylated gene of interest were compared with the Ct values of the unmethylated gene of interest.

Global DNA methylation - Global DNA methylation was determined by means of DNA quantification using 5-methyl cytosine (5-mC) monoclonal antibodies in an ELISA-like reaction using the Methylflash Methylated DNA Quantification Kit. DNA (100 ng) isolated from whole blood PBMCs was used for analysis. Each sample was analyzed in duplicate and the determination was repeated whenever there was a failure in detection. The calculation of the amount of 5-mC was done with the use of a standard curve.

Methylation levels were calculated relative to the methylated control DNA and expressed as a percentage of methylated DNA.

Statistical analysis - The mean value was calculated for three independent experiments (3 blood donors), whereas for each individual an experimental point was a mean value of at least 2 (methylation analysis) or 3 replications. Statistical analysis was conducted using the Mann-Whitney test, the Student's t-test and one-way analysis of variance (ANOVA) with a post hoc multiple comparisons procedure. The differences were considered to be statistically significant when $p<0.05$.Data analysis was performed using STATISTICA software.

Results

Analysis of DNA strand-breaks and DNA repair - DNA damage (single and double strand-breaks and alkali-labile sites formation) was statistically significantly increased from a glyphosate concentration of 0.5 mM on. At 10 mM the statistically significant increase in DNA damage exceeded 13 times the control value. After 120 minutes of recovery significant repair was observed of the DNA lesions induced by glyphosate (5.61 % vs 2.93 %, 10.51 % vs 5.07 %, , 14.91 % vs 7.76 %, and 27.49 % vs 11.05 % at 0.5 mM, 5 mM, 7.5 mM, and 10 mM of glyphosate, respectively.

DNA methylation status - As compared to control cells, the percentage of the global DNA methylation level was statistically significantly decreased by glyphosate at 0.25 mM, but not at 0.5 mM. On the contrary, p53 promoter methylation was statistically significantly increased at both concentrations of glyphosate. Methylation of the p16 gene promotor was increased after treatment with glyphosate but this change was not statistically significant.

Discussion and Conclusions

This study revealed that glyphosate decreased global DNA methylation in PBMCs statistically significantly at a concentration of 0.25 mM. Surprisingly, the effect of glyphosate at 0.5 mM on global DNA methylation was not statistically significant although the mean value from three independent experiments was still decreased as compared to control. Along with the decreased global DNA methylation, a statistically significant increase in methylation of the p53 promoter region was observed at 0.25 and 0.5 mM. Altered p53 promoter hypermethylation is an epigenetic pattern frequently observed in human cancers. Thus, the results of this study suggest that glyphosate at high concentrations (≥ 0.25 mM) may cause a down-regulation of p53 gene expression and activate proto-oncogenes or retrotransposable sequences which may induce genomic alterations by insertion and/or homologous recombination. This study showed for the first time that glyphosate may induce DNA damage in human leucocytes and cause epigenetic alterations in animal cells.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:

It was the objective of this study to investigate the effect of high glyphosate concentrations on DNA integrity and DNA methylation in PBMCs *in vitro*. It was demonstrated that glyphosate increased statistically significantly DNA damage (single and double strand-breaks and alkali-labile sites formation) from 0.5 mM up to 10 mM. Repair of the DNA lesions was significant at all concentrations tested after 120 minutes of recovery. The percentage of the global DNA methylation level was statistically significantly decreased by glyphosate at 0.25 mM but not at 0.5 mM. On the contrary, p53 promoter region methylation was statistically significantly increased as compared to control cells at 0.25 and 0.5 mM.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the lowest concentration at which DNA damage was observed (0.5 mM) is higher than the blood concentrations in rats (0.3 mM) obtained after dosing at the limit dose of 2000 mg/kg bw where no MN effects were seen.

2. Full summary of the study according to OECD format

A study was realized to ascertain whether glyphosate and other selected pesticides would induce double strand breaks (DSB) in lymphocyte cultures and whether this damage would induce greater levels of proteins Rad51 participating in homologous recombination or of p-Ku80 participating in nonhomologous end joining. Only five pesticides were found to induce DSB of which only glyphosate and another one pesticide induced a significant increase of p-Ku80 protein, indicating that nonhomologous end joining recombinational DNA repair system would be activated. The type of gamma-H2AX foci observed was comparable to that induced by etoposide at similar concentrations. These results are of importance since these effects occurred at low concentrations in the micromolar range, in acute treatments to the cells. Effects over longer exposures in actual environmental settings are expected to produce cumulative damage if repeated events of recombination take place over time.

Materials and Methods

Chemicals - Endosulfan, glyphosate, pentachlorophenol, permethrin, propoxur, paraoxon, AMPA (glyphosate metabolite), endosulfan lactone (endosulfan metabolite), and etoposide (positive control) were obtained from Sigma-Aldrich, Mexico. Purity was not reported.

Evaluation of DNA double strand breaks (DSB)- Three mL of blood were obtained from fully informed healthy young male donors of 21 to 35 years old. The volunteers were nonsmokers, did not consume alcohol and had not taken medication or were not subjected to radiation for medical purposes. The concentrations of glyphosate tested were 0, 0.4, 2, 10, and 50 µM, and those of AMPA were 0, 40, 200, 1,000 and 5,000 µM. Whole blood was diluted in RPMI-1640 medium and treated with the test compound 1.5 hours at 37 ºC, after which 0.075M KCl was added and the incubation continued for 30 minutes. Lymphocytes were recovered by centrifugation and formaldehyde added to reach a final concentration of 4 %. Then PBS and Triton X-100 were added followed by an incubation of 30 minutes. Thereafter the cells were washed, supplemented with 4 % fetal bovine serum and isolated by centrifugation and 1mL of cold 50 % methanol added. After one night at −20 ºC the samples were centrifuged at 0 ºC, and cold methanol added to the cells which were kept at −20ºC until analysis. Treatments were done in duplicate. DNA double strand breaks were detected by means of immunofluorescence of phosphorylated histone H2AX foci. Staining of lymphocyte nuclei was done as follows: the slides were washed and blocked with KCMT buffer for 1 hour at room temperature. Primary antiphospho-histone H2AX (Ser139) in blocking solution was added and left to incubate overnight followed by washes with KCMT buffer. Then the cells were incubated with the

secondary antibody Alexa-Fluor 555 goat anti-mouse for 1 hour at room temperature. The slides rinsed in deionized water before mounting in DAPI mounting medium and subsequently analyzed for γ-H2AX foci under a fluorescence microscope. Evaluation of foci was done in 2 slides per concentration and 50 cells were evaluated in 3 different regions per slide. In total, 300 cells were evaluated per treatment. When a nucleus presented one or more foci, it was considered positive. The extent of DNA damage was classified in 3 categories: percentage of cells without γ-H2AX foci (no DNA damage), with less than 10 γ-H2AX foci (moderate DNA damage) and with more than 10 γ-H2AX foci (severe DNA damage). Additionally, the damage was expressed as mean percentage of γ-H2AX positive nuclei.

Cytotoxicity - Cytotoxicity was tested using The CellTiter 96 AQueous One Solution Reagent from PROMEGA and following the manufacturer's instructions. Mononuclear cells were isolated from blood using Histopaque-1077. The cells were plated in well plates at 100,000 cells per well, and treated with the test compounds in triplicate for each concentration. Absorbance at 490 nm was recorded using a 96-well plate reader. The percentage of survival was calculated as (Absorbance at 490 nm of treatment/Absorbance at 490 nm of the negative control) × 100.

Western blot analysis of proteins participating in DNA recombination - Mononuclear cells were isolated with Histopaque-1077 and treatments were applied to cells resuspended in RPMI-1640 at 500,000 cells per tube. Glyphosate was tested in duplicate at 1.25, 2.5, and 5 µM. The cells were then centrifuged, the supernatant discarded and 0.5 M sodium azide added. After centrifugation, the cell pellets were kept at −70 ºC until used for Western blot analysis. Two separate experiments were performed per test compound, with two donors each time. RIPA lysis buffer solution containing phosphatase and protease inhibitors was added to each cell pellet. The samples were then sonicated, incubated in ice, and centrifuged. The supernatant was recovered and 5 µL of each sample was placed in a 96-well plate for protein quantification. The Lowry assay was performed with the DC Protein Assay kit and the concentration determined in a plate reader at 750 nm. The samples were then stored at −70∘C until use.
For the determination of phosphorylated Ku80 (phospho-T714) and Rad51 by Western blotting 35 µg of total protein was separated in a 10 % SDS-polyacrylamide gel and transferred to a nitrocellulose membrane with a Trans-Blot SD Semi-Dry Transfer Cell. After incubation with blocking solution and rinsing the appropriate membrane zones were isolated and incubated with rabbit anti-Rad51 polyclonal antibody or rabbit anti- phosphorylated Ku80 (phosphoT714) polyclonal antibody (p-Ku80). Incubation with primary goat anti-Actin polyclonal antibody was done for the determination of β-actin as the internal control. The membranes were then rinsed and incubated with secondary antibody goat anti-rabbit IgG-HRP for Rad51 and p-Ku80 detection and donkey anti-goat IgG-HRP for actin detection. After rinsing the protein fractions were quantified with a luminescence kit. Optical densities were measured with Quantity One software, version 4.1.1. The values obtained for each protein (Rad51 or p-Ku80) were normalized with respect to β-actin and the mean of the normalized negative controls. Results are presented as the % with respect to normalized negative controls. Two membranes were prepared per separate experiment with each test compound .

Statistical Analysis - Statistical calculations were made with the GraphPad Prism 6 software package and the results for γ-H2AX foci and optical density from Western blot analysis were evaluated with the Kruskal-Wallis test and Dunn's multiple comparison as a post hoc test. The value of etoposide as a positive control at the concentration of 50 µM was analyzed with the Mann-Whitney *U* test with respect to the negative control. Cytotoxicity was analyzed with linear regressions. The results were considered statistically significant if $p<0.05$.

Results

Identification of DNA double strand breaks(DSB) - For glyphosate, the mean of the % cells with more than 10 γ-H2AX foci was 0.33, 1.67, 9.33, 8.83, and 3.17 for 0, 0.4, 2, 10, and 50 µM (linear regression, $R^2 = 0.2$, $p = 0.02$). No effect was seen with AMPA. The positive control, etoposide, showed a significant correlation with dose (, $R^2 = 0.82$, $p < 0.0001$) for cells with more than 10 foci.

Cytotoxicity - The concentrations used for the determination of DSB were also used to assess the

cytotoxicity of the test compounds that produced DSB. The survival range for glyphosate was 100 % to 70 % viability for concentrations ranging from 1.25 to 5 µM.

Quantification of p-Ku80 and Rad51 Proteins
The test compounds that showed positive for DSB were further tested to determine whether DNA recombination would be induced. Glyphosate was found to induce statistically significantly p-Ku80 protein in a dose-dependent manner, whereas Rad51 was not significantly affected. Etoposide consistently induced p-Ku80, although with a wide variation between tests at 10 µM.

Discussion and Conclusions
Pesticides amongst which glyphosate were evaluated for their capacity to induce DNA double strand breaks, a lesion related to the formation of chromosomal rearrangements and leukemia risk. Glyphosate exhibited an ability to induce this kind of DNA damage in the form of phosphorylated γ-H2AX foci in the nuclei of human lymphocytes in at least two of the concentrations tested. AMPA tested negative. It is noticeable that the positive control, etoposide, induced more than 85 % of cells with more than 10 foci at 50 *µ*M although it induced foci in a manner comparable to glyphosate at lower concentrations. This extent of DNA damage seems to be of relevance to the increase of repair proteins like p-Ku80, since glyphosate also produced a significant increase in this protein, whereas the rest of the test compounds that induced a lower percentage of cells with γ-H2AX foci did not. To evaluate proteins participating in DNA recombination, the highest concentration of glyphosate used was 5 µM to avoid cytotoxicity. Exposure of cells in a non-proliferative state to glyphosate not only induced the breakage of DNA, but also the phosphorylation of Ku80, a protein that participates in the c-NHEJ repair pathway. This pathway is known for being prone to error, introducing micro deletions or micro insertions, which could be mutagenic and alter cell behavior if they occur in coding or regulatory sequences. This is one possible outcome of the DSB in non-proliferating cells. Etoposide, the positive control, is well known as a topo II inhibitor capable of producing complex DSB. The DNA damage induced by etoposide in this study was comparable to the damage induced by paraoxon and glyphosate (DSB and pKu80 induction), so the question emerging from these results is whether the outcome for cells damaged by glyphosate would be similar to the outcome of cells damaged by etoposide and whether they would also induce chromosomal rearrangements.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The objective of this study was to assess whether glyphosate and its metabolite AMPA produced DNA double strand breaks in human peripheral lymphocytes and whether proteins involved in DNA repair were induced. The results show that glyphosate, but not AMPA, increased the mean of the percent cells with more than 10 γ-H2AX foci, however, without a clear dose-effect relationship. Glyphosate was found to induce statistically significantly a protein involved in DNA repair, p-Ku80, at 5 µM without a dose-effect relationship (when measured as median OD).

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because glyphosate as a test chemical was not sufficiently characterized and the effect found on an indicator of DNA double strand breaks was not concentration related and occurred at concentrations that were much lower than the systemic concentrations (approx. 300 µM) of regulatory *in vivo* MN tests at 2000 mg/kg bw which were negative.

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

he DNA damage and cytotoxicity of various glyphosate concentrations on human cells was studied to evaluate DNA damaging potential. Utilizing human Raji cells, DNA damage was quantified using the comet assay, while cytotoxicity was further analyzed using MTT viability assays. Several glyphosate concentrations were assessed, ranging from 15 mM to 0.1 μM. It was found that glyphosate treatment is lethal to Raji cells at concentrations above 10 mM, yet has no cytotoxic effects at concentrations at or below 100 μM. Treatment concentrations of 1 mM and 5 mM induce statistically significant DNA damage to Raji cells following 30-60 min of treatment, however, cells show a slow recovery from initial damage and cell viability is unaffected after 2 h. At these same concentrations, cells treated with additional compound did not recover and maintained high levels of DNA damage. While the cytotoxicity of glyphosate appears to be minimal for physiologically relevant concentrations, the compound has a definitive cytotoxic nature in human cells at high concentrations.

Materials and Methods

Chemicals and reagents - Glyphosate (95 % w/w purity) was obtained from Sigma-Aldrich, Inc. (Milwaukee, WI).

Cell culture - Burkitt's Lymphoma (Raji) cells (ATCC CCL-86) were obtained from American Type Culture Collection (ATCC) and cultured according to ATCC recommendations. Cells were cultured in RPMI 1640 and supplemented with 10 % FBS and 2 mM L-glutamine. Media were replaced every 48 hours and the cells used for testing were placed in exponential growth with a minimum viability of 95 %. Raji cells were selected for this study because the replication time is 18 hours allowing the assays to cover the entire cell cycle.

Cell viability assay - For use in the MTT viability assay, glyphosate was diluted in cell culture RPMI media to the final test concentrations and stored at 4° C. Glyphosate stock solutions were diluted in RPMI media to their final test concentrations. Raji cells were incubated for 24 hours in a 96-well plate at 37° C and 5 % CO2. Afterwards, MTT reagent was added to each well. Following 3 hours of incubation, 100 μL of DMSO detergent was added to each well and incubated for 2 hours at 4 oC, and cytotoxicity evaluated at 570 nm absorbance.

Alkaline comet assay - Raji cells were incubated with either hydrogen peroxide as the positive control, PBS as the negative control, or glyphosate. The concentration and time points varied depending on the experimental run. The time intervals tested included 10, 20, 30, 40, 50, 60, 75, 90, 105, and 120 minutes. The concentrations of glyphosate used at each of the time points were 0.1, 1, 10, and 100 μM, and 1, 5, 10, and 15 mM. 200,000 cells per 100 μL were incubated with positive and negative controls and several concentrations of glyphosate at 37 ºC. Once treated, the cells were washed with PBS and suspended at 200,000 cells per 100 μL of PBS for the conduct of the comet assay. The test samples were mixed with

low melting point agarose and layered on double frosted microscope slides and placed in alkaline lysis buffer for 60 minutes, rinsed with purified water and then placed in alkaline electrophoresis buffer for 20 minutes and submitted to electrophoresis. After fixation and drying, the slides were stained with propidium iodide and imaged using a Zeiss Axioscope fluorescence microscope. All comets were scored using TriTek CometScore Freeware v1.5. Every experimental run tested a single concentration for multiple time points. Each time point contained a minimum of two slides as replicas. Approximately 50 comets were analyzed per slide, totaling 100 comets per time point and per treatment concentration. Each concentration was replicated multiple times to ensure consistency. Comet assay results are reported as tail moment which is defined as the product of the tail length and the percentage of DNA in the tail. A similar protocol was followed to test the effects of secondary glyphosate exposure at 1 mM and 5 mM by adding 200 µL glyphosate solution to the cells after 60 minutes of initial treatment, while 200 µL of PBS was added to the negative control.

Statistical analysis - Relationships between exposure time and tail moment were modeled statistically using a natural spline to account for nonlinearity. The number of knots was selected based on Akaike Information Criteria (AIC) and parameters were estimated using least squares. P-values of <0.05 were considered statistically significant.

Results

MTT analysis of Raji cells exposed to various glyphosate concentrations for 24 hours indicated a significant loss of cell viability at 10 and 15 mM. Glyphosate concentrations of 5 mM and lower did not have a significant effect on viability when compared to the negative control.

Comet assay analysis of Raji cells exposed to 10 and 15 mM glyphosate indicated severe DNA damage and cell death soon after exposure. Within 30 min of treatment, all cells had adopted an apoptotic profile which is characterized by a loss of a defined comet head and a large, fragmented DNA tail. Tail moments were significant after just 10 minutes of glyphosate exposure. Raji cells exposed to glyphosate concentrations of 1 and 5 mM produced statistically significant DNA damage after 40 minutes of treatment. Tail moments reached a maximum after 60 and 80 minutes of treatment at 5 mM and 1 mM, respectively. A steady decrease in tail moment was observed in later time points and the cells were able to recover to full viability after 120 minutes of treatment. Cells exposed to 10 and 100 µM of glyphosate did not show statistically significant DNA damage, and the cells retained full viability throughout 120 minutes of treatment. Raji cells exposed to physiologically relevant concentrations of glyphosate for 120 minutes did not experience any significant DNA damage. Following treatment with 10 µM glyphosate, Raji cells showed no signs of DNA damage and the 'head' of the cells stayed intact throughout the 2-hour exposure time. To further investigate the comet results at 1 and 5 mM, cells were treated again with glyphosate at these concentrations one hour after initial treatment. A significant difference could be observed between cells receiving only primary treatment and cells receiving the additional treatment. Raji cells exposed twice to glyphosate did not show the same pattern of recovery, with tail moments reaching levels above 20 for 1 mM and 25 for 5 mM. Cells with only primary exposure to glyphosate showed a decrease in DNA damage, with tail moments dropping from 15 to 5.8 for 1 mM and 23.67 to 6.74 for 5 mM.

Discussion

The results show that the DNA damaging and cytotoxic potential of glyphosate is related to exposure length and treatment concentration. Glyphosate only induced significant DNA damage at concentrations several orders of magnitude larger than those attainable *in vivo*. The data support the established evidence that glyphosate is not genotoxic in human cells at physiologically relevant concentrations. While these data ultimately support glyphosate's classification as a potential carcinogen, they suggest that its effects are negligible when exposure is minimal. Furthermore, study results obtained at 1 mM and 5 mM suggest that cells initially damaged by glyphosate may have the ability to repair and regain viability after single exposure. The results show also that the extent of DNA damage changed drastically across different incubation time points. For example, incubation at 1 mM for one hour produced severe DNA damage whereas no DNA damage was evident after 2 hours at the same concentration. If cells had only been evaluated at this time point, results would suggest that there was no cytotoxic activity and the initial DNA

damaging event would be missed. Cytotoxic activity might also be underestimated by standard viability assays in which the DNA damage is insufficient to induce cell death. Considering multiple time points made it possible to observe both DNA damage as well as the ensuing recovery.

Conclusion
Exposure of human cells to glyphosate produces minimal cytotoxicity and DNA damage at concentrations at or above 1 mM.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The purpose of this study was to investigate the concentration and time dependent DNA damaging potential of glyphosate in Burkitt's B Cell Lymphoma (Raji) cells using the comet assay and MTT viability assay. The cells were exposed to glyphosate concentrations ranging from 0.1 µM to 15 mM and resulting DNA damage and loss of cell viability were measured after various lengths of exposure. DNA damage could only be observed at 1mM and higher which are concentrations that cannot be attained in vivo. The DNA damage seen at 1 and 5 mM reached its maximum between 60 and 80 minutes of incubation which returned to control values thereafter. To reach 1 mM of systemic concentration *in vivo* experimental animals have to be treated orally with glyphosate at dose levels that are much higher than those used in long term carcinogenicity studies which showed no carcinogenic effect of glyphosate.

This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions because it complies with most of the reliability criteria for *in vitro* testing although no historical control data were reported. The significance for the risk assessment of glyphosate is limited because DNA damage has only been demonstrated at concentrations of glyphosate that cannot be attained in *in vivo* test systems.

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

Abstract
The photo-inducible cytogenetic toxicity of glyphosate, aminomethyl phosphoric acid (AMPA), and their various mixtures was assessed by the in vitro micronucleus assay on CHO-K1 cells. Results demonstrated that the cytogenetic potentials of pesticides greatly depended on their physico-chemical environment. The mixture made with the four pesticides exhibited the most potent cytogenetic toxicity, which was 20-fold higher than those of the most active compound AMPA, and 100-fold increased after light-irradiation. Intracellular ROS assessment suggested the involvement of oxidative stress in the genotoxic impact of pesticides and pesticide mixtures.

Materials and methods
Chemicals - Glyphosate and AMPA were purchased from Sigma-Aldrich Chemical Company, St Quentin-

Fallavier, France.

Cell culture - Experiments were performed in CHO-K1 cells (ATCC-LGC Standards Sarl, Molsheim, France). CHO-K1 cells were maintained in McCoy's 5A medium supplemented with 10 % bovine calf serum, 1 mM glutamine, and 100 U/mL-10 µg/mL penicillin-streptomycin. Cells were incubated at 37 °C in a humidified atmosphere containing 5 % CO_2.

Metabolic activation mixture (S9-mix) - The metabolic activation system used was a 9000g centrifuged supernatant (S9) of a 10 % liver homogenate prepared from male Sprague-Dawley rats treated with a single injection of Aroclor 1254 (500 mg/kg bw), 5 days before sacrifice. The protein concentration in the S9 homogenate was 26 mg/mL. For the micronucleus assay, the S9-mix contained 10 % S9, 5 mM glucose-6-phosphate, 4 mM NADP, 33 mM KCl and 8 mM $MgCl_2$ diluted in PBS.

Photoactivation - To reproduce photoinduction during exposure to glyphosate and AMPA in the environment, the micronucleus assay was performed with a photoactivation procedure. Irradiation of cell cultures was carried out 1 hour after the addition of test compound using a solar simulator Suntest CPS+ apparatus equipped with a xenon arc lamp (1,100 W), a special glass filter restricting transmission of light below 290 nm and a near IR-blocking filter. The irradiance for the photoactivation was fixed at 750 W/m^2 throughout testing. The combined light dose was 4.5 J/cm^2 for one minute irradiation (0.03 J/cm^2 of UVB, 0.41 J/cm^2 of UVA and 4.06 J/cm^2 of visible light). This irradiation dose is representative of a 1-3 minute period of solar exposure during a clear summer day in the United Kingdom. The temperature of the samples was kept at 4 °C. UVA-visible light (320-800 nm) was obtained using the solar ID65 filter plus a window glass filter.

Micronucleus assay - A total of 50,000 CHO-K1 cells was plated in chamber slides and incubated for 24 hours at 37 °C in a humidified atmosphere containing 5 % CO_2. Various concentrations of glyphosate (5, 10, 50, and 100 µg/mL) and AMPA (0.005, 0.01, 0.05, and 0.1 µg/mL without S9-mix; 0.1, 0.5, 1, and 5 µg/mL with S9-mix; 0.00005, 0.0001, 0.0005, and 0.001 µg/mL with light irradiation) were incorporated into duplicate CHO-K1 cell cultures. To determine the background DNA-damage levels in CHO cells in the dark and with light irradiation 2 negative controls were added for glyphosate and AMPA: culture medium and PBS. Mitomycine C (0.06 µg/mL) without S9-mix and benzo[a]pyrene (5 µg/mL) with S9-mix were selected as positive controls. After 3 hours of exposure, cells were rinsed with PBS and incubated in fresh medium containing cytochalasin B (3 µg/mL) for an additional 24 hours to stop cytokinesis. At the end of the incubation period, cells were rinsed twice with PBS and fixed with methanol. The slides were air dried and stained with 5 % Giemsa stain in Milli-Q water for 15 minutes. The Cytokinesis Blocked Proliferation Index (CBPI) was used to select adequate concentrations for the assessment of micronuclei. CBPI was determined by scoring the number of mononucleated (M1), binucleated (M2), and trinucleated (M3) cells among 500 Giemsa-stained cells with well-preserved cytoplasm: CBPI = [(M1) + (2 x M2) + (3 x M3)]/500. When a cytotoxic effect was observed, micronucleated cell rates were determined for concentrations inducing less than a 50 % decrease of CBPI. When no cytotoxic effect was observed, the maximal concentration assessed was 100 µg/mL. When a clastogenic/aneugenic activity was observed, 4 relevant concentrations were selected to obtain a dose-response relationship. A total of 2000 binucleated cells were examined for each concentration, and micronuclei were identified according to the morphological criteria previously defined.

Intracellular ROS analysis - Intracellular ROS was determined with the cell-based OxiSelect™ Intracellular ROS Assay Kit using 2',7'-dichlorodihydrofluorescein diacetate (DCFH-DA). After diffusion into the cell, this fluorescent probe is deacetylated by cellular esterases to non-fluorescent 2',7'-dichlorodihydrofluorescein (DCFH), which is rapidly oxidized to the highly fluorescent 2',7'-dichlorofluorescein (DCF) by ROS. A total of 50,000 cells were seeded in a black 96-well cell culture plate and incubated at 37 °C for 24 hours. Cells were rinsed 3 times with PBS and incubated in 100 µL of DCFH-DA/media solution at 37 °C for 60 minutes. Cells were subsequently rinsed with PBS and treated with glyphosate or AMPA. Experiments were performed in triplicate. The concentrations tested were the same as those assessed for the micronucleus assay. H_2O_2 (100 µM) was used as the positive control. After a 30-

minute incubation period, fluorescence was measured with a fluorometric plate reader at 480 nm and 530 nm.

Statistical analysis – Statistically significant differences between negative controls and treated samples were determined using the ^{2}test. The standard micronucleus assay was considered positive when a dose-response relationship could be established between the numbers of micronucleated cells and the concentrations of pesticide solutions, and when at least one concentration induced a significant increase of micronucleated cells as compared to the medium-only control culture. The dose-response relationships were calculated by nonlinear regression analysis with TableCurve2D®. Model significance was based on three criteria: (i) correlation coefficient r^2 being > 0.62; (ii) model probability (P) being < 0.05; (iii) error probability (PE) being > 0.05. The Minimal Clastogenic Concentration (MCC) was defined as the lowest concentration of test item (µg/mL) that induced a significant increase of micronucleated cells. The Cytogenetic Potency (CP) was defined as the slope of the dose–response curves. It was calculated by non-linear regression analysis with TableCurve2D®.
For the determination of ROS, the dose-response relationships were calculated by linear regression analysis with TableCurve2D®. Model significance was based on three criteria: (i) correlation coefficient r^2 being > 0.62; (ii) model probability (P) being < 0.05; (iii) error probability (PE) being > 0.05. The Oxidative Potency was defined as the slope of the dose-response curves and was calculated according to a standard curve obtained with various concentrations of fluorescent DCF.

Results
No statistically significant increase in the incidence of bi-micronucleated cells (BMC) was observed with glyphosate in the dark and without S9-mix at concentrations up to 100 µg/mL. In the presence of S9-mix a statistically significant and dose-related increase was noted from 10 µg/mL. The calculated minimal clastogenic concentration (MCC) was 5.8 µg/mL. With light irradiation a statistically significant increase in BMC was noted at the highest concentration of glyphosate tested (100 µg/mL) with a MCC of 93.4 µg/mL. Without S9-mix a statistically significant and dose-related increase in BMC was produced by AMPA from a concentration of 0.01 µg/mL with a MCC of 0.006 µg/mL. In the presence of S9-mix a statistically significant increase in BMC was seen with AMPA from 1 µg/mL with a MCC of 0.78 µg/mL. With light irradiation, the lowest test concentration of AMPA with a statistically significant increase in BMC was 0.0005 µg/mL with a MCC of 0.0004 µg/mL. The oxidative potency of H_2O_2, used as a positive control, was 333.3 nM DCF/µM^{-1} (data not shown). Only AMPA exerted an elevated oxidative effect (5.9 nM DCF/µg mL^{-1}), whereas the oxidative potency of glyphosate was very low.

Discussion
The results obtained in the present study confirmed the cytogenetic toxicity of glyphosate and AMPA *in vitro*. In the dark, glyphosate was not directly active in the absence of S9-mix, but it induced micronuclei in the presence of S9-mix. On the contrary, without S9-mix, AMPA displayed a direct cytogenetic effect which was 1,000 fold higher than that of its parent compound. The weak mutagenic activity of glyphosate with S9-mix could be explained by its weak metabolization yield *in vivo*. After sunlight irradiation, glyphosate was weakly active, whereas the cytogenetic effect of AMPA was about 20-fold increased. Since the photodegradation of glyphosate by UV light has been shown to produce AMPA, the photoinducible genotoxic potential of glyphosate could be partially explained by the formation of its metabolite AMPA in the intracellular environment. In the present study, cells were subjected to a very low irradiation that did not induce intrinsic DNA damage. The results of the present study implied more probably the involvement of a photoinduced oxidative stress, which transformed glyphosate and AMPA into photoactivated intermediates favoring interactions with cellular targets.

Conclusion
The results of this study demonstrated that light-irradiation, corresponding to a few minutes of solar exposure, greatly potentiated the cytogenetic impact of AMPA. *In vitro* experiments showed that the genotoxic impact of pesticides greatly depend on their physico-chemical environment,

3. Assessment and conclusion

Assessment and conclusion by applicant:

The cytogenetic effect of two herbicides (glyphosate and atrazine), their metabolites (AMPA and DEA), and mixtures thereof was investigated in CHO-K1 cells in the *in vitro* micronucleus test. Only the results of glyphosate and AMPA tested alone are reported and discussed in the summary. Glyphosate and AMPA were tested with and without metabolic activation and with light irradiation. Also the potency of glyphosate and AMPA to produce ROS was investigated. The concentrations tested ranged from 5 to 100 µg/mL for glyphosate and from 0.00005 to 5 µg/mL for AMPA. No statistically significant increase in the incidence of bi-micronucleated cells (BMC) was observed with glyphosate at concentrations up to 100 µg/mL in the dark and without metabolic activation. However, a statistically significant and dose-related increase in BMC was noted from 10 µg/mL in the presence of metabolic activation. With light irradiation a statistically significant increase in BMC was noted for glyphosate at a concentration of 100 µg/mL. AMPA produced a statistically significant and dose-related increase in BMC from a concentration of 0.01 µg/mL in the dark and without metabolic activation. With metabolic activation a statistically significant increase in BMC was seen with AMPA from 1 µg/mL. With light irradiation the lowest test concentration of AMPA with a statistically significant increase in BMC was 0.0005 µg/mL. Only AMPA was found to produce an elevated oxidative effect, whereas the oxidative potency of glyphosate was very low. The results of glyphosate in the *in vitro* micronucleus test with metabolic activation reported in this study are surprising since glyphosate is essentially unmetabolized *in vitro* in the presence of a rat liver S9 homogenate. Moreover, these results are not corroborated by regulatory *in vivo* micronucleus tests in the mouse dosed up to more than 2,000 mg/kg bw.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate and AMPA tested were not sufficiently characterized and no positive and control historical data were reported. The *in vitro* micronucleus test carried out was in compliance with OECD TG 487.

2. Full summary of the study according to OECD format

In this study the authors determined the levels of thiobarbituric acid reactive substances (TBARs); quantified superoxide dismutase (SOD) and catalase (CAT) activity in liver, kidney, lung and heart, and performed the comet assay in blood and liver of mice administered glyphosate (40 or 400 mg/kg/day) or AMPA (100 mg/kg/day) in drinking water for 14 days. Exposure to glyphosate 400 mg/kg induced a

statistically significant ($p < 0.05$) decrease of SOD activity in heart and an increase in CAT activity in kidney. In the comet assay there were statistically significant differences in all the treatments and tissues studied in comparison to control animals ($p \leq 0.01$). The major results of this study were that mice administered glyphosate or AMPA in drinking water for 14 days induced a significant increase in DNA damage in liver and blood but minor effects on oxidative stress parameters. DNA effects on liver and blood indicate that these compounds could be of concern in terms of their potential to damage the genetic material, and that oxidative stress does not seem to be the mechanism causing that effect.

Materials and Methods

Chemicals - Analytical grade glyphosate (96 % purity), and analytical grade AMPA, (99 % purity) were obtained from Sigma-Aldrich, Argentina.

Animals - Twenty-four Balb C mice of approximately 45 days of age were used in this study. Four groups of six animals each (a control group, 2 groups treated with glyphosate and a group treated with AMPA) were used for the determination of oxidative stress (TBARs, SOD and CAT) and DNA damage in the comet assay. During 7 days prior to the beginning of the study, the volume of water ingested per day was measured in every 2 animals per cage to determine the concentration of glyphosate and AMPA in the drinking water to be supplied to each group. Mice received approximately 40 or 400 mg/kg bw/day of glyphosate and 100 mg/kg bw/day of AMPA. The control group received drinking water without test compound. After 14 days of exposure, before sacrifice, peripheral blood was drawn from the tail vein to perform the comet assay. At necropsy, heart, lungs, liver, and kidneys were removed for the determination of TBARs, SOD and CAT and frozen at -80 ºC pending analysis. A part of the liver was homogenized in phosphate buffer (pH 7.4) immediately after excision for the conduct of the comet assay. All determinations were performed in triplicate.

Single cell gel electrophoresis assay in mouse blood and liver - The protocol followed the general guidelines proposed by Singh et al. (Exp. Cell Res., 175, 184-191, 1988) with minor modifications. The slides were fixed in absolute ethanol, stained with ethidium bromide and scored using fluorescence microscopy. Images of 100 "nucleoids" counted for each animal were captured with a camera attached to the fluorescence microscope and linked to the Comet Score 1.5 software. Tail moment (TM), percentage of DNA in tail (% of DNA) and tail length (TL) were used to estimate DNA damage (in arbitrary units).

TBARs, SOD and CAT determinations - Tissue homogenates (10 %) were prepared in chilled 0.05 M potassium phosphate buffer at pH 7.4. TBARs concentrations, expressed as nmol of malondialdehyde MDA/g of tissue, were measured spectrophotometrically at 532 nm in liver and kidney homogenates. TBARs concentrations were determined using a standard curve at different concentrations of MDA versus optical density, individually prepared for each tissue. Superoxide dismutase (SOD) activity was assessed spectrophotometrically in the supernatant of liver homogenates. One unit of enzymatic activity has been defined as the amount of enzyme capable of causing 50 % inhibition of auto-oxidation of epinephrine. Catalase (CAT) activity was measured at 240 nm by the decomposition of the H_2O_2.

Statistical analysis

Statistical analysis was performed using Prism software (PRISM, 1997). The Kolmogorov-Smirnov test was performed to verify if the results follow a normal distribution. ANOVA followed by the Dunnett's test, or the Kruskal-Wallis test followed by the Dunn's test were performed for data with and without normal distribution respectively.

Results

The volume of water ingested per animal/day did not show any statistically significant differences among the experimental groups throughout treatment. No statistically significant differences were found in liver, kidney, lung and heart for all oxidative stress parameters measured with the exception of a decrease in SOD in the heart and an increase in CAT in the kidney at a daily glyphosate dose of 400 mg/kg bw. A non-statistically significant increase in CAT was observed in the lung. There were no statistically significant changes in the concentrations of MDA/g of tissue at 40 and 400 mg/kg bw/day of glyphosate and at 100

mg/kg bw/day of AMPA. Tail intensity, tail length and tail moment were statistically significantly elevated in blood and liver of all dosed groups with the exception of tail intensity in liver at 40 mg/kg bw/day glyphosate.

Discussion and Conclusion

The presence of glyphosate or AMPA in drinking water did not affect water consumption. Statistically significant differences in oxidative stress (decrease in SOD activity in the heart and increase in CAT activity in the kidney) were only observed in mice treated with glyphosate at 400 mg/kg bw for 14 days. The increase in CAT activity in the lungs was not statistically significant. A non-statistically significant decrease in SOD activity was observed in all tissues of animals treated with 100 mg/kg bw AMPA but no effect of AMPA was found on CAT activity. Liver was the only tissue where no effects were recorded, neither in TBA reactive substances nor in SOD and CAT activity. In the comet assay of blood statistically significant differences from control were seen for glyphosate and AMPA in tail intensity, tail length and tail moment. Tail moment values in the comet assay were similar for both glyphosate and AMPA treatments. In this study, genotoxic changes were observed with glyphosate at 40 and 400 mg/kg bw/day and AMPA at 100 mg/kg bw/day. However, statistically significant changes in the levels of SOD and CAT especially in heart and kidney were only seen with glyphosate at 400 mg/kg bw/day. This suggests that the genotoxic effects of glyphosate and AMPA are much more important than the indicators of oxidative stress.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The objective of this study was to investigate the effect of glyphosate and AMPA on indicators of oxidative stress and DNA integrity in mice after oral exposure for 14 days via the drinking water. The results of this study indicate that no statistically significant differences have been found in liver, kidney, lung and heart for all oxidative stress parameters measured with the exception of a decrease in SOD activity in the heart and an increase in CAT activity in the kidney at a daily glyphosate dose of 400 mg/kg bw. There was an increase in CAT activity in the lung but this was not statistically significant and did not show a dose-effect relationship. A statistically significant increase in DNA damage parameters was observed for glyphosate and AMPA with the exception of tail intensity in the liver for glyphosate at 40 mg/kg bw/day. No clear dose-effect relationship was evident for DNA damage parameters in blood after treatment with glyphosate. A dose-effect relationship was present for tail length and tail moment in the liver.

This publication is considered relevant for glyphosate risk assessment but reliable with restrictions because the increased DNA damage seen (only 2 dose levels tested for glyphosate with too few animals) didn't show a dose-effect relationship in blood and occurred at dose levels (40 and 400 mg/kg bw/day) that are much lower than the 2000 mg/kg bw used in regulatory *in vivo* MN tests in the mouse with negative results.

Assessment and conclusion by RMS:

2. Full summary of the study according to OECD format

Aim of this study was to investigate the cytotoxic and genotoxic properties of glyphosate (G) and Roundup (R) (UltraMax) in a buccal epithelial cell line (TR146), as workers are exposed via inhalation to the herbicide. R induced acute cytotoxic effects at concentrations > 40 mg/l after 20 min, which were due to membrane damage and impairment of mitochondrial functions. With G, increased release of extracellular lactate dehydrogenase indicative for membrane damage was observed at doses > 80 mg/l. Both G and R induced DNA migration in single-cell gel electrophoresis assays at doses > 20 mg/l. Furthermore, an increase of nuclear aberrations that reflect DNA damage was observed. The frequencies of micronuclei and nuclear buds were elevated after 20-min exposure to 10 -20 mg/l, while nucleoplasmatic bridges were only enhanced by R at the highest dose (20 mg/l). R was under all conditions more active than its active principle (G).

Materials and Methods

Chemicals - Glyphosate (purity 95 % w/w) and Roundup (Roundup Ultra Max, 450 g/L glyphosate acid) were obtained from Monsanto Europe S.A.

Storage and cultivation of the indicator cells - The human cell line TR146 was cultured under standard conditions in DMEM supplemented with 10 % heat-inactivated fetal calf serum. The medium was changed every 2–3 days. When the cultures reached confluency, the cells were washed with Dulbecco's PBS, detached with TrypLE Express, centrifuged, and sub-cultured. TR146 cells express ultrastructural characteristics of normal human buccal epithelial cells, e.g. intermediate filaments, microvilli-like processes, and lack of complete keratinization.

Cytotoxicity assays - For cytotoxicity experiments, $5x10^4$ indicator cells were seeded in 96-well plates and exposed to concentrations of glyphosate and Roundup ranging from 0 to 200 mg glyphosate equivalents/L for 20 minutes. Toxicity due to damage of the cell membrane was determined with the extracellular LDHe assay that is based on the measurement of the oxidation of NADH to NAD. Alterations of mitochondrial functions were studied in XTT (2,3-bis(2-methoxy-4-nitro-5-sulfophenyl)-5-[(phenyl-amino)carbonyl]-2H-tetrazolium hydroxide) assays that measure succinate dehydrogenase activity of viable cells. The SRB test was used to monitor total protein synthesis as a marker of cell proliferation. SRB binds to cellular proteins and can be quantified after solubilization. The neutral red assay was conducted to evaluate membrane integrity and lysosomal activity of the cells. All experiments are based on spectrophotometric measurements and were evaluated with an automated microplate reader. In all experiments, three measurements were performed per dose and repeated at least once.

Single-cell gel electrophoresis (SCGE) assay - SCGE assays were performed to determine the effect of glyphosate and Roundup on DNA stability. The concentrations of glyphosate and Roundup used in this assay ranged from 0 to 2000 mg glyphosate equivalents/L. TR146 cells were seeded in 24-well plates and allowed to attach. Thereafter, the culture medium was replaced by 400 µL of different concentrations of glyphosate dissolved in serum-free medium. After incubation in the dark at 37ºC and 5 % CO_2 for 20 minutes, the medium was discarded and the cells washed twice with DPBS and detached. After two washing

steps with DMEM and centrifugation, the pellets were resuspended in low melting point agarose, spread onto slides precoated with normal melting point agarose and lysed in the dark at 4°C for at least 1 hour. After 20 minutes unwinding in an alkaline electrophoresis solution electrophoresis was carried out. Air-dried slides were stained with ethidium bromide and the percentage of tail DNA was measured using a computer-aided image analysis system (Comet IV, Perceptive Instruments Ltd., Haverhill, UK). For each experimental point, 3 cultures were made in parallel and from each culture, one slide was prepared and 50 randomly distributed cells evaluated.

Cytokinesis-block micronucleus (CBMN) cytome assay - The CBMN assay using the cytochalasin B technique was performed to determine the effect of glyphosate and Roundup on chromosome integrity. The concentrations of glyphosate and Roundup used in this assay ranged from 0 to 20 mg glyphosate eq./L. Into 6-well plates, 4.5 x 10^5 cells were seeded and allowed to attach overnight. After treatment for 20 minutes with the test compounds or 100 µg/mL methyl methanesulfonate as the positive control, the cells were washed twice with PBS and cultured in DMEM containing 10 % FCS and cytochalasin B for 48 hours. Subsequently, the cells were washed twice with DPBS and harvested. The slides were made by cytocentrifugation and subsequently air-dried, fixed, and stained with Diff Quick stain. The total number of micronuclei (MNi) in binucleated cells (BN) as well as the number of binucleated cells with micronuclei (BN-MNi), nuclear buds (NB), nucleoplasmic bridges (NPB), and apoptotic and
necrotic cells was determined. Cells that divided after addition of cytochalasin B were recognized as binucleated. The nuclear division index (NDI) was determined in 500 cells. For each experimental point, TR146 cultures were prepared in triplicate. From each culture, >1,000 binucleated cells were evaluated under 400-fold magnification (Nikon Photophot-FXA, Tokyo, Japan).

Statistical analysis - Data analyses of the cytotoxicity and SCGE assays were performed with the GraphPad Prism 5 Project software system. Results are reported as means ± standard deviations (SD). The results were analyzed using one-way ANOVA and Dunnett's test and p values ≤0.05 were considered as statistically significant. The chi-square test with Yate's correction was used for the evaluation of the CBMN experiments and p values ≤0.05 were considered statistically significant.

Results

Cytotoxicity - Clear differences have been found between the effects of glyphosate and Roundup. Roundup was in all cases more cytotoxic than the active ingredient. In the LDHe test Roundup NADH consumption was statistically significantly increased from 10 mg glyphosate eq./L on whereas this was the case with glyphosate from 80 mg/L. In the XTT test, a statistically significant decrease in cellular integrity was seen with Roundup from concentrations of 40 mg glyphosate eq./L on while there was no effect with glyphosate up to 200 mg/L. In the SRB test there was a statistically significant decrease in cellular integrity from 100 mg glyphosate eq./L on whereas there was no effect with glyphosate up to 200 mg/L. The same difference in cytotoxicity was evident in the NR assay where Roundup produced a statistically significant decrease in cell integrity from 100 mg glyphosate eq./L on whereas there was no effect with glyphosate. The LC_{50} values for the cytotoxicity of Roundup were about 100 mg glyphosate eq./L for the XXT test, 140 mg/L for the NR assay and 150 mg/L for the SRB assay.

SCGE assay - In the SCGE assay, glyphosate produced at statistically significant increase in tail intensity from 20 mg/L on or without a dose-effect relationship from 40 to 2,000 mg/L. A statistically significant and dose dependent increase in tail intensity was observed with Roundup from 20 mg glyphosate eq./L up to 200 mg glyphosate eq./L, a dose level with 0 % cell integrity.

CBMN assay - The endpoints recorded in this assay were the frequency of binucleated (BN) cells with micronuclei (MNi), the total number of MNi, nuclear buds (NB) and nucleoplasmic bridges (NPB). After addition of cytochalasin B for 48 h, more than 75 % of the cells were binucleated (BN) and the nuclear division index (NDI) in untreated cultures was 1.89 ± 0.09. Treatment of the cells with 100 µg/mL of the positive control MMS for 20 minutes produced a significant induction of BN cells with MNi, total number of MNi, NB and NPB. Exposure of the cells to glyphosate and Roundup at 10, 15 and 20 mg glyphosate eq./L for 20 minutes led to a statistically significant and dose-dependent increase of the frequency of MN,

BN-MN, NB and NPB. The number of necrotic cells was statistically significantly increased for glyphosate and Roundup at 20 mg/L. The number of apoptotic cells was statistically significantly increased with glyphosate at 20 mg/L but not with Roundup.

Discussion

The results show that Roundup but not glyphosate causes pronounced cytotoxic effects in human-derived buccal epithelial cells. The genotoxicity tests show that glyphosate as well as its formulation induce DNA strand breaks as well as nuclear anomalies that reflect DNA instability including chromosomal damage. Glyphosate did not induce effects in the NR, SRB, and in the XTT assay up to concentrations of 200 mg/L, while a clear effect was seen in the LHDe assay from 80 mg/L on. On the contrary, statistically significant cytotoxic effects were observed with Roundup in all four assays, and significant changes were seen in the LDHe assay from 10 mg glyphosate eq./L and in the XTT test from 40 mg glyphosate eq./L on. Comparisons of the sensitivity of the different toxicity tests indicate that Roundup causes membrane damage at lower concentrations than the inhibition of mitochondrial functions in embryonic and placental-derived cells (JEG3), while umbilical vein cord endothelial cells (HUVEC) were equally sensitive to both endpoints. High concentrations of glyphosate affected in these experiments primarily mitochondrial functions while no effects were seen in an assay detecting changes of cell membrane functions.

The results of the SCGE assays show that glyphosate as well as Roundup induce comet formation under alkaline conditions. The effects increased as a function of the exposure and DNA migration was also observed under conditions that did not affect the cellular integrity. Also in earlier investigations with human-derived cells, SCGE assays were used to monitor the DNA-damaging effects of glyphosate. Significant induction of DNA migration was seen in human hepatoma cells (HepG2) with Roundup 400 with glyphosate levels of more than 5 mg/L after 24 hours of treatment. Other cell lines such as normal human fibroblasts (GM38) and the human fibrosarcoma line HT1080 were less sensitive in long-term (72 h) exposure studies. Taken together, these effects show that distinct differences exist in the sensitivity of cells from different organs and indicate that drug-metabolizing enzymes, which are represented in the enzyme activation mix and in HepG2 cells, increase the DNA-damaging properties of glyphosate. The most relevant finding of the present study is the observation of a statistically significant, dose-dependent induction of MNi, BN-MNi, and NB reflecting the genomic damage by glyphosate and its formulation. The most sensitive endpoint was MNi induction. Treatment of the cells with highest level (20 mg glyphosate eq./L) of Roundup caused a 3-fold increase over the background. A weaker effect was seen with the corresponding concentration of glyphosate. NPB was a less responsive endpoint with a statistically significant increase with glyphosate and Roundup at all dose levels. These results indicate that the damage seen in the SCGE assays is not completely repaired but leads to persisting alterations of the genetic material. MNi reflect numerical as well as structural chromosomal aberrations, while NB are formed as a consequence of gene amplification or expulsion of intact chromosomes or fragments; NPB are caused by formation of dicentric chromosomes.

The findings of the present study suggest that buccal epithelial cells are more sensitive toward the cytotoxic and DNA-damaging effects of glyphosate and Roundup than cells from the hematopoietic system. The Roundup formulation that was tested contains 450 g/L of glyphosate and should be diluted according to the instructions of the manufacturer to 1–3 % before use (final concentration 4,500–13,500 mg/L). The fact that we found significant acute and genotoxic effects at levels between 10 and 20 mg/L after 20 min indicates that short contact with a 225–1,350-fold dilution of the formulation may cause adverse effects in cells from the oral cavity (and possibly also in other respiratory epithelia).

3. Assessment and conclusion

Assessment and conclusion by applicant:

The objective of the present study was to find out whether exposure of human-derived buccal epithelial TR146 cells to glyphosate and Roundup causes adverse effects. In cytotoxicity experiments, four different endpoints were used, which reflect different modes of action. To assess the effect of glyphosate and Roundup on DNA stability, single cell gel electrophoresis assays (SCGE) were conducted under

standard alkaline conditions reflecting the formation of single- and double-strand breaks. Additionally cytokinesis-block MN cytome assays have been conducted in which different nuclear anomalies were measured. This study demonstrated that there is a big difference in cytotoxicity between glyphosate and Roundup. This is not surprising since the surfactants present in glyphosate formulations decrease the integrity of cell and mitochondrial membranes causing toxicity and ensuing DNA instability. Glyphosate was found to significantly increase tail intensity as of 20 mg/L but without any further increase with dose from 40 to 2000 mg/L. Roundup increased in a dose dependent manner the tail intensity from 20 mg glyphosate eq./L up to 200 mg glyphosate eq./L with increasing cytotoxicity and 0 % cell integrity at 200 glyphosate eq. mg/L. This indicates that there is a relationship between the cytoxicity of Roundup and DNA instability. This study has demonstrated a greater sensitivity of buccal epithelial cells for glyphosate and its formulations than hematopoietic cells where no effects have been noted in *in vivo* MN tests with doses up to 2,000 mg/kg bw. Since there is no direct exposure of the buccal epithelium with the Roundup formulation (unless it is swallowed) during application and the inhalation of aerosol of the spray dilution during application is negligible (Jauhiainen A *et al*. (1991) Am. Ind. Hyg. Assoc. J. 52, 61–64) the likelihood of DNA damage in epithelial cells of the GI and the respiratory tract remains very low.

This publication is considered relevant for the risk assessment of glyphosate and reliable with restrictions. Although it complies with most of the reliability criteria of an *in vitro* toxicology study, no blinded scoring of coded slides is reported. Also, concentrations with positive findings (20-2000 mg/L) noted significant effects on necrosis and apoptosis markers in parallel experiments at the low dose of 20 mg/mL.

Assessment and conclusion by RMS:

Reliability criteria for *in vitro* toxicology studies

Publication: Koller *et al.*, 2012.	**Criteria met? Y/N/?**	**Comments**
Guideline-specific		
Study in accordance to valid internationally accepted testing guidelines	N	
Study performed according to GLP	N	
Study completely described and conducted following scientifically acceptable standards	Y	
Test substance		
Test material (Glyphosate) is sufficiently documented and reported (i.e. purity, source, content, storage conditions)	Y	Purity of 95 %. Source: Monsanto Europe S.A.
Only glyphosate acid or one of its salts is the tested substance	Y	Also formulation (Roundup Ultra Max) was tested
AMPA is the tested substance	N	
Study		
Test system clearly and completely described	Y	
Test conditions clearly and completely described	Y	
Metabolic activation system clearly and completely described	NA	
Test concentrations in physiologically acceptable range (< 1 mM)	Y	10-1000 µg/mL
Cytotoxicity tests reported	Y	
Positive and negative controls	Y	

Complete reporting of effects observed	Y	
Statistical methods described	Y	
Historical negative and positive control data reported	N	
Dose-effect relationship reported	Y	Roundup, but not glyphosate causes pronounced cytotoxic effects in human-derived buccal epithelial cells. The alkaline comet test results show that glyphosate as well as Roundup induce comet formation that reflect strand breaks and apurinic sites. 20 µg/mL glyphosate in Roundup caused a 3-fold increase over the background, with glyphosate alone a weaker effect was seen.
Overall assessment		
Reliable without restrictions		
Reliable with restrictions	Y	
Not reliable		
This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions because it complies with most of the reliability criteria of an in vitro toxicology study. Although it complies with most of the reliability criteria of an in vitro toxicology study, no blinded scoring of coded slides is reported. Also, concentrations with positive findings (20-2000 mg/L) noted significant effects on necrosis and apoptosis markers in parallel experiments at the low dose of 20 mg/mL.		

CA 5.5 Long-term toxicity and carcinogenicity

The long-term toxicity and carcinogenic potential of glyphosate has been assessed in rats and mice. The study results are summarised in Table 5.5-1 and Table 5.5-91. In long-term studies in rats and mice there was no evidence of carcinogenicity. Furthermore, in rats, there was no adverse effects on survival or clinical signs. Reductions in body weight gain, increases in alkaline phosphatase and liver weight changes, an increase in incidence of cataracts, inflammation of the gastric mucosa and histopathological changes in the salivary glands were observed sporadically across the studies previously reviewed. In the mouse, non-neoplastic treatment related effects were limited to high dose males in the [redacted] (1983) study and comprised of a reduction in body weight gain, hepatocyte hypertrophy and bladder epithelial hyperplasia.

In conclusion, there was no evidence that glyphosate acid is carcinogenic in any of the studies submitted.

The majority of the *in vitro* studies in the literature performed with glyphosate did not indicate a potential effect of glyphosate to induce tumorigenesis. In two out of five *in vitro* publications, glyphosate showed some activity in the underlying models, but without relevance for the risk assessment. Hypomethylation by

glyphosate was observed in MCF10A cells, but did not lead to tumour development as seen in other demethylating agents. In a study with Vk*MYC mice (multiple myeloma mouse model) and C57Bl/6 mice (wild-type, WT), glyphosate was reported to induce benign monoclonal gammopathy in WT mice as well as promoting myeloma progression in Vk*MYC mice. Due to several restrictions with regards guideline study requirements the results are considered supplementary only, as the data do not allow a direct risk assessment.

Long-term and carcinogenicity studies in the rat

The most recent rat dietary carcinogenicity study was conducted in 2009 by [redacted] (CA 5.5/001), there were no adverse treatment related effects at the highest dose tested. No indication of a carcinogenic effect was observed. The NOAEL for systemic toxicity was 1077 and 1382 mg/kg bw/day for males and females, respectively. Minor changes as reduced body weight gain (-9 %) in males only, transient increase in ALP activity or fatty infiltration of the bone marrow are not considered to fulfil the criteria for an adverse effect. Adverse effects include consistent effects with toxicologically significant changes affecting the function or morphology of a organ or producing serious changes to haematology or biochemistry parameters of the organism. Isolated elevation of alkaline phosphatase activity is considered to be related to an adaptation of the metabolism rather than to damage of (liver) cells. Liver damage is not to be considered the reason for the ALP increase, as no other plasma enzyme activities commonly linked to damage of this organ were changed nor was any pathological and histopathological finding reported. ALP is not only changed based on cell damage but also due to adaptive changes. The isolated increase of ALP activity of up to 160 % of the control values is not considered adverse against a normal adaptive background showing marked fluctuation. Okamura[19] *et al*. (2011) reported background levels of ALP in RccHan™:WIST rats at 8 to 32 weeks of age from 195 to 608 IU/L for males and 63 to 322 IU/L for females. In humans the reference range is between 70-175 U/I in males and 55-147 in females[20]. The conclusion on liver enzyme fluctuation is that, in the absence of correlating histopathological changes are considered adaptive and reversible rather than adverse.

In another combined chronic toxicity and carcinogenicity study ([redacted] 2001, CA 5.5/002), which was performed with glyphosate technical in rats receiving diets providing 0, 2000, 6000 or 20000 ppm glyphosate acid, the NOAEL was set at 6000 ppm equivalent to 361 and 437 mg/kg bw/day for males and females, respectively. The limiting effects were based on liver and kidney, prostatitis, periodontal inflammation, urinary acidosis and haematuria, which may be attributed to the acidity of the test substance. The salivary gland findings reported by [redacted] (1996, CA 5.5/006) were not confirmed although the study was run in the same laboratory employing rats of the same strain. It is concluded that Glyphosate technical is not carcinogenic. In a further study, by [redacted] (1997, CA 5.5/004), rats received diets providing 0, 3000, 10000 or 30000 ppm glyphosate. The NOAEL for toxicity is 3000 ppm equivalent to 104 and 115 mg/kg bw/day for males and females, respectively, based on histopathological and clinical effects of the caecum together with follicular hyperkeratosis and/or folliculitis/follicular abscess in the mid and high dose groups. No carcinogenic potential was observed.

A further 2-year study from [redacted] (1996, CA 5.5/005) in Wistar rats with up to 741 mg/kg bw/day glyphosate concluded that glyphosate was not carcinogenic to rats. A NOAEL of 741 mg/kg bw/day (combined sexes) was also established for systemic toxicity based on the lack of toxicity treatment related. Single and inconsistent changes of clinical chemistry parameters were considered not treatment-related. Histopathology did not reveal any treatment-related changes in any organ further supporting the conclusion that clinical chemistry parameters changes were not related to treatment-related adverse effects.

A 1-year toxicity study ([redacted] 1996, CA 5.5/006) was performed in rats with dietary doses of 0, 2000, 8000 and 20000 ppm glyphosate acid. Based on body weight and salivary gland effects at 20000 ppm, the

[19] Okamura T, Suzuki S, Ogawa T, *et al*. Background Data for General Toxicology Parameters in RccHan:WIST Rats at 8, 10, 19 and 32 Weeks of Age. *J Toxicol Pathol*. 2011;24(4):195-205. doi:10.1293/tox.24.195

[20] Thomas, L.: Labor und Diagnose. TH Books Verlagsgesellschaft 5. Auflage 2005: page 38

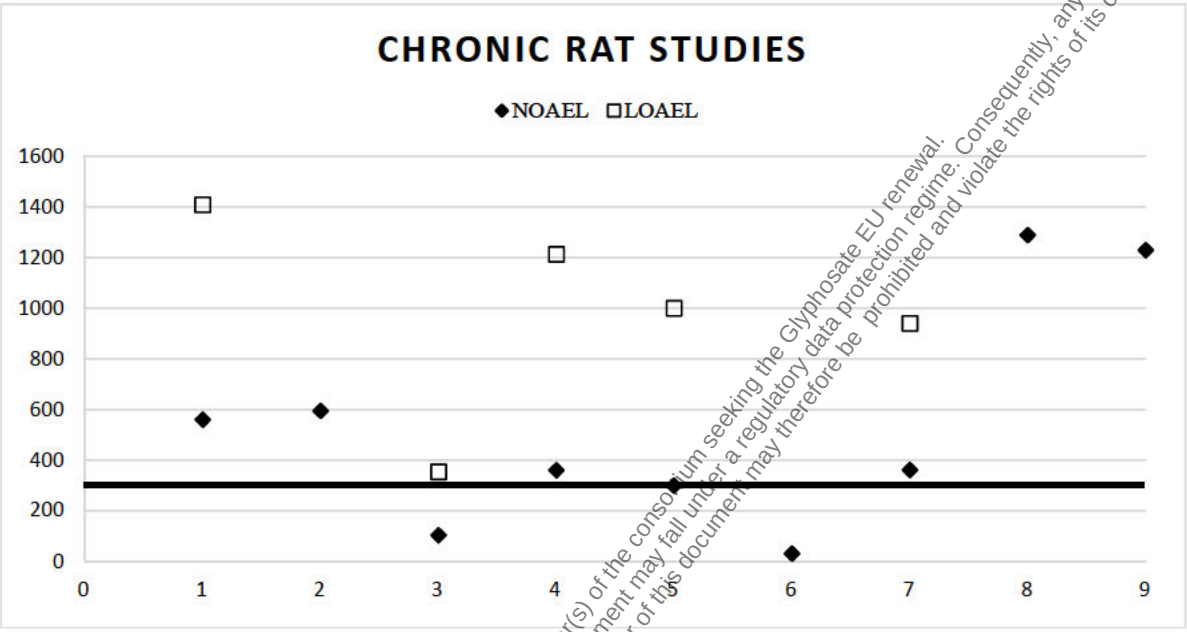
NOAEL for toxicity for glyphosate acid was 8000 ppm equivalent to 560 mg/kg bw/day in males and 671 mg/kg bw/day in females. There was no evidence of carcinogenicity.

In a 2-year oral diet study where Sprague-Dawley rats were continuously exposed to diets of up to 1000 mg/kg bw/day glyphosate ([redacted], 1993, CA 5.5/007-009) no carcinogenic potential was observed. Based on the study results and the lack of toxicological significance of the salivary gland findings, as well as a slight increase of plasma ALP observed at 300 mg/kg bw/day, the NOAEL in rats after chronic exposure to glyphosate technical for 104 weeks is considered to be 300 mg/kg bw/day. Cellular alteration of the parotid/mandibular salivary gland was considered an adaptive response based on the addition of glyphosate acid to the diet. This effect is in concordance with findings in other studies with glyphosate acid as well as with citric acid (see CA 5.8.2). Furthermore, the effect on the salivary glands was not clearly dose related but may be following a threshold effect potentially related to pH changes. This assumption is also supported by the fact that the effects on the salivary glands were already observed after 52-weeks and did not increase in incidence or severity. Increased ALP activity is not considered an adverse effect as the increase was slight, not accompanied by other liver enzymes or treatment-related histopathological changes in the liver. Furthermore, the liver weight was comparable between control and treatment groups.

[redacted] (1990, CA 5.5/010) concluded that glyphosate was not carcinogenic in Sprague-Dawley rats following continuous dietary exposure of up to 20000 ppm for 24 months (corresponding to 940 mg/kg bw/day in males and 1183 mg/kg bw/day in females). The NOAEL for toxicity is 8000 ppm (corresponding to 362 mg/kg bw/day in males and 437 mg/kg bw/day in females), based on reduced body weights in females and cataract lens changes in males at 20000 ppm.

The 2-year dietary rat study conducted by [redacted] (1997, CA 5.5/003) concluded that there were no adverse treatment related effects and the NOAEL was 30000 ppm equivalent to 1290/1740 mg/kg bw/day in males and females respectively. However, this study is considered invalid because no core information on the test substance was recorded and there were further deficiencies compared to the guideline. A further study was considered to be not acceptable due to too low dose levels and serious reporting deficiencies ([redacted] 1981, CA 5.5/011). In this study, glyphosate was not carcinogenic in Sprague-Dawley rats following continuous dietary exposure of up to 300 ppm for 26 months (corresponding to 31.49 mg/kg bw/day in males and 34.02 mg/kg bw/day in females). The NOAEL for toxicity is 300 ppm (corresponding to 31.49 mg/kg bw/day in males and 34.02 mg/kg bw/day in females), based on the absence of findings in body weight changes, haematology, clinical chemistry, organ weight data or histopathological examinations.

Figure 5.5.1-1: Chronic rat NOAEL and LOAEL values, showing an overall NOAEL of 300 mg/kg bw/day [1. [redacted] (1996); 2. [redacted] (1996); 3. [redacted] (1997); 4. [redacted] (2001); 5. [redacted] (1993); 5. [redacted] (1981); 7. [redacted] (1990); 8. [redacted] (1997); 9. [redacted] (2009)]



The overall chronic NOAEL in rats is 300 mg/kg bw/day. No test substance related carcinogenic potential in rats was concluded in all studies.

Salivary gland

Histological changes described as "cellular alteration" in the parotid and mandibular salivary glands and a higher organ weight of these glands were noted at 100 mg/kg bw/day and higher in the study from [redacted] (1993, CA 5.5/007-009). In addition similar changes have been observed in subchronic rat studies (see CA 5.3). In contrast, there are several chronic studies where no effects on the salivary glands were reported. Furthermore, in the more recent performed studies by [redacted] (2001) (same laboratory and rat strain as [redacted] 1996) and [redacted] (2009) salivary gland findings were not observed. These differences may be more or less pronounced depending on the rodent strain used or methodological differences. Additional studies were conducted to examine species sensitivity, reversibility of the effects and the hypothesis previously suggested in the WHO/FAO 2004 evaluation of glyphosate; that local irritation of the oral cavity by the organic acid mixed into diet may result in an adaptive salivary gland response (CA 5.8.2/002 and CA 5.8.2/003). Based on the outcome of these examinations the treatment-related pathological findings (increased salivary gland size and flow) can be considered as adaptive responses due to oral irritation from the ingestion of glyphosate acid in the diet.

Table 5.5-1 Summary of long-term toxicity and carcinogenicity studies in rats

1. Information on the study

Data point:	CA 5.5/001
Report author	[redacted]
Report year	2009
Report title	Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat
Report No	2060-0012
Document No	NA
Guidelines followed in study	OECD 453 (1981), JMAFF Guideline 2-1-16 (2005), US OPTTS 870.4300 (1996)

Deviations from current test guideline (OECD 453, 2018)	Yes, the appearance of the urine was not investigated; the organ weights of the epididymides, thyroid/parathyroids and the uterus were not determined; histopathological observations of the cervix, coagulating gland; lacrimal gland and the upper respiratory tract were not performed.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity and carcinogenic potential of Glyphosate technical was assessed in a 24-month feeding study in 51 male and 51 female Wistar rats at dietary concentrations of 0, 1500, 5000 and 15000 ppm (equivalent to mean achieved dose levels of 0, 95.0, 316.9 and 1229.7 mg/kg bw/day) Glyphosate technical. To ensure that a received dose of 1000 mg/kg bw/day overall was achieved, the highest dose level was progressively increased to 24000 ppm. In addition, three satellite groups with 15 rats per sex each were included for interim sacrifice at the 12th month to study non-neoplastic histopathological changes.

Observations covered clinical signs, behavioural assessment, functional observations, body weight, food consumption, ophthalmology, haematology, clinical chemistry and urinalysis as well as organ weights, necropsy and histopathological examination.

The treatment-related findings of this study were elevations in plasma electrolyte values for both sexes at 18 months. Elevations in alkaline phosphatase activity were seen at 6, 12 and 18 months in males only. Histopathological examinations revealed at 15000 ppm a significant difference in the site of mineral deposition within the kidneys compared with controls. There was a lower incidence of pelvic/papillary deposition and an increase in the corticomedullary deposition. At the same time there was a reduction in the incidence of renal pelvic hyperplasia; which is considered a consequence of decreased mineral deposition. An increase in severity of adipose infiltration into the bone marrow of males only was observed. This finding was not seen amongst high dose females but was seen at both 5000 and 1500 ppm group females.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate Technical
Description:	White crystalline solid
Lot/Batch #:	H05H016A
Purity:	95.7 % w/w
Stability of test compound:	No data
2. Vehicle and/ or positive control:	Diet

3. Test animals:

Species:	Rat

Strain:	Wistar Han Crl:WI (GLx/BRL/Han) IGS BR
Source:	[redacted]
Age:	5 - 6 weeks
Sex:	Males and females
Weight at dosing:	Males: 112 – 183 g, females: 98 – 150 g
Acclimation period:	At least ten days
Diet/Food:	Rat and Mouse SQC Ground Diet No.1 (BCM IPS Ltd., London, UK), *ad libitum*
Water:	Mains drinking water, *ad libitum*
Housing:	Initially in groups of three per sex in polypropylene solid-floor cages.
Environmental conditions:	Temperature: 21 ± 2 °C Humidity: 55 ± 15 % Air changes: at least 15/hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 2005-09-01 to 2007-08-31

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 51 Wistar rats per sex received daily dietary doses of 0, 1500, 5000 and 15000 ppm (equivalent to mean achieved dose levels of 0, 95.0, 316.9 and 1229.7 mg/kg bw/day) Glyphosate technical. To ensure that a received dose of 1000 mg/kg bw/day overall was achieved, the highest dose level was progressively increased to 24000 ppm.

In addition, three satellite groups with 15 rats per sex each were included for interim sacrifice at the 12th month to study non-neoplastic histopathological changes. The satellite control group with 12 rats per sex served as veterinary control. The animals were to be used for investigations should any health problems have developed with study animals. No such problems occurred and therefore the observations of these animals have not been included in the report.

Test diets were prepared weekly by mixing a known amount of the test substance with a small amount of basal diet for 19 minutes at a constant speed. This pre-mix was then added to larger amount of basal diet and blended for further 30 minutes.

The stability and homogeneity of the test substance in the diet was determined in an in-house stability study. The homogeneity and achieved concentrations of the test substance preparations was determined at monthly intervals until Week 26, and in 3-month intervals thereafter.

Clinical observations
Rats were examined for toxic signs, ill-health or behavioural changes once and for pre-terminal deaths twice a day. A routine clinical observation session including veterinary examination was made weekly, including palpation for new or existing masses. Ophthalmic examination was done at the start of the study in all satellite animals and at Week 50 in ten satellite animals per sex of the control and high dose group. Prior to treatment and at weekly intervals thereafter all satellite animals were observed for behavioural toxicity.

Body weight
Individual body weights were recorded prior to start of treatment, at weekly intervals from Week 1 to 13

and every four weeks thereafter until termination as well at terminal kill.

Food consumption and compound intake
Food consumption was recorded once weekly for each cage group from Week 1 to Week 13 and subsequently for one week in each four weeks until termination.

Water consumption
Water intake was observed daily, for each cage group, by visual inspection.

Haematology and clinical chemistry
Haematological examinations were performed on ten animals per sex from the satellite and main groups at 3, 6 and 12 months. Further haematological investigations were performed on 20 animals per sex from the main groups at 18 and 24 months. The following parameters were measured: haematocrit, haemoglobin, erythrocyte count, MCV, MCH, MCHC, platelet count, total leukocyte count, differential leukocyte count, reticulocyte count, prothrombin time, and activated partial thromboplastin time.

Blood chemical investigations were performed on ten animals per sex from the satellite groups at 6 and 12 months and from the main groups at 18 and 24 months. The following parameters were determined: urea, glucose, total protein, albumin, albumin/globulin ratio, sodium, potassium, chloride, calcium, inorganic phosphorus, ASAT, ALAT, alkaline phosphatase, creatinine, total cholesterol, total bilirubin, and cholinesterase.

Urinalysis
Urinalytical investigations were performed on ten animals per sex from satellite groups at 3, 6 and 12 months and from main groups at 18 and 24 months. The following measurements were made: specific gravity, volume, pH, protein, glucose, ketones, blood, urobilinogen, reducing substances and microscopic examination of sediment.

Sacrifice and pathology
Necropsy was conducted for all animals surviving until study termination (main groups: 104 weeks; satellite groups: 52 weeks) as well for all animals found dead or killed in extremis.

The following organ weights were determined from 10 rats per sex and main group and from all satellite animals: adrenals, brain, gonads, heart, kidneys, liver, spleen and thymus.

Tissue samples were taken from the following organs: adrenals, aorta (thoracic), bone & bone marrow (sternum and femur incl. joint), brain (cerebrum, cerebellum, pons), caecum, colon, duodenum, epididymides, eyes (with optic nerve), gross lesions including palpable masses, head (pharynx, nasopharynx, paranasal sinuses), heart, Harderian gland, ileum (incl. Peyer's patches), jejunum, kidneys, liver, lungs (with bronchi), lymph nodes (cervical and mesenteric), mammary gland, muscle (skeletal), oesophagus, ovaries, pancreas, pituitary, prostrate, rectum, salivary glands (submaxillary), sciatic nerve, seminal vesicles, skin (hind limb), spinal cord (cervical, mid-thoracic and lumbar), spleen, stomach, testes, thymus, thyroid/parathyroid, tongue, trachea, urinary bladder, uterus and vagina. A detailed histopathological examination was performed on all sampled tissues of the control and high-dose animals. In addition, gross lesions and masses from low and intermediate dose groups at termination were examined microscopically.

Histopathological examination was initially carried out on all tissues collected from control and high dose groups; all pre-terminally dead and moribund sacrificed rats and on all lesions and palpable masses of the terminally sacrificed rats from the low and mid dose groups.
Since there were no indications of treatment-related bone marrow changes, examination was subsequently extended to the remaining treatment groups.

Statistics

Where appropriate quantitative data was analysed by the ProvantisTM Tables and Statistics Module. For each variable, the most suitable transformation of the data was found; the use of possible covariates checked and the homogeneity of means assessed using ANOVA or ANCOVA and Bartletts's test. The transformed data was analysed to find the lowest treatment level that shows a significant effect, using the Williams Test for parametric data or the Shirley Test for non-parametric data. If no dose response is found, but the data shows non-homogeneity of means, the data will be analysed by a stepwise Dunnett (parametric) or Steel (non-parametric) test to determine significant differences from the control group. Finally, if required, pair-wise tests are performed using the Student t-test (parametric) or the Mann-Whitney U test (non-parametric). Histopathology data were analysed using the following methods to determine significant differences between control and treatment groups for the individual sexes.

1. Chi squared analysis for differences in the incidence of lesions occurring with an overall frequency of I or greater.
2. Kruskal-Wallis one way non-parametric analysis of variance for the comparison of severity grades for the more frequently observed graded conditions.

II: RESULTS

A. ANALYSIS OF DOSE FORMULATIONS

Stability assessment demonstrated that the test material preparations in the diet were stable for at least six weeks.

Analyses for achieved concentrations showed that the diet preparations were within an acceptable range. On one occasion the achieved concentrations of the low, mid and high-dose group were 79 %, 83 %, and 87 %, respectively. At week 2 the concentration in the mid dose group was 112 %. However, these isolated deviations from the nominal range were still considered to be acceptable.

B. MORTALITY

No significant treatment-related effects on mortality were observed during the study.
The numbers of pre-terminal deaths in the main group are displayed in the table below:

Table 5.5-2 Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat ([redacted], 2009): Cumulated mortalities after 104-week dietary exposure to Glyphosate technical

	Dose group (ppm)			
Sex	**0**	**1500**	**5000**	**15000-24000**
Male	12	14	13	6
Female	14	17	15	12

C. CLINICAL OBSERVATIONS

No significant treatment-related clinical observations occurred during the study.

There were no treatment-related effects on behavioural assessments, functional performance tests or sensory reactivity assessments observed.

D. BODY WEIGHT

Body weights were not statistically significantly changed in any dose group. At the end of the dosing period the body weight of males/females of the high dose group was reduced by 7 %/3 % compared to the control without being statistically significant. Body weight gains were partly changed in dose groups compared to the control. However, the variation of body weight changes was generally very high and increases as well as decreases were observed comparing control and dose groups. In conclusion, the changes in body weight and body weight gains was not considered an adverse effect.

Table 5.5-3 Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat ([redacted], 2009): Intergroup comparison of body weights

E. FOOD CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food consumption or food efficiency for either sex noted during the study.

The group mean achieved doses are summarised below.

Table 5.5-5 Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat ([redacted], 2009): Group mean achieved dose levels

Dose group	Dietary concentration (ppm)		Mean achieved dose level (mg/kg bw/day)		
			Males	Females	Overall mean
1 (control)	0				
2 (low)	1500		85.5	104.5	95.0
3 (mid)	5000		285.2	348.6	316.9
4 (high)	15000	Week 1-11	1077.4	1381.9	1229.7
	17000	Week 12-15			
	19000	Week 16-26			
	21000	Week 27-39			
	24000	Week 40-104			

The results show a higher test material intake for females when compared to males for each dose level. The mean intake for each dose group is 95.0, 316.9 and 1229.7 mg/kg bw/day for 1500, 5000, and 15000-24000 ppm, respectively. The mean intake values represent the combination of satellite and main group values.

F. WATER CONSUMPTION

There were no treatment-related effects on water consumption during the study.

G. OPHTHALMOSCOPY

There were no treatment-related effects observed.

H. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

All variations were considered to be incidental and unrelated to treatment because of the lack of either a true dose response, a consistent change throughout the study, a lack of progression of change with time and/or lack of concomitant effect in both sexes.

Clinical chemistry

At the highest dose level there was an increase in alkaline phosphatase activity for satellite group males and females compared with controls at 6 and 12 months. Main group males were also affected at 18 months. Values for all alkaline phosphatase activity values are presented as follows:

Table 5.5-6 Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat ([redacted], 2009): Alkaline phosphatase activity (IU/L)

	Dose level							
	Control		Low		Intermediate		High	
Timepoint	♂	♀	♂	♀	♂	♀	♂	♀
Month 6 (Satellite)	87.8	49.6	↑94.5	↑62.9	↑103.4	↑62.0	↑128.5**	↑91.9**
Month 12 (Satellite)	87.7	46.1	↑96.5	↑59.7	↑116.3*	↑58.1	↑140.2**	↑91.3**
Month 18 (Main)	93.3	65.7	↑110.5	↓55.8	↑110.9	↑70.9	↑125.0*	↑92.7
Month 24 (Main)	107.2	66.0	↓98.8	↓58.5	↓101.0	↑81.7	↑111.9	↑86.8

* $p < 0.05$; ** $p < 0.01$

The magnitude of the effect does not appear to increase with age plus the lack of a consistent effect for females and the absence of any histopathological correlation does suggest this to be of limited toxicological importance.

At the 18 month evaluation there was an increase in plasma electrolytes for both sexes. Sodium and chloride values for males and females and potassium values for males only were increased compared with controls. Female calcium levels were lower than controls. These elevations/decrements were also observed at lower dose levels but were not seen in a dose related trend. In addition at the 12 month evaluation for satellite females a lower sodium value was seen for females. Values for all calcium and chloride values are presented as follows:

Table 5.5-7 Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat ([redacted], 2009): Calcium and chloride values (mmol/L)

	Dose level							
	Control		Low		Intermediate		High	
Timepoint	♂	♀	♂	♀	♂	♀	♂	♀
Calcium								
Month 6 (Satellite)	2.587	3.693	↑2.701	↑3.752	↑2.617	↓3.637	↓2.508	↓3.604*

Table 5.5-7 Glyphosate Technical: Dietary Combined Chronic Toxicity/Carcinogenicity in the Rat ([redacted], 2009): Calcium and chloride values (mmol/L)

	Dose level							
	Control		Low		Intermediate		High	
Timepoint	♂	♀	♂	♀	♂	♀	♂	♀
Month 12 (Satellite)	2.530	2.602	↑2.543	↓2.587	↓2.458	↓2.475	↓2.514	↓2.483
Month 18 (Main)	2.231	2.775	↑2.523	↓2.645*	↑2.656	↓2.554**	↑2.598	↓2.468**
Month 24 (Main)	2.431	2.293	↑2.487	↑2.396	↑2.511	↓2.288	↓2.297	↑2.347
Chloride								
Month 6 (Satellite)	107.7	105.8	↓107.1	↑106.1	↓107.0	↑106.1	↑108.5	↑106.7
Month 12 (Satellite)	105.6	103.9	↓105.1	↑104.8	↓104.3	↑104.7	↑105.9	↑104.2
Month 18 (Main)	103.3	101.8	↑105.8**	↑104.2**	↑105.8**	↑106.4**	↑107.6**	↑107.8**
Month 24 (Main)	104.5	103.4	↓104.4	↓103.1	↓104.3	↓102.2	↑105.4	↓102.8

* $p < 0.05$; ** $p < 0.01$

At intermediate level similar findings to the highest dose level were seen for plasma electrolytes at the 18 month evaluation. A slight increase in alkaline phosphatase activity was seen for satellite group males at 12 months. At the low dose level there was a similar effect on the plasma electrolytes for both sexes at the 18 month evaluation of main group animals. Whilst these observations were seen at the highest dose level, the lack of dose response or the effect being limited to one sex does make the toxicological significance questionable.

All other differences were isolated in their finding and are therefore not toxicologically relevant.

I. URINALYSIS

There were no treatment-related effects observed.

J. NECROPSY

Gross pathology

There were no treatment-related macroscopic findings observed during the study period.

Organ weights

No effects on organ weight values were observed.

Histopathology

Adipose infiltration of the bone marrow was seen for the majority of animals examined, with both sexes being more or less equally affected in terms of incidence and severity. However, greater effects were seen among male rats dosed at the highest level and this attained statistical significance for terminal kill animals. This data indicates the possibility of myeloid hypoplasia as a consequence of treatment. However, given the normal variability of this condition and the influence of other pathological conditions upon marrow cellularity in ageing rats, the effect was not altogether convincing but cannot be dismissed. A similar effect was not seen among male rats in the remaining treatment groups but among premature deaths for animals of both sexes at the intermediate level and only low-dosed females. However, the variable duration of exposure and significant background pathology for premature death animals further negates this as an effect of treatment upon marrow cellularity for female rats.

Moreover, at the highest dose level there was a significant difference in the site of mineral deposition within the kidneys compared with controls. Pelvic mineralisation was commonly seen in both sexes and was more prevalent among female rats; however corticomedullary mineralisation was seen in female rats only. Nephrocalcinosis in rats is generally considered to be related to diet and hormonal status. There was a lower incidence of pelvic/papillary deposition and an increase in the corticomedullary deposition. At the same time there was a reduction in the incidence of renal pelvic hyperplasia in both sexes; which is considered

to be a consequence of the decreased mineral deposition.

The effects on pelvic and corticomedullary mineralisation, and hyperplasia of the pelvic/papillary epithelium were confined to high dose animals with no indication of a similar effect at any other treatment level for either sex.

No other treatment-related changes were observed.

Neoplastic changes
No significant effects associated with tumour development were observed.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Based on the study results the NOAEL in rats after chronic exposure to Glyphosate technical for 24 month is 24000 ppm (corresponding to 1229.7 mg/kg bw/day for combined sexes). It is concluded that Glyphosate technical is not carcinogenic in rats.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/002
Report author	[redacted]
Report year	2001
Report title	Glyphosate Acid: Two Year Dietary Toxicity and Oncogenicity Study in Rats
Report No	[redacted]/PR1111
Document No	NA
Guidelines followed in study	OECD 453 (1981), EEC B.33 (1988), MITI (1992), US OPTTS 870.4300 (1998)
Deviations from current test guideline (OECD 453, 2018)	Yes, organ weights of epididymides, thyroid/parathyroid and uterus were not determined; histopathological examination of coagulating glands, gall bladder, upper respiratory tract, peripheral nerve and vagina were not performed.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity and carcinogenic potential of glyphosate acid was assessed in a 24-month feeding study in 52 male and 52 female Wistar rats with 0, 2000, 6000 and 20000 ppm (equivalent to mean achieved dose levels of 0, 121, 361 and 1214 mg/kg bw/day for males and 0, 145, 437 and 1498 mg/kg bw/day for

females). In addition, three satellite groups with 12 rats per sex each were included for interim sacrifice at the 12th month to study non-neoplastic histopathological changes.

Observations covered clinical signs, body weight, food consumption, haematology, clinical chemistry and urinalysis as well as organ weights, necropsy and histopathological examination.

Treatment related findings in this study were found in the liver and kidney and were confined to animals (predominantly males) fed 20000 ppm glyphosate acid. There were a number of changes in males and females fed 20000 ppm, notably renal papillary necrosis, prostatitis, periodontal inflammation, urinary acidosis and haematuria, which may be attributed to the acidity of the test substance. Despite the findings at 20000 ppm, survival was better in males fed 20000 ppm than in the controls and lower dose groups. This improved survival was associated with lower food consumption, lower bodyweights and a decreased severity of renal glomerular nephropathy.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate acid (technical material)
Description:	White solid
Lot/Batch #:	P30
Purity:	97.6 % w/w
Stability of test compound:	At least 2 years when stored at -20 °C

2. Vehicle and/or positive control: Diet

3. Test animals:

Species:	Rat
Strain:	Wistar (Alpk:APfSD)
Source:	[redacted]
Age:	3 weeks (on delivery)
Sex:	Males and females
Weight at dosing:	Males: 155.0 – 156.6 g (mean values); females: 136.0 – 138.4 g (mean values)
Acclimation period:	At least 10 days
Diet/Food:	CT1 diet (Special Diet services Ltd., Essex, UK), *ad libitum*
Water:	Mains drinking water, *ad libitum*
Housing:	Initially in litters, sexes separately, after assignment to experimental groups in group of four rats per sex per cage
Environmental conditions:	Temperature: 22 ± 3 °C Humidity: 30 - 70 % Air changes: at least 15/hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1998-04-07 to 2000-05-07

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 52 Wistar-derived rats per sex received daily dietary doses of 0, 2000, 6000 and 20000 ppm glyphosate acid (equivalent to mean achieved dose levels of 0, 121, 361 and 1214 mg/kg bw/day for males and 0, 145, 437 and 1498 mg/kg bw/day for females).
A further twelve animals per sex were added to each group and were designated for interim kill after one year to study chronic toxicity and non-neoplastic histopathological changes.

Test diets were prepared in 60 kg batches by mixing a known amount of the test substance with 1 kg of basal diet. This pre-mix was then added to the remainder of the 60 kg batch of basal diet and mixed thoroughly. The stability and homogeneity of the test substance in the diet was determined in an in-house stability study at 2000 and 20000 ppm.

Clinical observations
Rats were examined for toxic signs, ill-health or behavioural changes and pre-terminal deaths prior to the start of the study and once a day afterwards. Detailed clinical observations were conducted weekly. Ophthalmic examination was done in all animals at the start of the study, at Week 52 and prior to termination. A functional observational battery including motor activity was conducted in Week 52 in animals allocated to the chronic toxicity assessment of the study.

Body weight
Individual body weights were recorded prior to start of treatment, at weekly intervals from Week 1 to 15 and every two weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded once weekly for each cage group from Week 1 to Week 14, once in week 16 and every fourth week thereafter.

Haematology and clinical chemistry
Blood was collected from 13 animals per sex and group at Week 14, 27, 53, 79 and at termination. Different animals were used for the tail vein haematology and clinical chemistry samples.

The following blood parameters were measured: haematocrit, haemoglobin, erythrocyte count, MCV, MCH, MCHC, blood cell morphology, platelet count, total leukocyte count, differential leukocyte count, reticulocyte count, red blood cell distribution width, prothrombin time, activated partial thromboplastin time. The following clinical chemistry parameters were measured: alkaline phosphatase, aspartate amino transferase (AST), alanine aminotransferase (ALT), γ-glutamyl-transferase, creatine kinase, creatinine, urea, total protein, glucose, albumin, globulin, albumin/globulin ratio, total bilirubin, triglycerides, total cholesterol, inorganic phosphorus, calcium, sodium, potassium, and chloride.

Urinalysis
Individual urine samples were collected from the same animals as those used for haematology analyses at Week 13, 26, 52, 78 and prior to termination. The following parameters were determined: volume, abnormal colour and appearance, specific gravity, pH, glucose, ketones, protein, bilirubin, and blood.

Sacrifice and pathology
Necropsy was conducted on all animals. The following organ weights were determined from all animals surviving to scheduled termination: adrenals, brain, gonads, heart, kidneys, liver and spleen.

Tissue samples were taken from the following organs: adrenals, aorta, bone and bone marrow (femur incl. joint), brain (cerebrum, cerebellum, brainstem), caecum, cervix, colon, duodenum, epididymides, eyes (retina, optic nerve), gross lesions including palpable masses, Harderian gland, heart, ileum, jejunum, kidneys, lachrymal gland, larynx, liver, lung, lymph nodes (cervical and mesenteric), mammary gland, muscle, oesophagus, ovary, pancreas, pharynx, pituitary, prostrate, rectum, salivary glands (submandibular,

parotid), seminal vesicles, skin, spinal cord (cervical, thoracic, lumbar), spleen, sternum, stomach, testes, thymus, thyroid/parathyroid, trachea, urinary bladder and uterus.

Statistics
All data were evaluated using analysis of variance and/or analysis of covariance for each specified parameter using the MIXED procedure in SAS (1996). Kaplan-Meier survival estimates (Kaplan and Meier, 1958) were calculated separately for each sex and treatment group.
The overall incidence of each tumour type was considered by comparing each treated group and the control group using Fisher's Exact Test. In addition, a test for trend with group number was performed using the Cochran-Armitage Test described in Gart *et al*. (1986). Analyses were carried out for all animals, intercurrent deaths and at terminal kill.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
The mean achieved concentrations of glyphosate acid in each dietary preparation were within 10 % of the nominal concentration and the overall mean concentrations were within 1 % of nominal.

The homogeneity of glyphosate acid in diet at concentrations of 2000 and 20000 ppm was satisfactory; percentage deviations were within 2 % of the overall mean for the 20000 ppm group and within 4-9 % of the overall mean for the 2000 ppm group.

The stability tests determined at 2000 and 20000 ppm showed that the test substance stability was satisfactory at room temperature and when stored at -20 °C for at least 45 days which covered the period of use in the current study.

B. MORTALITY
The male groups were terminated in Week 100 because survival in the control, low and mid dose groups was approaching 25 % (criteria for termination of the study). Statistically significantly better survival was observed in males fed 20000 ppm than in the other groups ($p = 0.02$). A statistically significant overall trend was also observed for males ($p = 0.03$).

The female groups survived to scheduled termination and there were no significant differences in mortality between the groups.

The survival rates are displayed in the table below.

Table 5.5-8 Glyphosate Acid: Two Year Dietary Toxicity and Oncogenicity Study in Rats ([redacted], 2001): Survival rates during up to 104-week dietary exposure to glyphosate technical

	Dose group (ppm)							
	0		2000		6000		20000	
	♂	♀	♂	♀	♂	♀	♂	♀

Week 104	—*	0.62	—*	↓0.56	—*	0.77	—*	↓0.57

* Terminated in Week 100 because survival in the control, low and mid dose groups was approaching 25 % (criteria for termination of the study).

C. CLINICAL OBSERVATIONS

At 20000 ppm there was a treatment related increase in the incidence of red-brown staining of tray papers, particularly in males.

There were no other treatment-related clinical observations.

There were also no treatment-related effects noted in the functional observational battery.

D. BODY WEIGHT

The bodyweights of the animals fed 20000 ppm glyphosate acid were statistically significantly lower than controls throughout the study. The maximum reduction from control values was approximately 5 % for males and 8 % for females.

There were no treatment related effects in animals fed 2000 or 6000 ppm glyphosate acid.

* Statistically significant difference from the control group mean at the 5 % level (Student's t-test, two-sided)

E. FOOD CONSUMPTION AND COMPOUND INTAKE

Food consumption was lower throughout the first year of the study in animals fed 20000 ppm glyphosate acid. In females the difference was statistically significant over the first 11 weeks (with a maximum reduction of approximately 5 %) and again in weeks 40-56 (with a maximum reduction of 6 %). In males, the difference was statistically significant over most of the first 6 months with a maximum reduction of 6 %.

The group mean achieved doses are summarised below.

Table 5.5.-5.5-10 Glyphosate Acid: Two Year Dietary Toxicity and Oncogenicity Study in Rats ([redacted], 2001): Group mean achieved dose levels

Dose group	Dietary concentration (ppm)	Mean achieved dose level (mg/kg bw/day)	
		Males	Females
1 (control)	0		
2 (low)	2000	121	145
3 (mid)	6000	361	437
4 (high)	20000	1214	1498

The results show a higher test material intake for females when compared to males for each dose level. The mean intake for each dose group is 0, 121, 361 and 1214 mg/kg bw/day for males and 0, 145, 437 and 1498 mg/kg bw/day for females for 0, 2000, 6000 and 20000 ppm, respectively.

F. OPHTHALMOSCOPY

There were no treatment-related effects observed.

G. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

Minor variations from control values were obtained for most parameters but showed no consistency and were confined to intermediate time points and/or dose groups and were considered not to be treatment-related. An increased haemoglobin concentration and decreased platelet count was seen in all female treated groups at the interim kill but, in the absence of any apparent dose-response or effects at other time points, these variations from mean control values are considered not to be treatment-related (see table below).

* $p < 0.05$; ** $p < 0.01$

Clinical chemistry

In rats fed 20000 ppm glyphosate acid, increases in plasma alkaline phosphatase were present until Week 79 (**Table 5.5-12**). Increases in alanine aminotransferase activities were present consistently in males until Week 79 and in females in Weeks 14, 79 and 105. Increased total bilirubin was also present in these males throughout the study and increased plasma aspartate aminotransferase activity was present in males at the interim kill. Plasma triglycerides and cholesterol levels were reduced (from Weeks 14-53 and Weeks 53 onwards, respectively) in males.

In animals fed 6000 ppm, there were small increases in alkaline phosphatase activity over the first year of the study and variable increases in plasma alanine aminotransferase activity at intermediate time points throughout the study.

Plasma creatinine values were lower in all treated female groups at Week 27 and in females receiving 6000 and 20000 ppm at Week 14, but in the absence of any effects later in the study, this is considered to be of no toxicological significance.

Other minor variations from mean control values were confined to intermediate dose groups or time points and/or showed no dose response, and so were considered not to be treatment-related.

H. URINALYSIS

Urinary pH was lower throughout the study in males fed 20000 ppm glyphosate acid (**Table 5.5-13**). Moreover, in the same dose group an increased incidence and severity of blood/red blood cells was present in males and, to a lesser extent, in females.

There were no other treatment related findings in the urinalysis.

I. NECROPSY

Gross pathology

Treatment-related macroscopic findings were seen in males fed 20000 ppm and/or 6000 ppm in the kidneys, liver, prostate and testes. These findings consisted of a minor increase in incidence of enlarged kidneys, single masses in the liver, firmness of the prostate and a reduction in the incidence of reduced testes.

Additional findings were not considered to be treatment related.

Organ weights

Significant lower relative adrenal gland weight was noted at the interim kill in females fed 20000 ppm and 6000 ppm glyphosate acid. Furthermore, the liver weight was significantly lower at the interim kill in males fed 20000 ppm glyphosate acid. Significantly reduced the kidney weights were recorded at 6000ppm. The absolute ovary weight at the highest dose group was reduced although the ovary weight relative to body weight did not appear as significantly reduced.

There were no other significant and dose-related effects on organ weights.

Histopathology

A minor increase in the incidence but not severity of proliferative cholangitis in the liver was present in males fed 20000 ppm glyphosate acid at interim and terminal kill (see table below).

Moreover, in males fed 20000 ppm glyphosate acid an increased incidence of hepatitis and periodontal inflammation was observed. The incidence of prostatitis was higher than the control group in all treated males and there was a decrease in the incidence of tubular degeneration of the testis in males fed 20000 ppm glyphosate acid. The incidence of prostatitis was within historical background levels in all treated groups but, as the control value in this study was low, the relationship to treatment at the high dose level cannot be entirely dismissed.

The main changes in interim and terminal kill males and, to a lesser extent, females fed 20000 ppm glyphosate acid, were observed in the kidney. These changes consisted of slight increased incidence of papillary necrosis with varying degrees of mineralisation of the papilla and/or transitional cell hyperplasia. There was also a very small increased incidence of papillary mineralisation only (males and females fed 20000 ppm glyphosate acid) and transitional cell hyperplasia alone (20000 ppm males only).

All other observed differences in the incidence of findings either fall within the historical background level or are considered to be unrelated to the treatment with glyphosate acid.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In conclusion, glyphosate acid was not carcinogenic in the Wistar rats following continuous dietary exposure of up to 20000 ppm for 24 months (corresponding to 1214 mg/kg bw/day in males and 1498 mg/kg bw/day in females). The NOAEL for toxicity is 6000 ppm (corresponding to 361 mg/kg bw/day in males and 437 mg/kg bw/day in females). In addition, there was no evidence of neurotoxicity.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/003
Report author	[redacted]
Report year	1997
Report title	Combined Chronic Toxicity/Carcinogenicity Study of Glyphosate Technical in Sprague Dawley Rat
Report No	1231
Document No	Not reported
Guidelines followed in study	OECD 453 (1981)
Deviations from current test guideline (OECD 453, 2018)	Haematology was performed without determining haematocrit, mean corpuscular volume, mean corpuscular haemoglobin, mean corpuscular haemoglobin concentration, prothrombin time, activated partial thromboplastin time, platelet count; clinical chemistry was performed without determining inorganic phosphorous, calcium, chloride, sodium,

	potassium, cholesterol, creatinine, T3, T4, TSH; organ weights were not determined for all animals; weights of heart, spleen, (para)thyroids and uterus were not determined; histopathology was performed without determining Harderian gland, cervix, coagulating gland, gall bladder, lacrimal gland, upper respiratory tract, vagina.
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid: - Information on test substance identification not available and several deviations from the current OECD TG 453 evident.
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

The chronic toxicity and carcinogenic potential of Glyphosate technical was assessed in a 24-month feeding study in male and female Sprague Dawley rats. Groups of 50 rats per sex received daily dietary doses of 0, 3000, 15000, and 25000 ppm Glyphosate technical (equivalent to mean achieved dose levels of 0, 0.15, 0.78 and 1.29 g/kg bw/day (males) and 0, 0.21, 1.06 and 1.74 g/kg bw/day (females)). In addition 20 rats/sex/group were included for interim sacrifice at Week 52, to study non-neoplastic histopathological changes with a different high dose level of 30000 ppm. The dietary doses correspond to 0.18, 0.92 and 1.92 g/kg bw/day (males) and 0.24, 1.13 and 2.54 g/kg bw/day (females) for 3000, 15000 and 30000 ppm, respectively. Observations covered clinical signs, body weight, food consumption, haematology, clinical chemistry and urinalysis as well as organ weights, necropsy and histopathological examination.

There were no treatment-related deaths or clinical signs in any of the dose-groups. Moreover, there were no treatment-related effects on food consumption noted. Significantly reduced body weight gain that lasted throughout study until termination was observed in males receiving the highest dose. In all other groups body weight gain was comparable to the control at termination. Apart from increased alkaline phosphatase levels in the high dose of the carcinogenicity study at study termination, all other significant changes observed in haematological, biochemical and physio-pathological parameters of urine were within the range of the historical control data and hence appear to be of no biological significance.

Gross pathology and histopathological examination revealed no treatment-related and dose-dependent effects. Regarding organ weights, significant and dose-dependent effects after 52 weeks were found only in animals dosed at 30000 ppm. After 104 weeks the effects were seen as well in the mid dose group. Increased organ weights that were observed after 52 weeks but not after 104 weeks could be due to the different high dose level, e.g. 25000 ppm and 30000 ppm, respectively.

In conclusion, Glyphosate technical was not carcinogenic in the Sprague Dawley rats following continuous dietary exposure of up to 1.29 g/kg bw/day for males and 1.74 g/kg bw/day for females for 24 months. The NOAEL for toxicity is 1.29 g/kg bw/day for males and 1.74 g/kg bw/day for females.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	No data given in the report
Lot/Batch #:	No data given in the report
Purity:	No data given in the report
Stability of test compound:	No data given in the report
2. Vehicle and/ or positive control:	Diet
3. Test animals:	
Species:	Rat
Strain:	Sprague-Dawley
Source:	[redacted]
Age:	Approx. 6 weeks
Sex:	Males and females
Weight at dosing:	Males: 70.0 – 93.2 g, females: 70.0 – 90.6 g
Acclimation period:	One week
Diet/Food:	Powdered rat feed (Lipton India Ltd, India), *ad libitum*
Water:	Filtered pure water, *ad libitum*
Housing:	Initially in groups of five in polypropylene cages, in groups of three from Week 24 to 52 and in groups of two from Week 53 to termination
Environmental conditions:	Temperature: 22 - 25 °C Humidity: 50 - 70 % Air changes: 10 - 15/hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1994-06-09 to 1996-06-12

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 50 Sprague Dawley rats per sex received daily dietary doses of 0, 3000, 15000 and 25000 ppm (equivalent to mean achieved dose levels of 0, 0.15, 0.78 and 1.29 g/kg bw/day (males) and 0, 0.21, 1.06 and 1.74 g/kg bw/day (females)) Glyphosate technical for two years. In addition, for the control and each dose group 20 rats per sex were included for interim sacrifice in Week 52 to study non-neoplastic histopathological changes (chronic toxicity study). Selected dose levels were the same except for the highest dose which was 30000 ppm. Here the dietary doses correspond to 0.18, 0.92 and 1.92 g/kg bw/day (males) and 0.24, 1.13 and 2.54 g/kg bw/day (females) for 3000, 15000 and 30000 ppm, respectively.

Test diets were prepared weekly by mixing appropriate amounts of the test substance with the basal diet. The stability and homogeneity of the test substance in food was determined in-house stability study at all dose levels before the start of dosing. Analyses for achieved concentrations were performed monthly during the study period.

Clinical observations
Rats were examined for toxic signs once and pre-terminal deaths twice a day. Ophthalmic examination was done at the start of the study, at interim sacrifice and at termination in the control and high dose group.

Body weight

Individual body weights were recorded on Day 0, at weekly intervals thereafter until the end of Week 13 and every 4 weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded once weekly for each group from Week 1 to Week 13 and subsequently in Week 25, 38, 51, 65, 78, 92 and 104.

Haematology and clinical chemistry
Haematology
Individual blood samples were collected from 20 rats/sex/group of the main groups at 3, 6, 12, 18 and 24 months and from all surviving animals of the satellite group at 12 months. Before sampling animals were fasted overnight. The following parameters were measured: Haemoglobin, erythrocyte count, PCV, thrombocytes, total leukocyte count and differential leukocyte count.

Blood chemistry
Individual plasma samples were collected from 10 rats/sex/group of the main groups at 6, 12, 18 and 24 months and from all surviving animals of the satellite group at 12 months. Before sampling animals were fasted overnight. The following parameters were measured: Total serum proteins, albumin, ALT, AST, GGTP, SAP, blood urea nitrogen and blood glucose.

Urinalysis
Individual urine samples were collected from 20 rats/sex/group of the main groups at 3, 6, 12, 18 and 24 months and from all surviving animals of the satellite group at 12 months. The following measurements were made: Specific gravity, volume, appearance, pH, protein, glucose, occult blood, ketones, microscopy of sediments.

Sacrifice and pathology
Necropsy was performed on all animals at scheduled termination.

The following organ weights were determined from 10 rats per sex per main group and on all animals of the satellite groups: adrenals, brain, gonads, kidneys and liver.

Histopathological examination was carried out on all tissues collected at interim sacrifice, control and high dose groups; all pre-terminally dead and moribund sacrificed rats of the low and mid dose groups and on all lesions of the terminally sacrificed rats from the low and mid dose groups.

Tissue samples were taken from the following organs of all animals: adrenals, aorta, body cavities, brain, caecum, colon, duodenum, epididymides, eyes (both), femur, heart, ileum, jejunum, kidneys, liver, lungs, lymph nodes (mesenteric and mandibular), mammary gland, oesophagus, ovaries, pancreas, pituitary, preputial gland, prostrate, rectum, salivary glands, sciatic nerve, seminal vesicles, skeletal muscle, skin, spinal cord, spleen, sternum with bone marrow, stomach, testes, thymus, thyroid/parathyroid, trachea, urinary bladder and uterus.

Statistics
Probabilities of survival were estimated by the product-limit procedure of Kaplan and Meier (1958). Animals withdrawn from study during the interval (those taken for moribund sacrifice) are taken into consideration by giving enough weightage.

The incidence of neoplasms was analysed by Life table analysis for fatal tumour incidence and Peto's incidental tumour analysis.

In addition to these tests the Fisher exact test for pairwise comparisons and the Cochran Armitage linear trend test for dose response trends were carried out. All reported P-values for the tumour incidence analysis

are one-sided.

The biochemical, haematological and organ weight data was analyzed for significance using Student 't' test or Cochran 't' test.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS

Analyses for concentrations showed that the diet preparations recovered 86.1 - 98.3 % of the target concentration. Thus, the concentrations of the test substance in the test diets were within acceptable limits. Analyses for homogeneity recovered 87.5 - 90.0 % for 3000 ppm, 91.7 - 93.9 % for 15000 ppm, 94.3 - 95.1 % for 25000 ppm and 91.8 - 92.6 % for 30000 ppm. Hence, the results indicated a good homogeneity. Moreover, stability analyses showed that recovery one month after diet preparation ranged between 87.5 and 95.0 %.

B. MORTALITY

No treatment-related clinical signs or deaths were observed in the satellite groups, e.g. the chronic toxicity study.

In the carcinogenicity study, e.g. after 104 weeks, male animals of the high dose group exhibited slight but statistically insignificant higher mortalities.

The numbers of pre-terminal deaths in the main group are displayed in the table below:

Table 5.5-17 Combined Chronic Toxicity/Carcinogenicity Study of Glyphosate Technical in Sprague Dawley Rat ([redacted], 1997): Cumulated mortalities after 104-week dietary exposure to Glyphosate technical*

Sex	Dose group (ppm)			
	0	3000	15000	25000
Male	16/50	17/50 (2)	18/50 (4)	23/50 (14)
Female	19/50	20/50 (2)	20/50 (2)	25/50 (12)

* Values in parentheses indicate increases in mortality compared to control in percent.

C. CLINICAL OBSERVATIONS

No significant toxic signs were observed in treated or control groups.

D. BODY WEIGHT

Significantly reduced body weight gain that lasted throughout study until Week 104 was observed in males receiving the highest dose. In all other groups body weight gain was comparable to the control at termination. At 104 weeks the reduction of body weight was 8 % in males of the satellite group and 10 % in males of the main group. The effect on body weight was not considered adverse as the decrease of body weight was only about 10 % and no general toxic signs or effects on organ function were observed. Furthermore, the effect was observed at doses above 1000 mg/kg bw/day.

E. FOOD CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food consumption for either sex or group noted during the study. The results show a higher test material intake for females when compared to males for each dose level. The mean intake in the chronic toxicity study for each dose group is 0.18, 0.92 and 1.92 g/kg bw/day (males) and 0.24, 1.13 and 2.54 g/kg bw/day (females) for 3000, 15000 and 30000 ppm, respectively.

The mean intake in the carcinogenicity study for each dose group is 0.15, 0.78 and 1.29 g/kg bw/day (males) and 0.21, 1.06 and 1.74 g/kg bw/day (females) for 3000, 15000 and 25000 ppm, respectively.

The group mean achieved doses are summarised below.

Table 5.5-20 Combined Chronic Toxicity/Carcinogenicity Study of Glyphosate Technical in Sprague Dawley Rat ([redacted], 1997): Group mean achieved dose levels

Dose group	Dietary concentration (ppm)	Mean achieved dose level (g/kg bw/day)*	
		Males	Females
		Chronic toxicity study (52 weeks)	
low	3000	0.18	0.24
mid	15000	0.92	1.13
high	30000	1.92	2.54
		Carcinogenicity study (104 weeks)	
low	3000	0.15	0.21
mid	15000	0.78	1.06
high	25000	1.29	1.74

* Calculations were done with values from Week 13 (chronic) and Week 25 (carcinogenicity)

F. OPHTHALMOLOGICAL EXAMINATION

Ophthalmological examinations revealed no abnormalities.

G. LABORATORY INVESTIGATION

Haematological examination did not reveal any abnormalities attributable to the treatment. Regarding the clinical chemical investigations, a significant increase in the alkaline phosphatase level was only seen in the high dose of the carcinogenicity study at study termination (see table below).

Other significant changes observed in haematological and biochemical parameters were within the range of the historical control data and hence appear to be of no biological significance.

*= $p \leq 0.05$

H. URINALYSIS

Urinalysis did not reveal any abnormalities attributable to the treatment.

I. NECROPSY

Gross pathology

There were no treatment-related macroscopic findings observed during the study period.

Organ weights

Significant and dose-dependent effects in the chronic toxicity study were found in both sexes of the high-dose group. In males, weights of kidneys, brain and testes were increased. In females, in addition to kidneys and brain, the liver weight was increased as well.

In the carcinogenicity study which lasted 52 weeks longer, significant and dose-dependent effects in males consisted of increased weight of brain and testes in the mid and high dose group. Effects on the kidneys were not observed, perhaps due to the lower dose level in the highest group compared to the chronic toxicity study, e.g. 25000 ppm to 30000 ppm, respectively.

In females, significant and dose-dependent effects after 24 months occurred only in kidneys. Like for male animals, this increase could be due to the different high dose levels.

Histopathology
Histopathological changes were found at all dose levels including control. Based on histopathology observation no treatment-related effects were observed.

Neoplastic changes
There were no treatment-related neoplasms observed.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Based on the mild toxic effects on body weight gain and the increased organ weights without histopathological changes the NOAEL in rats after chronic exposure to Glyphosate technical for 24 month is 25000 ppm (corresponding to 1290 mg/kg bw/day for males and 1740 mg/kg bw/day for females). It is concluded that Glyphosate technical is not carcinogenic in rats.
Based on the deviations such as lack of information on test substance identification, storage conditions and several deviations from the current OECD TG 453 the study is not considered reliable for hazard and risk assessment. Drawing any reliable conclusion concerning a NOAEL from the study is not possible.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/004
Report author	[redacted]
Report year	1997
Report title	HR-001: 24-Month Oral Chronic Toxicity and Oncogenicity Study in Rats
Report No	[redacted] 94-0150
Document No	NA
Guidelines followed in study	OECD 453 (1981), JMAFF 59 NohSan 3850 (1984), US-EPA (1989)
Deviations from current test guideline (OECD 453, 2018)	Yes, mortality was observed only once per week; prothrombin time and activated partial thromboplastin time were not investigated; organ weights of epididymides, heart, ovaries, spleen and uterus were not measured; gall bladder, lacrimal gland and upper respiratory tract were not investigated histopathologically. No historical control data available.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity and carcinogenic potential of HR-001 (Glyphosate technical) was assessed in a 24-month feeding study in male and female Sprague-Dawley rats. Groups of 50 rats per sex received daily dietary doses of 0, 3000, 10000, and 30000 ppm HR-001 (equivalent to 0, 104, 354 and 1127 mg/kg bw/day for males and 0, 115, 393 and 1247 mg/kg bw/day for females). In addition, 30 rats/sex/group were included for interim sacrifice at 26, 52 and 78 weeks to study non-neoplastic histopathological changes. Observations covered clinical signs, body weight, food consumption, haematology, clinical chemistry and urinalysis as well as organ weights, necropsy and histopathological examination.

There were no treatment-related deaths in any of the dose-groups. Clinical observations consisted of loose faeces together with soiled fur in the perianal region in the high dose group as well as increased incidences of tail mass in the mid and high dose group. Moreover, decreases in body weight were observed in both sexes in the mid and high dose group along with a lower food consumption. Ophthalmological examinations, urinalysis and haematological and blood biochemical analyses did not demonstrate apparent toxicity of the test substance in either sex or group.

Necropsy supported the clinical signs of loose stool by increased incidences of distension of the caecum in the high dose group together with increased absolute and relative caecum weights in the mid and high dose group. Moreover, the increased incidences of thickened areas in the skin of the tail, corresponding to the increased incidences of tail mass, were histopathologically diagnosed as follicular hyperkeratosis and/or folliculitis/follicular abscess in the mid and high dose group.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical, Code: HR-001
Description:	White crystal
Lot/Batch #:	T-941209; T-950308
Purity:	97.56 %; 94.61 %
Stability of test compound:	No data given the report.

2. Vehicle and/or positive control: Diet

3. Test animals:

Species:	Rat
Strain:	Sprague-Dawley (Crj:CD)
Source:	[redacted]
Age:	5 weeks (males), 6 weeks (females)
Sex:	Males and females
Weight at dosing:	65 – 85 g
Acclimation period:	At least one week
Diet/Food:	MF Mash (Oriental Yeast Co., Ltd, Japan), *ad libitum*
Water:	Well water treated with sand and charcoal filter, HCl and UV rays, *ad libitum*
Housing:	In groups of ten animals of the same sex in wire-mesh stainless steel cages during the acclimatisation period. During the study males were housed in groups of 5 per cage until week 72, in groups of ≤3 until week 78 and individually thereafter. Females were housed in groups of five until week 78, and individually thereafter.
Environmental conditions:	Temperature: 24 ± 2 °C Humidity: 55 ± 15 % Air changes: 15/hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1994-12-19 to 1996-12-25

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 50 Sprague-Dawley rats/sex/group received daily dietary doses of 0, 3000, 10000 and 30000 ppm (equivalent to mean achieved dose levels of 0, 104.7, 354.0 and 1127.0 mg/kg bw/day in males and 0, 114.7, 393.0 and 1247.0 mg/kg bw/day in females) HR-001. In addition, 30 rats/sex/group were included for interim sacrifices at 26, 52 and 78 weeks.

Test diets were prepared weekly by mixing a known amount of the test substance with a small amount of basal diet. This pre-mix was then added to a larger amount of basal diet and blended by a blending machine. The stability of the test substance in food was previously determined in a 4-week dose-range finding study in mice. Homogeneity analyses were performed on samples of each dose level of the first diet preparation. Analyses for achieved concentrations were done for each dose level in monthly intervals.

Observations

Rats of all groups were examined for toxic signs and pre-terminal deaths once a day. In addition a detailed veterinary examination was made at least once per week. Ophthalmic examination was done at the start of the study and at termination.

Body weight
Individual body weights were recorded at weekly intervals until the end of Week 13 and every 4 weeks thereafter and before necropsy, except for dead or moribund satellite animals, which were discarded without body weight determination.

Food consumption and compound intake
Food consumption was measured for a period of three consecutive days weekly from Week 1 to 13 and every four weeks from Week 16 to 104. Mean individual food consumption, group mean food consumption and group compound intake were calculated.

Haematology and clinical chemistry
Blood samples were collected from 10 rats/sex/group of the satellite groups in Week 26, 52, from all surviving animals of the satellite group in Week 78 and from 10 rats/sex/group of the main group in week 104. Before sampling animals were fasted overnight. The following parameters were measured: hematocrit, haemoglobin, erythrocyte count, MCV, MCH, MCHC, platelet count, total leukocyte count, differential leukocyte count, alkaline phosphatase (ALP), glutamic-oxalacetic transaminase (GOT), glutamic-pyruvic transaminase (GPT), γ-glutamyl-transpeptidase, creatine phosphokinase, creatinine, blood urea nitrogen, total protein, glucose, albumin, globulin, albumin/globulin ratio, total bilirubin, total cholesterol, inorganic phosphorus, calcium, sodium, potassium, and chloride.

Urinalysis
Individual urine samples were collected from 10 rats/sex/group of the satellite groups in Week 26, 52, from all surviving animals of the satellite group in Week 78 and from 10 rats/sex/group of the main group in Week 104. The following measurements were made: density, volume, appearance, pH, protein, glucose, occult blood, ketones, urobilinogen, sediments.

Sacrifice and pathology
Necropsy and histopathological examinations were carried out on all tissues collected at interim and terminal sacrifice. The following organ weights were determined from all animals: adrenals, brain, caecum, kidneys, liver and testis.

Tissue samples were taken from the following organs: adrenals, aorta, bone & bone marrow (sternum and femur incl. joint), brain (cerebrum, cerebellum, pons and medulla oblongata), caecum, colon, duodenum, epididymides, eyes, gross lesions, Harderian glands, heart, ileum, jejunum, kidneys, liver, lungs, mammary gland, lymph nodes (cervical and mesenteric), oesophagus, ovaries, pancreas, pituitary, prostrate, rectum, salivary glands (submaxillary and sublingual), sciatic nerve, seminal vesicles and coagulating glands, skeletal muscle, skin (females only), spinal cord (cervical, thoracic and lumbar), spleen, stomach, testes, thymus, thyroid/parathyroid, trachea, urinary bladder, uterus (horns and cervix) and vagina.

Statistics
Statistical significance of the difference between the control group and the treated groups was estimated at 5 % and 1 % levels of probability.

The data of body weight (main group only), food consumption, urine specific gravity, urine volume, haematological parameters, blood biochemical parameters, and organ weights were evaluated by Bartlett's test for equality of variance. When group variances were homogeneous, a parametric analysis of variance of a one-way layout type was conducted to determine if any statistical differences existed among groups. When the analysis of variance was significant, Dunnett's (when sample size of each group was equal) or Scheffé's (when sample size of each group was different) multiple comparison test was applied to evaluate differences between the treated and the control groups. When the group variances were heterogeneous, the

data were analyzed by Kruskal-Wallis non-parametric analysis of variance. When significant, Dunnett type (when sample size of each group was equal) or Scheffé type (when sample size of each group was different) mean rank sum test was applied to determine if any significant differences existed between the treated and the control groups.

The data of urinalysis except for specific gravity and urine volume were assessed by Mann-Whitney's U test.

Mortality was analysed by Life table analysis.

The data of clinical sign (main group only), ophthalmology, necropsy, and histopathology were evaluated by Fisher's exact probability test.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS

The coefficient of variation for the homogeneity of the test substance for each dose level was 2.2 % and less. Hence, the results indicated a good homogeneity.

Analyses for concentrations showed that the diet preparations achieved 97 - 98 % of the target concentration. Thus, the concentrations of the test substance in the test diets were within acceptable limits.

B. MORTALITY AND CLINICAL SIGNS

In the high dose group neither sex showed an increase in mortality. Mortality in males was lower than the control during the last half of the treatment period with statistical significance in most of the weeks. In all other groups mortality was comparable to control. The final mortality is given in **Table 5.5-23**:

Table 5.5-23 HR-001: 24-Month Oral Chronic Toxicity and Oncogenicity Study in Rats ([redacted], 1997): Final mortality at termination of treatment (%)

Sex	Dose group (ppm)*			
	0	3000	10000	30000
Male	32/50 (64)	30/50 (60)	32/50 (64)	21/50 (42)
Female	35/50 (70)	31/50 (62)	34/50 (68)	36/50 (72)

* number of mortalities / total number of rats/group (% mortality)

C. CLINICAL OBSERVATIONS

In the high dose group, significant increases in incidence of bradypnea, mass, and soiled fur were observed in males when compared to the control. Analysis of location of each mass showed that the ones in the tail were present in 27 males, which was apparently high in incidence compared to 11 of the control. The incidences of mass in other locations were comparable to the control. With respect to soiled fur, the sign was located at the external genital or perianal region. Males in this group also showed significant decreases in incidence of tactile hair loss, wound, and hair loss. In females, a significant increase in incidence of wetted fur was observed; the sign was mainly seen in the external genital region. Besides the signs mentioned above, loose stool was observed in all cages of this group from Week 24 in males and Week 23 in females until the end of the treatment. Animals showing loose stool could not be identified because of group housing, therefore the sign is only described here in the text but not included in the table below.

In the mid dose group, the incidence of tactile hair loss was significantly decreased in males and significantly increased in females when compared to the respective control.

In the low dose group, significant increases in incidence of decreased spontaneous motor activity,

bradypnea, and soiled fur and a significant decrease in incidence of tactile hair loss were observed in males. Analysis of location of the soiled fur demonstrated predominant occurrences of the sign in the external genital region and foreleg. Females in this group showed significant increases in incidence of ptosis and tactile hair loss.

D. BODY WEIGHT

In the high dose group, body weights were lower than the control throughout the treatment period; significant decreases in their body weights were observed during Weeks 1 to 80 in males and at Week 7 and during Weeks 9 to 60 in females. The final group mean body weights of males and females at termination of the treatment period were both 93 % of the respective control.

In the mid dose group, males showed a decreased body weight gain during the first few weeks of treatment with a statistically significant difference from the control at Week 6. Their retarded growth persisted throughout the treatment period, and the final group mean body weight at termination of treatment was 95 % of the control. Body weight change in females was comparable to the control throughout the treatment period.

In the low dose group, body weights of both sexes were comparable to the control except for a significant increase in females at Week 16.

E. Food consumption and compound intake

In the high dose group, consistent with the decreasing body weight or decreasing body weight trends, food consumption showed a decreasing trend in males during the first few weeks.

In the other groups, food consumption in males and females was comparable to the respective control.

Table 5.5-26 HR-001: 24-Month Oral Chronic Toxicity and Oncogenicity Study in Rats ([redacted], 1997): Summary of food consumption data (g)

G. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematological and blood biochemical analyses did not demonstrate apparent toxicity of the test substance in either sex or group. The increase of haematocrit and decrease of platelet count is considered incidental and partly due to very low (RBC parameters) or high (platelets) control values when compared to other time points. These changes were only observed in one sex, at one time point and without any dose-response relationship. Compared to the control haematocrit values were 108 %, 111 % and 131 % for males and 99 %, 84 % and 96 % for females in the 3000, 10000 and 30000 ppm dose groups. No changes of these parameters have been observed at the other time points.

Statistically significant changes in haematology and blood chemistry are displayed in the tables below.

Table 5.5-29 HR-001: 24-Month Oral Chronic Toxicity and Oncogenicity Study in Rats ([redacted], 1997): Statistically significant changes in haematology

* Statistically significant ($p \leq 0.05$) ; * Statistically significant ($p \leq 0.01$); numbers in brackets represent the animal numbers of the respective endpoint different from 10 animals per group

G. URINALYSIS

Urinalysis did not demonstrate apparent toxicity of the test substance in either sex or group. Statistically significant changes in urinalysis parameters are displayed in **Table 5.5-31**. Data on time points other than 104 weeks were only included in the table below in case of any differences to the 104 week time point.

* Statistically significant ($p \leq 0.05$) ; * Statistically significant ($p \leq 0.01$); numbers in braces represent the animal numbers of the respective endpoint different from 10 animals per group

Metabolism of glyphosate after absorption from the intestine is minimal. Thus, most of the glyphosate is excreted *via* urine as the unchanged parent compound. In the urine glyphosate dissociates into the free acid, which can lead to a reduction of the urinary pH. Therefore, the reduced urinary pH might be of no toxicological significance.

H. NECROPSY

In the high dose group significant increases in incidence of distension of the caecum were observed in both sexes, accompanied by soiled fur in the perianal region in males. Moreover, significant increases in absolute and relative weights of the caecum in both sexes in the high and mid dose group were seen, but not associated with histopathological abnormalities (Tables below).

The incidences of thickened areas in the skin of the tail, corresponding to the tail mass in the clinical observations, were significantly increased in the mid and high dose group. The lesion was diagnosed as follicular hyperkeratosis and/or folliculitis/follicular abscess. An increased incidence of hair loss was also observed in high-dosed females, but it lacked corresponding histopathological changes (Table 5.5-36).

From this, it is concluded that the test compound at the doses tested does not cause treatment or dose related gross and histopathological changes and it is not carcinogenic under the testing conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In conclusion, HR-001 was not carcinogenic in the Sprague-Dawley rats following continuous dietary exposure of up to 30000 ppm for 24 months. The NOAEL for toxicity is 3000 ppm, corresponding to 104.0 mg/kg bw/day for males and 114.7 mg/kg bw/day for females.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/005
Report author	[redacted]
Report year	1996
Report title	Combined Chronic Toxicity and Carcinogenicity Study with Glyphosate Technical in Wistar Rats
Report No	886.C.C-R
Document No	Not reported
Guidelines followed in study	OECD 453 (1981)
Deviations from current test guideline (OECD 453, 2018)	Yes, individual animals exceed the 20 % range in body weight; mortality was observed only once per day (instead of twice per day); haematological parameters: prothrombin time, activated partial thromboplastin time, reticulocyte count were not observed; clinical chemistry: P, Cl, Na, K, cholesterol, bilirubin, creatinine, T3, T4 and TSH were not observed; urinalysis: osmolality/spec gravity and occult blood was not determined; organ weights of epididymis, heart, spleen, thyroid/parathyroid and uterus were not determined. Histopathological examination of the Harderian gland, cervix, coagulating glands, gall bladder, lacrimal gland, rectum and vagina was not performed. An evaluation with regards to historical control data was provided in the study report by the study director.
Previous evaluation	Yes, accepted in the RAR (2015).
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity and carcinogenic potential of glyphosate technical was assessed in a 24-month feeding study in male and female Wistar rats. Groups of 50 rats per sex received daily dietary doses of 0, 100, 1000, and 10000 ppm glyphosate technical (equivalent to mean achieved dose levels of 0, 7.4, 73.9 and 764.8/740.6 mg/kg bw/day for 12/24 months respectively). In addition, one vehicle control with ten rats per sex and one high dose group with 20 rats per sex were included for interim sacrifice at the 12th month to study non-neoplastic histopathological changes. Observations covered clinical signs, body weight, food consumption, haematology, clinical chemistry and urinalysis, as well as organ weights, necropsy and histopathological examination.

There were no treatment-related deaths or clinical signs in any of the dose-groups. Moreover, there were no treatment-related effects on body weight gain or food consumption. All dose- or treatment-related significant changes observed in haematological, biochemical parameters as well as the urinalysis were within the range of the historical control data and hence appear to be of no biological significance.

Gross pathology, organ weight data and histopathological examination demonstrated no treatment-related and dose-dependent effects.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	White odourless crystals
Lot/Batch #:	60; 046
Purity:	96.8 %; 96 %
Stability of test compound:	More than two years at ambient temperature
2. Vehicle and/ or positive control:	Diet
3. Test animals:	
Species:	Rat
Strain:	Wistar
Source:	[redacted]
Age:	6 weeks
Sex:	Males and females
Weight at dosing:	Males: 90 – 179 g, females: 80 – 151 g
Acclimation period:	At least one week
Diet/Food:	Standard "Gold Mohur" (M/S Lipton India Ltd, India), *ad libitum*
Water:	Deep bore well water treated with charcoal filter and UV rays, *ad libitum*
Housing:	Initially in groups of five per sex in polypropylene cages and in groups of three from Week 12 onwards.
Environmental conditions:	Temperature: 19 - 25 °C Humidity: 40 - 70 % Air changes: not reported 12 hours light/dark cycle

B: Study design and methods

In life dates: 1992-03-04 to 1994-03-04

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 50 Wistar rats per sex received daily dietary doses of 0, 100, 1000 and 10000 ppm (equivalent to mean achieved dose levels of 0, 7.4, 73.9 and 740.6 mg/kg bw/day for 24 months respectively) glyphosate technical. In additional one vehicle control with ten rats per sex and one high dose group with 20 rats per sex were included for interim sacrifice at the 12th month to study non-neoplastic histopathological changes.

Test diets were prepared fortnightly by mixing a known amount of the test substance with a small amount of basal diet. This pre-mix was then added to larger amount of basal diet and blended for further 20 minutes. The stability of the test substance in food was determined at day 1, day 15 and day 30 in an in-house stability study at 2000 and 20000 ppm. It was stated that homogeneity of samples was also determined but no results were provided.

Observations
Veterinary examination was made before and after grouping and at the end of each month of experimental schedule. Rats were examined for toxic signs and pre-terminal deaths once a day. Ophthalmic examination

was done at the start of the study and at termination.

Body weight
Individual body weights were recorded before dosing, at weekly intervals until the end of week 13 and every 4 weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded once weekly for each cage group from Week 1 to Week 13 and subsequently over one week in every 4 weeks until termination.

Haematology and clinical chemistry
Haematology
Individual blood samples were collected from 20 rats/sex/group at 3, 6, 12, 18 and 24 months. The following parameters were measured: Haemoglobin, haematocrit, erythrocyte count, clotting time and total leukocyte count and differential leukocyte count.

Blood chemistry
At the scheduled intervals of 6, 12, 18 and 24 months, blood collected from 10 rats/sex/group was subjected to clinical chemistry analysis. The following parameters were measured: Total proteins, albumin, ALT, AST, GGT, ALP, blood urea nitrogen and blood glucose.

Urinalysis
Individual urine samples were collected from 10 rats/sex/group at 3, 6, 12, 18 and 24 months. The following measurements were made: Volume, appearance, pH, nitrite, urobilinogen, bilirubin, erythrocytes, protein, glucose, ketones, microscopy of sediments.

Sacrifice and pathology
Histopathological examination was carried out on all tissues collected at interim sacrifice, control and high dose groups; all pre-terminally dead and moribund sacrificed rats of the low and mid dose groups and on all lesions of the terminally sacrificed rats from the low and mid dose groups.

The following organ weights were determined from 10 rats per sex per group: adrenals, brain, gonads, kidneys and liver.

Tissue samples were taken from the following organs: adrenals, aorta (main group animals), bone & bone marrow (sternum and femur incl. joint), brain, caecum, colon, duodenum, epididymides (main group animals), eyes (with optic nerve), heart, ileum, jejunum, kidneys, liver, lungs, mammary gland, lymph nodes (mesenteric, mandibular and mediastinal), muscle (femoral), oesophagus, ovaries, pancreas, pituitary, prostrate, rectum, salivary glands, sciatic nerve, seminal vesicles and coagulating glands, skin, spinal cord (cervical, thoracic and lumbar), spleen, stomach, testes, thymus, thyroid/parathyroid, trachea, tumour/mass, urinary bladder and uterus.

A detailed histopathological examination was performed on all sampled tissues of the control and high-dose animals, and on animals that died or were killed in extremis. In addition, gross lesions and masses from low and intermediate dose groups at termination were examined microscopically.

Statistics
Using specific computer programs, body weight, net body weight gain, food consumption, haematology, clinical chemistry and organ weight data of different groups were compared by Bartlett's test for homogeneity of intra group variances. When the variances proved to be heterogeneous, the data were transformed using appropriate transformation. The data with homogeneous intra group variances were subjected to one-way analysis of variance (ANOVA - Snedecor and Cochran, 1980). When 'F' value was significant, Dunnett's pair wise comparison (Scheffe, 1953) of means of treated groups with control mean was done individually.

Net food intake (g/kg bw/day) and test compound intake (mg/kg bw/day) was calculated for the whole study period using calculated means and food intake was statistically analysed by the procedure given above. Incidence of gross, histopathological changes of mass(es) and incidence of benign and malignant neoplasia in the treatment groups were statistically compared with control group by Z-test wherever it was applicable/necessary. The incidence of neoplasms was analysed by Cochran-Armitage linear trend test, Life table analysis for fatal tumour incidence and Peto's incidental tumour analysis.
When a significant difference to the control was observed in any of the treatment groups, the dose correlation co-efficient was estimated and subjected to t-test.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS

Analyses for achieved concentrations showed that the diet preparations of the control, low, mid- and high dose group were within an acceptable range. The mean achieved concentrations of the test substance of eight batches of the prepared test substance diets were 0.0, 99.1 ± 4.7, 995.3 ± 36.8 and 9993.1 ± 277.5 ppm, for the control, low, mid and high dose group, respectively.

B. MORTALITY

There were no treatment-related deaths observed during the study.
The numbers of pre-terminal deaths in the carcinogenicity study groups are displayed in the table below.

C. CLINICAL OBSERVATIONS

There were no treatment-related clinical signs of toxicity observed during the study.

D. BODY WEIGHT

There were no treatment-related effects on male and female overall body weight gain during the conduct of study. During the first weeks of exposure statistically significant decreases of body weights were observed in males only. As the slight reduction of body weight (<10 %) was only observed in males at the beginning of the study following no dose-response relationship it was considered no adverse effect.

* Statistically significant ($p \leq 0.05$)

The group mean achieved doses are summarised below.

Table 5.5-43 Combined Chronic Toxicity and Carcinogenicity Study with Glyphosate Technical in Wistar Rats ([redacted] 1996): Group mean achieved dose levels in the main groups

Dose group	Dietary concentration (ppm)	Mean achieved dose level (mg/kg bw/day)		
		Males	Females	Overall mean
1 (control)	0			
2 (low)	100	6.3	8.6	7.4
3 (mid)	1000	59.4	88.5	73.9
4 (high)	10000	595.2	886.0	740.6

The results show a higher test material intake for females when compared to males for each dose level. The mean intake for each dose group is 7.4, 73.9 and 740.6 mg/kg bw/day for 100, 1000, and 10000 ppm, respectively.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

The following significant dose related changes of the blood chemistry parameters were seen at the high dose:

decrease in GGT activity at 12 months in male rats
decrease in Albumin level at 6 months in female rats
increase in AP (alkaline phosphatase) activity at 6, 12 and 18 months in female rats. In the absence of further liver findings this is not considered to be an adverse effect.

ND not determined
* Statistically significant ($p \leq 0.05$)

No other dose or treatment related significant changes were observed in haematological, and biochemical parameters. These changes observed were only temporal and were not consistently seen at all sampling periods throughout the study. The dose related changes were also within the range of the historical control data and hence appear to be of no biological significance.

H. NECROPSY

Gross pathology

The incidence of liver lesions was increased in the high dose group males; three small mesenteric masses were seen in the males and females of the high dose group. The incidence of other changes was low and they appeared to be not related to the compound. Number of animals showing gross pathology changes was higher in high dose group compared to control group, this was especially due to findings in liver and lungs.

Organ weights

There were no treatment-related findings observed in organ weights or relative organ weights.

Pathology and Histopathology

None of the significant microscopic changes, both increased and decreased incidences (in liver, spleen, lymph nodes, adrenals, thymus, gonads, uterus, mammary gland) observed have shown dose relationship, hence appeared to be incidental and not related to the treatment with the test compound.

Cataract frequency was also comparable between control and dosing groups. Single incidences in the mid and high dose group were higher than in the control group, but were lacking a dose response relationship. Furthermore, when taking into account the physical examination of the eye (see table below) six control animals showed cataracts, meaning that 3 animals with cataract have not been evaluated at necropsy (possibly due to autolysis). Taking into account the physical examination no difference between control and dose group was observed. In addition, when taking into account damaged eye, cataract and corneal opacity no difference between control and dose groups was observed.

Neoplastic changes

The historical data on neoplasm incidence for the test species indicates that the incidences of various tumours observed in the present study are within the range. The types of tumours seen were also comparable to the historical records.

No statistically significant inter group difference between the control and low, mid and high dose treatment groups has been recorded in respect of the number of rats with neoplasms, number of malignant neoplasms and incidence of metastasis either by individual sex or for combined sex.

Incidentally, the number of benign tumours in the low and mid dose group males and combined sex was lower and higher in the mid dose group females. There was no dose-response relationship and therefore the occurrence of tumours was considered incidental.

The different liver tumours observed in the dead and moribund sacrificed and terminally sacrificed rats included hepatocellular adenoma, intrahepatic bile duct adenomas, cholangiocarcinoma, hepatocellular carcinoma, histiocytic sarcoma, fibrosarcoma and lymphosarcoma. Of these, hepatocellular adenomas and carcinomas occurred more frequently, as often observed in ageing rats. The occurrence of these tumours appeared to be incidental and not compound-related as their frequency of occurrence was not dose dependent. No reasons could be ascribed for the decrease in the number of benign tumours in the low and mid dose group males and for combined sex and for an increase seen in the mid group dose females (see

table above).

From this, it is concluded that the test compound at the doses tested does not cause treatment or dose related gross and histopathological changes and it is not carcinogenic under the testing conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Based on the study results the NOAEL in rats after chronic exposure to glyphosate technical for 24 month is 595 mg/kg bw/day for males, and 886 mg/kg bw/day for females (741 mg/kg bw/day for combined) for systemic toxicity and carcinogenicity. It is concluded that glyphosate technical is not carcinogenic in rats.

Single and inconsistent changes of clinical chemistry parameters were considered not treatment-related. (Isolated) Elevation of alkaline phosphatase activities is considered to be related to an adaptation of the metabolism rather than to damage of (liver) cells. Histopathology did not reveal any treatment-related changes in any organ further supporting the conclusion that clinical chemistry parameters changes were not related to treatment-related adverse effects.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/006
Report author	[redacted]
Report year	1996
Report title	Glyphosate Acid: One Year Dietary Toxicity Study in Rats
Report No	[redacted]/P/5143
Document No	Not reported
Guidelines followed in study	OECD 452, US EPA 83-1
Deviations from current test guideline (OECD 452, 2018)	Yes, mortality was observed only once per day (instead of twice per day); blood samples were not taken at the beginning of the study (but in week 14); organ weights of heart, ovaries, spleen, thyroid/parathyroid and uterus were not determined. Histopathological examination of the coagulating glands, gall bladder, lacrimal gland, mammary glands of the males and vagina was not performed. No historical control data available.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity potential of glyphosate acid was assessed in a 12-month feeding study in 24 male and female Wistar rats per group with 0, 2000, 8000 and 20000 ppm (equivalent to mean achieved dose levels

of 0, 141, 560 and 1409 mg/kg bw/day for males and 0, 167, 671 and 1664 mg/kg bw/day for females).

Observations covered clinical signs, body weight, food consumption, haematology, clinical chemistry and urinalysis as well as selected organ weights, necropsy and histopathological examination.

A reduction in bodyweight was evident in animals receiving 20000 ppm glyphosate acid, together with a marginal reduction in bodyweight in rats receiving 8000 ppm. There were no toxicologically significant or treatment-related effects on haematology, blood and urine clinical chemistry or organ weights.

The treatment-related pathological finding, increased incidence of mild focal basophilia of the acinar cells of the parotid salivary gland in both sexes which had received 20000 ppm glyphosate acid, is considered an adaptive response due to oral irritation from the ingestion of glyphosate, an organic acid, in the diet.

I. MATERIALS AND METHODS

A. Materials

1. Test material:

Identification:	Glyphosate acid
Description:	White solid
Lot/Batch #:	P24
Purity:	95.6 %
Stability of test compound:	At least 1 year when stored at RT
2. Vehicle and/ or positive control:	Diet
3. Test animals:	
Species:	Rat
Strain:	Wistar (Alpk:APfSD)
Source:	[redacted]
Age:	22 - 24 days (on delivery)
Sex:	Males and females
Weight at dosing:	Males: 150.5 – 151.5 g (mean values); females: 126.7 – 133.3 g (mean values)
Acclimation period:	Approximately 2 weeks
Diet/Food:	CT1 diet (Special Diet services Ltd., Essex, UK), *ad libitum*
Water:	Mains drinking water, *ad libitum*
Housing:	Initially in litters, sexes separately, after assignment to experimental groups in group of four rats per sex per cage.
Environmental conditions:	Temperature: 21 ± 2 °C Humidity: 55 ± 15 % Air changes: at least 15/hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1995-04-03 to 1996-06-03

Animal assignment and treatment:
In a chronic toxicity study groups of 24 Wistar-derived rats per sex received daily dietary doses of 0, 2000, 8000 and 20000 ppm glyphosate acid (equivalent to mean achieved dose levels of 0, 141, 560 and 1409 mg/kg bw/day for males and 0, 167, 671 and 1664 mg/kg bw/day for females).

Test diets were prepared in either 30 or 60 kg batches by mixing the appropriate amount of the test substance with the basal diet. The stability and homogeneity of the test substance in the diet was determined in an in-house stability study at 2000 and 20000 ppm.

Observations
Rats were examined for toxic signs, ill-health or behavioural changes and pre-terminal deaths prior to the start of the study and once a day afterwards. Detailed clinical observations were conducted weekly. Ophthalmic examination was done in all animals at the start of the study. The eyes of the control and high dose group were additionally examined one week to termination.

Body weight
Individual body weights were recorded prior to start of treatment, at weekly intervals from Week 1 to 14 and every two weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded once weekly for each cage group from Week 1 to Week 13, once in Week 16 and every fourth week thereafter.

Haematology and clinical chemistry
Blood was collected from 12 animals per sex and group at Week 14, 27 and at termination (Week 53). The following parameters were measured: Haematocrit, haemoglobin, erythrocyte count, MCV, MCH, MCHC, blood cell morphology, platelet count, total leukocyte count, differential leukocyte count, red blood cell distribution width, prothrombin time, activated partial thromboplastin time, alkaline phosphatase, aspartate amino transferase (AST), alanine aminotransferase (ALT), γ-glutamyl-transferase, creatine kinase, creatinine, urea, total protein, glucose, albumin, total bilirubin, triglycerides, total cholesterol, inorganic phosphorus, calcium, sodium, potassium, and chloride.

Urinalysis
Individual urine samples were collected from the same animals as those used for haematology analyses (except for Week 52) at Week 13, 26 and 52. The following parameters were determined: Volume, colour, appearance, specific gravity, pH, glucose, ketones, protein, urobilinogen and blood.

Sacrifice and pathology
Necropsy was conducted on all animals except for Rats 38 and 149-152, which were killed during Week 6/7 due to a sexing error. The following organ weights were determined from all animals surviving to scheduled termination: Adrenals, brain, epididymis, kidneys, liver and testes.

Tissue samples were taken from the following organs: Adrenals, aorta, bone & bone marrow (femur incl. joint), brain (cerebrum, cerebellum, brainstem), caecum, cervix, colon, duodenum, epididymis, eye, gross lesions, Harderian gland, heart, ileum, jejunum, kidneys, liver, lung, lymph nodes (cervical and mesenteric), mammary gland, nasopharyngeal cavity, sciatic nerve, oesophagus, oral cavity, ovary, pancreas, pituitary, prostrate, rectum, salivary glands, seminal vesicles, skin, spinal cord (cervical, thoracic, lumbar), spleen, sternum, stomach, testes, thymus, thyroid/parathyroid, trachea, urinary bladder, uterus and voluntary muscle.

Statistics
All data were evaluated using analysis of variance and covariance for each specified parameter using the GLM procedure in SAS (1989). Differences from control were tested statistically by comparing each

treatment group least- squares mean with the control group least-squares mean using a two-sided Student's t-test, based on the error mean square in the analysis. All statistical tests were two sided.

II. RESULTS

The mean achieved concentrations of glyphosate acid in each dietary preparation were within 8 % of the nominal concentration and the overall mean concentrations were within 4 % of nominal.

The homogeneity of glyphosate acid in diet at concentrations of 2000 and 20000 ppm was satisfactory; percentage deviations were within 7 % of the overall mean.

The stability tests determined at 2000 and 20000 ppm showed that the test substance is stable for at least 61 days when stored at room temperature.

A. MORTALITY AND CLINICAL SIGNS

There were no treatment-related deaths.

Table 5.5-56 Glyphosate Acid: One Year Dietary Toxicity Study in Rats ([redacted], 1996): Unscheduled deaths

B. CLINICAL OBSERVATIONS

There was a small increase in the number of animals in the 20000 ppm group which had urinary staining (wet or dry). All other clinical observations were of a type and incidence expected for rats of this strain.

C. BODY WEIGHT

Bodyweights of rats receiving 20000 ppm glyphosate acid were lower than those of controls throughout the study. Bodyweights in the intermediate group were slightly reduced throughout the study. The difference from control was not statistically significant in males and was statistically significant in females only from Week 46. As the pattern of the effect was similar to that of the high dose rats for both sexes this minor

difference in bodyweight is considered to be related to administration of glyphosate acid.

There was no effect on bodyweight in rats receiving 2000 ppm glyphosate acid.

The intergroup comparison of body weights are shown below.

D. FOOD CONSUMPTION AND COMPOUND INTAKE

Food consumption was generally lower in rats receiving 20000 ppm than in controls. The difference was most marked at the start of the study. Food consumption was generally slightly lower than controls in rats receiving 8000 ppm glyphosate acid. There was no effect on food consumption in rats receiving 2000 ppm.

* Statistically significant from control ($p \leq 0.05$; Student's t-test, two-sided)
** Statistically significant from control ($p \leq 0.01$; Student's t-test, two-sided)

The group mean achieved doses are summarised below.

Table 5.5-60 Glyphosate Acid: One Year Dietary Toxicity Study in Rats ([redacted], 1996): Group mean achieved dose levels

Dose group	Dietary concentration (ppm)	Mean achieved dose level (mg/kg bw/day)	
		Males	Females
1 (control)	0		
2 (low)	2000	141	167
3 (mid)	8000	560	671
4 (high)	20000	1409	1664

The results show a higher test material intake for females when compared to males for each dose level. The mean intake for each dose group is 0, 141, 560 and 1409 mg/kg bw/day for males and 0, 167, 671 and 1664 mg/kg bw/day for females for 0, 2000, 6000 and 20000 ppm, respectively.

E. OPHTHALMOSCOPY

There were no treatment-related effects observed.

Table 5.5-61 Glyphosate Acid: One Year Dietary Toxicity Study in Rats ([redacted] 1996): Ophthalmoscopical findings

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

A number of statistically significant differences from control were identified but there was no evidence of a relationship to dose and the differences were small and not seen consistently at all the time points and therefore were considered to be unrelated to glyphosate acid administration.

Clinical chemistry
Plasma cholesterol and plasma triglycerides were marginally reduced in males receiving 20000 or 8000 ppm at Weeks 14 and 27.

Moreover, there was a treatment- and dose-related increase in plasma ALP activity throughout the study. For rats receiving 2000 ppm glyphosate acid the increase was marginal and was statistically significant only for females at Week 14. The increase in the activity of plasma ALP in animals at all dose levels was compound-related but as there was no accompanying pathological change in either the liver or bone this is considered not to be of toxicological significance.

All other differences from control were small and/or were not dose-related and are considered to be incidental to administration of glyphosate acid.

Histopathology

An increased incidence and severity of focal basophilia of the acinar cells of the parotid salivary gland were seen in both sexes receiving 20000 ppm glyphosate acid. This effect was also evident in females receiving 8000 ppm. This change was considered to be related to treatment and consequently the salivary glands of the 8000 ppm dose group were examined. The examples of focal parotid basophilia seen at this dose were all of minimal severity and the incidence was comparable to that in the control group.

All other observed differences in the incidence of findings are considered to be unrelated to the treatment with glyphosate acid in view of the spontaneous incidence in this strain. No treatment-related neoplasms

were found.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Based on body weight and salivary gland effects at 20000 ppm, the NOAEL for toxicity for glyphosate acid was 8000 ppm equivalent to 560 mg/kg bw/day in males and 671 mg/kg bw/day in females. There was no evidence of carcinogenicity.At the mid dose, effects on the acinar cells of the parotid salivary gland were slightly increased (minimal severity) in females only. These effects when occurring at a minimal severity are generally considered adaptive being due to pH changes of the glyphosate acid. The body weight reduction was neither dose nor time-dependent. The effects on body weight was furthermore rather low at the mid dose level (<10 %) at most time points. The higher alkaline phosphatase activity at 8000 and 20000 ppm is not considered an adverse effect as no other enzyme activities were affected indicative of organ damage. Furthermore, histopathology did not indicate any damage of organs, e.g. liver. No indication of neoplastic changes was observed.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/007 CA 5.5/008 CA 5.5/009
Report author	[redacted]
Report year	1993
Report title	Glyphosate – 104 week combined chronic feeding/oncogenicity study in rats with 52 week interim kill (results after 104 weeks)
Report No	7867
Document No	153-GLY
Guidelines followed in study	US-EPA Pesticide Assessment Guidelines Subdivision F, 83-5 (1982); in general compliance with OECD 453
Deviations from current test guideline (OECD 453, 2018)	Yes, haematological examination of the mean corpuscular volume (MCV), the mean corpuscular haemoglobin (MHC), mean corpuscular haemoglobin concentration (MCHC), prothrombin time and activated partial thromboplastin time (APTT) were not performed; urinalysis was performed without determining glucose; organ weight of the thyroid/parathyroid was not determined; histopathological examinations were performed without Harderian gland, cervix, coagulating glands, gall bladder, gross lesions, lacrimal glands, upper respiratory tract, seminal vesicles and vagina.
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity and carcinogenic potential of glyphosate technical was assessed in a 104-week feeding study in male and female Sprague-Dawley rats. Groups of 50 rats per sex received daily dietary doses of 0,

10, 100, 300 or 1000 mg/kg bw/day glyphosate technical for 24 months. In addition, five groups of 35 rats/sex, receiving daily dietary doses of, 0, 10, 100, 300 or 1000 mg/kg bw/day, were included for interim sacrifice at the 12th month for evaluation of chronic toxicity. Observations covered clinical signs, body weight, food and water consumption, ophthalmoscopy, haematology, clinical chemistry and urinalysis, as well as organ weights, necropsy and histopathological examination.

Achieved doses throughout the study period were generally close to nominal. There were no treatment-related deaths or clinical signs in any of the dose-groups. Ophthalmoscopic examinations showed no inter-group differences. At 1000 mg/kg bw/day males and females had statistically significant reductions in body weight throughout the study. Reductions started at week one of dosing and were still apparent at week 104. The high-dose group males displayed the greatest reduction in body weights. Food and water consumption did not differ significantly from the controls. Moreover, there were no treatment-related changes in haematological parameters. Clinical chemistry evaluation indicated a treatment-related increase of ALP in males of the 1000 mg/kg bw/day dose group and females of the 100, 300 and 1000 mg/kg bw/day dose groups, as well as reduced urinary pH in males at 1000 mg/kg bw/day.

At necropsy no treatment-related gross lesions were observed. Organ weight data showed reduced liver weights in females at 100, 300 and 1000 mg/kg bw/day at interim kill in week 52, but not after 104 weeks. At week 52 salivary gland weights were increased in 100, 300 and 1000 mg/kg bw/day dose group males. Combined sublingual and submaxillary gland weights were also increased in males and females treated with 1000 mg/kg bw/day. However there were no significant inter-group differences by week 104. Histopathological examination noted cellular alteration of in submaxillary and parotid salivary glands in males and females of the 300 and 1000 mg/kg bw/day dose groups (week 52) and the 100, 300 and 1000 mg/kg bw/day dose groups of both sexes at week 104. These changes followed a dose-related pattern and are considered treatment related. However, these cellular alterations are similar to those seen occasionally in other subchronic or long-term studies and are considered to be an adaptive response to acidic diet and are of no adverse consequence.

No treatment-related neoplastic lesions were observed at termination.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	White powder
Lot/Batch #:	229-JaK-5-1; 229-Jak-142-6
Purity:	98.9 %; 98.7 %
Stability of test compound:	At least two years at ambient temperature in the dark
2. Vehicle and/ or positive control:	Diet
3. Test animals:	
Species:	Rat
Strain:	Sprague-Dawley
Source:	[redacted]
Age:	Approx. 4 weeks upon arrival at testing facility
Sex:	Males and females
Weight at dosing:	Males: 208 ± 1.9 g, females: 148.5 ± 1.6 g

Acclimation period:	14 days
Diet/Food:	SQC Expanded (Fine Ground) Rat and Mouse Maintenance Diet No. 1 (Special Diet Services Limited, UK), *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	In groups of five per sex in suspended polypropylene cages with stainless steel wire grid tops and bottoms
Environmental conditions:	Temperature: 20 ± 2 °C Humidity: 55 ± 10 % Air changes: 15 - 20 / hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1990-02-16 to 1992-03-09

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 50 Sprague-Dawley rats per sex received daily dietary doses of 0, 10, 100, 300 or 1000 mg/kg bw/day glyphosate technical. An additional five groups with 35 rats per sex receiving daily dietary doses of 0, 10, 100, 300 or 1000 mg/kg bw/day were included for the toxicity study. Fifteen rats per sex and per dose of the toxicity study were scheduled for interim sacrifice after 12 months. The dose levels were selected based on the results of a 13-week dietary toxicity study in rats.

Test diets were prepared once per week for the first 13 weeks and at least once every two weeks thereafter by direct admixture of the test substance to the plain diet and mixing for 20 minutes.

Analyses for achieved concentrations of the test substance in the diet were conducted from formulated diets at approximately fortnight intervals for the first 12 weeks and in intervals of 2 month thereafter.

The stability and homogeneity of the test substance in the diet was determined prior to the start of the study.

Clinical observations
A check for mortality was made twice daily on all animals throughout the study. In addition, all animals were examined for clinical signs during each day. A detailed clinical examination and check for palpable masses were done once each week on every animal. An ophthalmoscopic examination was conducted on 20 rats per sex of each group of the oncogenicity study before the start of the study and on 20 rats per sex of the control and high-dose group of the oncogenicity study at weeks 24 and 50. In addition, an ophthalmoscopic examination was conducted on all control and high-dose rats of the oncogenicity and toxicity study at week 102.

Body weight
Individual body weights were recorded for each animal before dosing, at weekly intervals until the end of week 13 and approximately every 4 weeks thereafter until termination.

Food and water consumption and compound intake
Food consumption was recorded once weekly for each cage group starting one week before treatment until Week 13 and subsequently every 4 weeks until termination. Water consumption was monitored by visual inspection throughout the study period.

Achieved dosages were calculated from nominal dietary concentration, taking into account actual food consumption and body weight data.

Haematology and clinical chemistry
Individual blood samples for haematology and clinical chemistry evaluations were collected from the orbital sinus of 10 rats/sex of each study group of the toxicity study after approximately 14, 25, 51, 78 and 102 weeks. Samples were taken where possible, on the same animals at each time point. Individual blood smears for differential blood counts were taken from the tail vein after approximately 52, 78, and 103 weeks of dosing from all surviving animals of the oncogenicity study.

Haematology
The following parameters were measured: Haemoglobin, haematocrit, total erythrocyte count total leukocyte count, differential leukocyte count, platelets, and clotting time. Absolute indices were calculated. Differential blood counts were evaluated with blood smear samples from all control and high-dose animals of the oncogenicity study at weeks 53 and 79. In addition, differential blood cell counts were evaluated on all surviving animals of the oncogenicity study at week 104.

Blood chemistry
The following parameters were measured: Total proteins, albumin, albumin-globulin ratio, ALT, AST, ALP, blood urea nitrogen, blood glucose, sodium, potassium, chloride, cholesterol, creatinine, calcium, phosphate, total bilirubin, plasma cholinesterase, creatine phosphokinase and red blood cell cholinesterase.

Brain cholinesterase activity determination
Brain cholinesterase activity was determined from 10 rats per sex from each dose group at the week 52 and 104 necropsies. Approximately 0.5 g of brain was removed at the week 52 and 104 necropsies and stored at -20 °C until analysis.

Urinalysis
Individual urine samples were collected from 10 rats/sex of each study group of the toxicity study after approximately 14, 25, 51, 78 and 102 weeks. Samples were taken where possible, on the same animals at each time point. Samples were collected over a period of 4 hours of food and water deprivation in metabolism cages. The following measurements were made: volume, specific gravity, pH, urobilinogen, bilirubin, blood pigments, protein, glucose, ketones, microscopy of sediments.

Sacrifice and pathology
At interim kill after 52 weeks 15 rats per sex from each toxicity study group were sacrificed and necropsied. All remaining toxicity study and surviving oncogenicity study animals were killed and necropsied after 104 weeks. All pre-terminally dead and moribund sacrificed rats were also necropsied.

The following organs were weighed from all interim kill animals of the toxicity study and from 10 rats per sex per group of the oncogenicity study: adrenals, brain, heart, kidneys, liver, lungs, ovaries (with fallopian tubes), parotid salivary glands, pituitary, prostrate, sublingual and submaxillary salivary glands (weighed together), spleen, testes including epididymides, thymus and uterus.

The following organs were collected: adrenals, aortic arch, any abnormal tissue, bladder, bone and bone marrow (sternum and rib), brain, ears, eyes, intestine (duodenum, jejunum, ileum, caecum, colon, rectum), kidneys, liver, lungs, mammary gland, lymph nodes (mesenteric and submandibular), muscle (thigh), nasal cavity (oncogenicity study only), oesophagus, optic nerve, ovaries (with fallopian tubes), pancreas, parotid salivary glands, pituitary, prostrate, sciatic nerve, seminal vesicles, skin, spinal cord (cervical, thoracic and lumbar), spleen, stomach (glandular and non-glandular), sublingual salivary glands, submaxillary salivary glands, testes with epididymides, thymus, thyroid/parathyroid, tongue, trachea, uterus and vagina.

A detailed histopathological examination was performed on all tissues collected from the control and high-dose animals at interim kill, all oncogenicity study animals, and all animals that died or were killed in extremis. In addition, a histopathological examination of the liver, kidneys and lungs was performed on all other toxicity study animals at interim kill and all oncogenicity study animals. Furthermore, the salivary glands of all low- and mid-dose animals at interim kill and the oncogenicity study were examined.

Statistics
Haematology, clinical chemistry, organ weight and body weight data were analysed for homogeneity of variance using the F-max test. If the group variances appeared homogeneous a parametric ANOVA was used and pair wise comparisons made *via* Student's t-test using Fisher´s F-protected LSD. If the variances were heterogeneous log or square root, transformations were used. If the variances remained heterogeneous a non-parametric test (e.g. Kruskal-Wallis ANOVA) was used. Organ weights were also analysed conditional on body weight (i.e. ANOVA). Differences in survival between the control and test substance groups from the oncogenicity study were assessed graphically using Kaplan-Meier plots and tested formally using the Gehan-Wilcoxon test. Because no notable survival differences were evident, histological lesion incidences were analysed using Fisher Exact test.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
Analyses for achieved concentrations showed that the diet preparations of all dose groups were within an acceptable degree of accuracy (± 10 %).

B. MORTALITY
There were 336 pre-terminal deaths throughout the study. There was no evidence to suggest that any of these deaths were treatment-related. There were also no significant treatment-related effects on the survival times in the oncogenicity study.

The numbers of pre-terminal deaths are summarised in the table below.

Table 5.5-70 Glyphosate – 104 week combined chronic feeding / oncogenicity study in rats with 52 week interim kill (results after 104 weeks) ([redacted] 1993): Cumulated mortalities after 104-week dietary exposure to glyphosate technical

Sex	Dose group (mg/kg bw/day)*				
	0	10	100	300	1000
Male	27/85	32/85	25/85	26/85	26/85
Female	42/85	41/85	42/85	40/85	35/85

* Number of dead / total number

C. CLINICAL OBSERVATIONS
The only notable clinical sign was pale faeces, from weeks 16-104, the majority or all the cages of animals (males and females) in the 300 and 1000 mg/kg /day dose groups had pale faeces. However, this clinical sign was not considered to be toxicologically significant. There were no other notable clinical signs considered to be treatment related.

Ophthalmoscopy examinations demonstrated no inter-group differences.

D. BODY WEIGHT
The high-dose group males and females had statistically significant reductions in body weight throughout the study. Reductions started at week one of dosing and were still apparent at week 104. The high-dose group males displayed the greatest reduction in body weights and body weight gains. The mean body weight gain data are summarised in the table below.

Table 5.5-71 Glyphosate – 104 week combined chronic feeding / oncogenicity study in rats with 52 week interim kill (results after 104 weeks) ([redacted] 1993): Body weight development (mean values) after 52 and 104-week dietary exposure to glyphosate technical – oncogenicity study

	Dose group (mg/kg bw/day)									
	0		10		100		300		1000	
	♂	♀	♂	♀	♂	♀	♂	♀	♂	♀
Weight gain (g) (0-52 weeks)	514	265	↓498	↑285	↑523	↑270	↓500	↑274	↓450	↓243
% of control	--	--	97	108	102	102	97	103	88	92

% of control	--	--	96	118	101	104	98	108	86	89

E. FOOD AND WATER CONSUMPTION AND COMOUND INTAKE

There were no treatment-related effects on food and water consumption for either sex noted during the study.
The overall group mean achieved doses are summarised in the table below.

Table 5.5-72 Glyphosate – 104 week combined chronic feeding / oncogenicity study in rats with 52 week interim kill (results after 104 weeks) ([redacted] 1993): Group mean achieved dose levels – oncogenicity study

Dose group	Nominal dose (mg/kg bw/day)	Mean achieved dose level (mg/kg bw/day)		Mean achieved dose level (% of nominal)	
		Males	Females	Males	Females
1 (control)	0	--	--	--	--
2 (low)	10	10	10	100	100
3 (mid I)	100	101	103	101	103
4 (mid II)	300	306	311	102	104
5 (high)	1000	1007	1018	101	102

Over the entire study duration the mean achieved dosages in all groups were close to the nominal.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

Haemoglobin, haematocrit and mean corpuscular haemoglobin were occasionally increased in 100 and 1000 mg/kg bw/day dose group males. Haemoglobin was also increased in males from the 300 mg/kg bw/day dose group and females from the 1000 mg/kg bw/day group. Females of the 1000 mg/kg bw/day dose group also had increased levels of mean corpuscular haemoglobin.

The haematological changes were not considered to be treatment related due to the lack of a clear dose–response relationship. In addition, the differences observed were rather small and no consistent trend became obvious throughout the study. In the absence of any histopathological change these small increases are not considered to be of toxicological significance (see table below).

Table 5.5-73 Glyphosate – 104 week combined chronic feeding / oncogenicity study in rats with 52 week interim kill (results after 104 weeks) ([redacted] 1993): Haematology findings (group mean values)

Clinical chemistry

Clinical chemistry measurements showed significant increased alkaline phosphatase levels in males at 1000 mg/kg bw/day and in females at 100, 300 and 1000 mg/kg bw/day. Although the increases were of small magnitude they were consistent and might be treatment-related. However, in the absence of any histopathological changes these small changes are not considered to be of toxicological significance. All other changes in clinical chemistry parameters were not considered to be treatment-related.

G. URINALYSIS

Urinary pH was slightly reduced in males at 1000 mg/kg bw/day. This change was consistent with that found in a previously conducted 13-week toxicity study with glyphosate.

H. NECROPSY

Gross pathology

There were no treatment-related macroscopic findings observed at the interim and terminal kill necropsies.

Organ weights

At the interim kill (week 52) absolute liver weights were reduced in males and females at doses of 100 mg/kg bw/day and above. However, for males this finding was not confirmed by the sensitive means of covariance analysis, i.e. with correction for final body weight. Absolute adrenal weights were reduced in males at 300 and 1000 mg/kg bw/day. However, this finding was also not confirmed by the sensitive means of covariance analysis, i.e. with correction for final body weight.

At the terminal kill (week 104) no statistical significant decrease in liver and adrenal weights was noted in any dose group. Absolute kidney weight was reduced in males at 100 and 1000 mg/kg bw/day after 104 weeks, but a clear dose relationship was lacking.

At 52 weeks parotid salivary gland weight was increased in males at 100, 300 and 1000 mg/kg bw/day. Combined sublingual and submaxillary gland weight was increased in high-dose males and females. However, salivary gland weights were not affected at week 104 at any dose level.

Histopathology

The most notable histological finding was seen in the salivary glands where cellular alteration was seen in submaxillary and parotid salivary glands in males and females at 300 and 1000 mg/kg bw/day at week 52, and in both sexes at 100, 300 and 1000 mg/kg bw/day at week 104. These changes followed a dose-related pattern and are considered to be treatment related; however, these cellular alterations are similar to those seen occasionally in other subchronic or long-term dietary studies and are considered an adaptive response due to oral irritation from the ingestion of glyphosate, an organic acid, in the diet and are of no adverse consequence (see discussion at the beginning of the section and CA 5.8.2/002; CA 5.8.2/003).

Another histopathological finding was a decreased incidence of nephropathy in males at 100, 300 and 1000 mg/kg bw/day at interim kill. This finding was also noted in high-dose males at 104 weeks, but with reduced severity. Nephropathy is a common finding in old rats and as the incidence is decreased this finding is not considered as toxicologically significant.

In addition, the decreased incidence of urothelial hyperplasia in high-dose females at week 52 and 104, as well as in females at 300 mg/kg bw/day at week 104, is also not considered to be of toxicological significance.

Neoplastic changes
Neoplastic lesions were seen in all dose groups, however there was no dose relationship in the incidence of any individual tumour or in the incidence of animals with tumours.

It is concluded that the test compound at dose levels up to and including 1000 mg/kg bw/day produced no carcinogenic effect.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In conclusion, glyphosate technical was not carcinogenic in male and female Sprague-Dawley rats following continuous dietary exposure of up to 1000 mg/kg bw/day (the limit dose for this type of study) for 104 weeks. Based on the study results and the lack of toxicological significance of the salivary gland findings, as well as a slight and isolated increase of plasma alkaline phosphatase observed at 300 mg/kg bw/day, the NOAEL in rats after chronic exposure to glyphosate technical for 104 weeks is considered to be 300 mg/kg bw/day.

Cellular alteration of the parotid/mandibular salivary gland was considered an adaptive response based on the addition of glyphosate acid to the diet. This effect is in concordance with findings in other studies with glyphosate acid as well as with citric acid (see CA 5.8.2/002). Furthermore, the effect on the salivary glands was not clearly dose related but may be following a threshold effect potentially related to pH changes. This assumption is also supported by the fact that the effects on the salivary glands were already observed after 52-weeks and did not increase in incidence or severity. Increased ALP activity is not considered an adverse effect as the increase was rather low, not accompanied but other liver enzymes and not related to any treatment-related histopathological changes in the liver. Furthermore, the liver weight was comparable between control and treatment groups.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/010
Report author	[redacted]
Report year	1990
Report title	Chronic study of glyphosate administered in feed to Albino rats
Report No	[redacted]-10495
Document No	M-651388-02-1
Guidelines followed in study	US-EPA Pesticide Assessment Guidelines Subdivision F, 83-5 (1982); in general accordance with OECD 453
Deviations from current test guideline (OECD 453, 2018)	Animals were approximately 8 weeks old at study begin (not >8 weeks); the top dose of the females exceeded 1000 mg/kg bw/day; haematological examinations were performed without prothrombin time and activated partial thromboplastin time; clinical chemistry was performed without gamma glutamyl transpeptidase or ornithine decarboxylase; volume of the urine was not determined; organ weights of adrenals, heart, ovaries, spleen, thyroid/parathyroid and uterus were

	not recorded; histopathological examinations of the coagulating glands, gall bladder, lacrimal glands, upper respiratory tract, mammary glands and vagina were not performed; overall survival at termination was below 50 %). Historical control attached for histopathological examinations.
Previous evaluation	Yes, accepted in the RAR (2015).
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The chronic toxicity and carcinogenic potential of glyphosate was assessed in a 24-month feeding study in 50 male and 50 female Sprague-Dawley rats with 0, 2000, 8000 and 20000 ppm (equivalent to mean achieved dose levels of 0, 89, 362 and 940 mg/kg bw/day for males and 0, 113, 457 and 1183 mg/kg bw/day for females). In addition, 10 rats per sex per dose were included for interim sacrifice after 12 month. Observations covered clinical signs, ophthalmic examinations, body weight, food consumption, haematology, clinical chemistry and urinalysis as well as organ weights, necropsy and histopathological examination.

There were no treatment-related effects on survival, clinical signs, food consumption, and haematology and clinical chemistry parameters. Observed increased urine specific gravity, decreased urinary pH, as well as increased absolute and relative liver weights in high-dose males were not considered to be of toxicological significance, since there were no correlated findings in clinical chemistry or histopathology. Increased incidences of inflammation of the stomach mucosa in mid-dose females, and pancreatic islet cell adenomas in low-dose males were not dose-related and considered incidental findings.

Treatment-related findings in this study were statistically reduced body weights in high-dose females, as well as increased incidences of cataractous lens changes in high-dose males. There was no evidence of a carcinogenic effect observed in any dose group of either sex.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate
Description:	White solid
Lot/Batch #:	XLH-264
Purity:	96.5 %
Stability of test compound:	Guaranteed for the study period. Confirmed by analysis.

2. Vehicle and/or positive control: Diet

3. Test animals:

Species:	Albino Rat
Strain:	Sprague-Dawley (CD)
Source:	[redacted]
Age:	Approx. 8 weeks (at start of study)

Sex:	Males and females
Weight at dosing:	Males: approx. 284 g; females: approx. 221 g
Acclimation period:	29 days
Diet/Food:	Purina Mills certified Rodent Chow #5002 (Purina Mills), *ad libitum*
Water:	Mains drinking water, *ad libitum*
Housing:	In stainless steel cages with wire mesh bottoms suspended over paper bedding
Environmental conditions:	Animal housing & husbandry were in accordance with the provisions of ´Guide to the Care and Use of Laboratory Animal´; USPHS-NIH Publ. No. 85-23 Temperature: 17.8 - 21.1 °C Humidity: 40 - 70 % Air changes: not specified 12 hours light/dark cycle

B: Study design and methods

In life dates: 1987-08-05 to 1989-08-10

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 50 Sprague-Dawley rats per sex received daily dietary doses of 0, 2000, 8000 and 20000 ppm glyphosate (equivalent to mean achieved dose levels of 0, 89, 362 and 940 mg/kg bw/day for males and 0, 113, 457 and 1183 mg/kg bw/day for females) for 24 months.

A further ten animals per sex were added to each group and were designated for interim kill after 12 month to study chronic toxicity and non-neoplastic histopathological changes.

	Dose (ppm)							
	0		2000		8000		20000	
	♂	♀	♂	♀	♂	♀	♂	♀
Compound intake (mg/kg bw/d)	0	0	89	113	362	457	940	1183
Main group (# of animals)	50	50	50	50	50	50	50	50
Interim kill (# of animals)	10	10	10	10	10	10	10	10

Test diets were prepared in approximately weekly intervals by mixing a known amount of the test substance with basal diet. The stability of the dietary formulations were determined by analysis of samples of the low- and high-dose levels after storage at room temperature for 7 and 14 days, and frozen after storage for 35 days. The homogeneity of the test substance in the diet was determined for the low- and high-dose level preparations in the first and 88th week of the study. Analyses for achieved concentrations were done for all dose levels for the first six weeks, and for at least one dose level in weekly intervals thereafter. The stability of the neat test substance was verified by analysis before the start of the study, during month 8, 14 and 21, and after termination.

Clinical observations
All rats were examined for mortality and clinical signs of toxicity twice daily. Detailed clinical observations were conducted weekly. An ophthalmic examination was done in all animals before the start of the study, and prior to termination.

Body weight
Individual body weights were recorded prior to start of treatment, at weekly intervals from Week 1 to 13 and every four weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded at weekly intervals for the first 13 weeks, and every fourth week thereafter.

Haematology and clinical chemistry
Blood was collected from 10 fasted animals per sex and group at Months 6, 12, 18 and at termination. The following parameters were measured: haematocrit, haemoglobin, total erythrocyte count, MCV, MCH, MCHC, platelet count, total leukocyte count, differential leukocyte count, reticulocyte count, alkaline phosphatase, aspartate amino transferase (AST), alanine aminotransferase (ALT), creatinine, blood urea nitrogen, total protein, glucose, albumin, globulin, total bilirubin, direct bilirubin, total cholesterol, inorganic phosphorus, calcium, sodium, potassium, and chloride.

Urinalysis
Individual urine samples were collected from the same animals as those used for haematology analyses at Month 6, 12, 18 and prior to termination. Sampling was done over a period of about 18-hours *via* metabolism trays. The following parameters were determined: appearance, specific gravity, pH, glucose, ketones, protein, bilirubin, urobilinogen and blood. In case that blood and / or protein in excess of the control urine samples were found, the sediment was examined for the presence of bacteria, epithelial cells, erythrocytes, leukocytes, casts or abnormal crystals.

Sacrifice and pathology
A gross necropsy was conducted on all surviving animals at scheduled sacrifice after 12 and 24 month. The following organ weights were determined: brain, kidneys, liver and testes with epididymides.

Tissue samples were taken from the following organs and subjected to a histopathological examination: adrenals, aorta, bone & bone marrow, brain, caecum, colon, duodenum, eyes, gross lesions including palpable masses, Harderian gland, heart, ileum, jejunum, kidneys, liver, lung (with main stem bronchi), lymph nodes (mesenteric and submandibular), muscle, nasal turbinates, oesophagus, ovaries, pancreas, pituitary, prostrate, rectum, sciatic nerve, seminal vesicles, skin (with mammary tissue), spinal cord (cervical, thoracic, lumbar), spleen, stomach, submaxillary salivary gland, testes with epididymides, thymus, thyroid/parathyroid, trachea, urinary bladder, uterus (corpus and cervix).

Statistics
Dunnett's Multiple Comparison Test (two-tailed) was used for body weights, cumulative body weight changes, food consumption, absolute leukocyte counts, reticulocyte counts, urine pH, urine specific gravity and clinical chemistry data obtained at Months 6, 12 and 18. Fisher´s exact test (one-tailed) was used for incidence of selected ocular lesions, as well as in combination with Bonferroni inequality procedure for incidences of non-neoplastic (at $p \leq 0.01$) and neoplastic lesions (at $p \leq 0.01$ and ≤ 0.05). EHL decision tree analysis was used for evaluation of terminal haematology, clinical chemistry, body weight, absolute and relative organ weight data and organ to brain weight ratios. Depending on the results either parametric (Dunnett´s Test and linear regression) or nonparametric (Kruskal-Wallis, Jonckheere´s and / or Mann-Whitney Tests) were applied. Mortality data were analysed by SAS lifetable procedure, and Peto Analysis was used for evaluation of histopathological data.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
The stability analyses proved the neat test substance to be stable throughout the study period.

The stability and homogeneity of glyphosate in diet at concentrations of 2000 and 20000 ppm was satisfactory. The mean achieved concentrations of glyphosate in each dietary preparation were 95 % of the nominal concentration.

B. MORTALITY

There were no statistically significant differences in the group survival rates. The percentage of survival in each of the dose groups are summarised below.

Table 5.5-75 Chronic study of glyphosate administered in feed to Albino rats ([redacted] 1990): Percentage survival at termination after 24-month dietary exposure to glyphosate

Sex	Dose group (ppm)			
	0	2000	8000	20000
Male	29	38	34	34
Female	44	44	34	36

C. CLINICAL OBSERVATIONS

There were no treatment-related clinical sings noted except the ophthalmological findings (see below).

Table 5.5-76 Chronic study of glyphosate administered in feed to Albino rats ([redacted] 1990): Clinical sings

		Number of animals affected / number of occurrences

D. BODY WEIGHT

There were no effects on body weight noted in males of any dose group. In high-dose females body weights were statistically significantly reduced from Week 7 through approximately the 20th month. During this time, absolute body weights gradually decreased to 14 % below the control value. The maximum difference in body weights was observed at 20th month. At this time-point the cumulative body weight gain in high-dose females was 23 % lower as compared to controls

There were no treatment-related effects in females fed 2000 or 8000 ppm glyphosate.

E. Food consumption and compound intake

There were no statistically significant decreases in food consumption in any group of either sex during the study period. However, significant increased food consumption was noted frequently in high-dose males, and on some occasions in low-dose males. The group mean achieved doses are summarised below.

Table 5.5-78 Chronic study of glyphosate administered in feed to Albino rats ([redacted] 1990): Summary of food consumption data

4 (high)	20000	940	1183

F. OPHTHALMOSCOPY

There were no treatment-related ocular effects observed in females of any dose group, as well as of males of the low-, and mid-dose group. In high-dose males a statistically increased incidence ($p \leq 0.05$) of cataractous lens changes were observed at the ophthalmic examination prior to termination. However, the observed incidence of 25 % was within the historical control range of 0-33 %. A second independent ophthalmic examination also performed prior to termination confirmed a statistically significant increase ($p \leq 0.05$) in the incidence of cataractous lens changes in high-dose males (1/14 (control) compared to 8/19 (high dose)). The results are summarised in the table below.

Table 5.5-80 Chronic study of glyphosate administered in feed to Albino rats [redacted] 1990): Incidences of cataract and lens fibre degeneration in males observed during ophthalmic examinations

HCD (range) [%]	0 - 33			

* Number of rats affected/ number of rats examined (% affected);
** Statistically significant from control ($p \leq 0.05$)

The histopathological examination confirmed a slightly, but not statistically, increased incidence of degenerative lens changes (i.e. cataract and/or lens fibre degeneration) in high-dose males (see table below).

Table 5.5-81 Chronic study of glyphosate administered in feed to Albino rats ([redacted] 1990): Histopathological confirmed incidences of cataract and lens fibre degeneration in males

	Dose group (ppm in diet)*			
	0	2000	8000	20000
Terminal sacrifice	2/14	↑3/19	↑3/17	↑5/17
All animals	4/60	↑6/60	↑5/60	↑8/60

* Number of rats affected / number of rats examined

To summarise, ophthalmic examinations performed at the end of the study revealed a statistically significant increase in the incidence of degenerative lens changes in high dose males; however, the incidence was within the historical control range in the first evaluation. Histopathological examination also indicated a slightly increased incidence of degenerative lens changes in high dose males, although the difference was not statistically significant. Interpretation of these data are difficult since the numbers of animals examined ophthalmologically and affected at the end of the study were small. Nonetheless, the occurrence of degenerative lens changes in high dose male rats appears to have been exacerbated by treatment. There is no indication of treatment-related ocular effects in low or mid dose males or in any group of treated females.

G. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology and clinical chemistry evaluations noted various changes in the examined parameters. However, the changes were not consistently noted at more than one time point, were within historical control ranges, small in magnitude, and/or did not occur in a dose-related manner. Therefore, they were considered to be either unrelated to treatment or toxicologically insignificant.

The statistically increased alkaline phosphatase level observed in high-dose females at termination was mostly due to an extremely high value for one animal. However, this finding is in line with observation made in other long-term studies in rats.

H. URINALYSIS

Urine specific gravity was statistically significant increased at the Month 6 examination. The observed statistically significant decreased urinary pH at 6, 18 and 24 months might be related to the renal excretion of glyphosate, which is an acid.

I. NECROPSY

Gross pathology

There were no treatment-related gross pathological findings observed at necropsy.

Organ weights

At interim kill after 12 months relative liver weights were slightly, but statistically significantly increased in high-dose males. At terminal sacrifice absolute liver weights, as well as liver to brain weight ratios were also statistically increased in high-dose males. Relative liver weights when compared to bodyweight were not significantly different compared to the control. There were no other significant and dose-related effects on organ weights.

Histopathology

Non-neoplastic lesions

Apart from the eye findings mentioned above histopathological examination showed only one other lesion that reached statistical significance. This was an increased incidence of inflammation of the stomach squamous mucosa in females fed 8000 ppm glyphosate (see table below).

Table 5.5-86 Chronic study of glyphosate administered in feed to Albino rats ([redacted] 1990): Incidence of inflammation and hyperplasia of the stomach squamous mucosa

		Dose group (ppm in diet)*			
		0	2000	8000	20000
Males	Inflammation	2/58	↑3/58	↑5/59	↑7/59
	Hyperplasia	3/58	3/58	↑4/59	↑7/59
Females	Inflammation	0/59	↑3/60	↑9/60**	↑6/59
	Hyperplasia	2/59	↑3/60	↑7/60	↑6/59

* Number of rats affected / number of rats examined
** Statistically significant at $p \leq 0.01$ (Fisher exact test with Bonferroni inequality)

Although the incidence of this lesion in mid-dose females (15 %) was slightly outside the historical control range (0 – 13.3 %) for the laboratory, there was no dose-related trend across all groups of females, and there was also no significance difference in male rats. Therefore, this finding is considered to be incidental and not related to treatment with glyphosate.

Neoplastic lesions
The only statistically significant difference in neoplastic lesions was an increased incidence of pancreatic islet cell adenomas observed in low-dose males (see **Table 5.5-87**). The incidence (14 %) in low-dose males was outside the historical control range (1.8 – 8.5 %) for this laboratory, but was in the historical control range ≥17 %) observed in reports from other laboratories. In addition, there was no dose-related trend for this finding in the male groups, as indicated by the lack of statistical significance in the Peto trend test. Due to the lack of a dose-related proliferative effect (hyperplasia) and or progression (carcinoma) of this lesion, and as such effects were not observed in females, this finding was not considered to be treatment-related.

Table 5.5-87 Chronic study of glyphosate administered in feed to Albino rats ([redacted] 1990): Incidence of pancreatic islet cell findings

Finding	Sex	Dose group (ppm in diet)*			
		0	2000	8000	20000

3. Assessment and conclusion

Assessment and conclusion by applicant: In conclusion, glyphosate was not carcinogenic in Sprague-Dawley rats following continuous dietary exposure of up to 20000 ppm for 24 months (corresponding to 940 mg/kg bw/day in males and 1183 mg/kg bw/day in females). The NOAEL for toxicity is 8000 ppm (corresponding to 362 mg/kg bw/day in males and 457 mg/kg bw/day in females), based on reduced body weights in females and cataract lens changes in males at 20000 ppm.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/011
Report author	[redacted]
Report year	1981
Report title	A Lifetime Feeding Study of Glyphosate (ROUNDUP® Technical) in Rats
Report No	77-2062
Document No	M-645914-01-1
Guidelines followed in study	None; in general accordance with OECD 451
Deviations from current test guideline (OECD 451, 2018)	Histopathological examinations of the cervix, coagulating glands, gall bladder, Harderian gland, lacrimal glands, rectum, skeletal muscle, upper respiratory tract, and vagina were not performed; Historical control attached for histopathological examinations. Dose levels selected were too low according to the recommendations given in OECD TG 451.
Previous evaluation	Not accepted in RAR (2015).
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid Dose levels too low, serious reporting deficiencies
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

This study, conducted for Monsanto Company, was designed to assess the toxicity of glyphosate (ROUNDUP® Technical) when administered orally *via* the diet to 300 Sprague-Dawley (CD) rats (50/sex/group).

During the first week of the study, the test substance was administered at dose levels of 30, 100 and 300 ppm. For the remainder of the study, dose levels of 3.05, 10.30 and 31.49 mg/kg bw/day for the males, and 3.37, 11.22 and 34.02 mg/kg bw/day for the females were maintained.

Clinical laboratory studies were performed at months 4, 8, 12, 18 and 24. Water consumption was measured over two 3-day periods at months 18 and 24. All male and female groups were terminated at 26 months, at which time survival had decreased to 30 % in one group/sex. Select organs were weighed and organ/body and organ/brain weight ratios were calculated. Histopathological evaluations were performed on all animals dying spontaneously, sacrificed in a moribund condition and sacrificed at terminal necropsy.

During most of the growth period, a slight but consistent trend toward reduced body weights in the treated males was evident. However, this difference decreased resulting in little difference in mean body weights between groups at termination. Because this effect was slight and not evident at termination, it is not considered to be toxicologically significant.

The treated females showed no statistically significant differences in mean body weights as compared to the controls through Month 19 of the study. However, for the following 2 months, the treated groups showed statistically significant reductions in group mean body weights, especially groups II and III, although not

in a dose-related fashion. Thereafter, the treated females gained weight relative to the control group, resulting in nearly identical group mean body weights at termination of the study.

Evaluations of mortality, food consumption and water consumption data, haematology, clinical chemistry, urinalysis and terminal organ and body weights, organ/body weight ratios and organ/brain weight ratios failed to reveal any effect attributable to the administration of glyphosate.

The incidence of interstitial cell tumours of the testes in the group IV males was elevated compared to the controls. Although an effect on the incidence of this tumour due to the administration of the test substance cannot be ruled out, the incidence in the group IV males is within the range observed in recent historical control data. In addition, the data suggest that the incidence in groups II through IV is within the normal biological variation observed for tumours at this site in this strain of rat. Where gross and microscopic changes occurred sporadically in the control and/or treated rats and were considered unrelated to the administration of the test substance.

I. MATERIAL AND MEDTHODS

A: Materials

1. Test material:

Identification:	Glyphosate (ROUNDUP® Technical)
Description:	Fine, white powder
Lot/Batch #:	XHJ-64
Purity:	98.7 %
Stability of test compound:	Not reported
2. Vehicle and/ or positive control:	Diet
3. Test animals:	
Species:	Rat
Strain:	Sprague-Dawley (CD®)
Source:	[redacted]
Age:	Approx. 6 weeks (at start of study)
Sex:	Males and females
Weight at dosing:	Males: approx. 124 g; females: approx. 102 g
Acclimation period:	12 days
Diet/Food:	Standard laboratory diet (Purina Lab Chow®), *ad libitum*
Water:	Automated water system (Elizabethtown Water Company), *ad libitum*
Housing:	Individually in elevated stainless steel cages
Environmental conditions:	Temperature: Not reported Humidity: Not reported Air changes: Not reported 12 hours light/dark cycle

B: Study design and methods

In life dates: 1978-07-12 to 1980-08-26 (males); 1978-07-12 to 190-09-04 (females)

Animal assignment and treatment:
In a lifetime feeding study groups of 50 Sprague-Dawley rats per sex received daily dietary doses of 0, 30, 100 and 300 ppm glyphosate (equivalent to mean achieved dose levels of 0, 3.05, 10.30 and 31.49 mg/kg bw/day for males and 0, 3.37, 11.22 and 34.02 mg/kg bw/day for females) for 26 months.

Appropriate amounts of test substance (adjusted by most recent weekly body weight and food consumption data) and standard laboratory diet were mixed weekly. Two 4 oz (about 120 g) samples of the control feed and each dietary level were taken at each feed preparation interval (Day 1). Extra feeder jars for each dietary level plus control were placed in the animal room and were sampled at the end of each feeding interval (Day 7). One set of samples for both Day 1 and Day 7 were shipped frozen to the sponsor for analyses. The other set of samples were stored frozen at the testing facility.

Clinical observations
All rats were examined for mortality and gross signs of toxicological or pharmacological effects twice daily. Detailed physical examinations for signs of local or systemic toxicity, pharmacologic effects and palpation for tissue masses were conducted weekly.

Body weight
Individual body weights were recorded twice prior to start of treatment, at weekly intervals from Week 1 to 14, biweekly thereafter and terminally (after fasting).

Food consumption and compound intake
Food consumption was recorded once prior to start of treatment, at weekly intervals for the first 14 weeks, and biweekly thereafter. The test substance intake was calculated from food consumption data. Based on nominal concentrations.

Water consumption
Water consumption was measured at month 18 and 24 over 2-three day periods.

H**aematology and clinical chemistry**
Blood was obtained *via* venepuncture of the orbital sinus (retrobulbar venous plexus) under light ether anaesthesia. Animals were selected randomly; the same animals were used at all intervals when feasible. Rats were fasted overnight prior to blood collections and were not dosed until after samples were collected. Blood was collected from 10 animals per sex and group at Months 4, 8, 12, 18 and 24. The following parameters were measured: haematocrit, haemoglobin, total erythrocyte count, platelet count, total leukocyte count, differential leukocyte count. The parameters for clinical chemistry were: serum glutamic oxaloacetic transaminase (AST), serum glutamic pyruvic transaminase (ALT), blood urea nitrogen, glucose, lactic acid dehydrogenase, total cholesterol, total bilirubin, direct bilirubin, total protein, albumin, globulin, inorganic phosphorus, calcium, potassium.

Urinalysis
Individual urine samples were collected from the same animals as those used for haematology analyses at Month 4, 12, 18 and 24. The following parameters were determined: appearance, specific gravity, pH, glucose, ketones, protein, bilirubin, occult blood and microscopic analysis.

Sacrifice and pathology
A gross necropsy was conducted on all surviving animals at scheduled sacrifice after 26 month and on all animals that died spontaneously or were killed in a moribund condition. The following organ weights were determined: Adrenals, brain, gonads, heart, kidneys, liver, pituitary, spleen and thyroid.

Tissue samples were taken from the following organs and subjected to a histopathological examination: adrenals, aorta, blood smear, bone & bone marrow, brain, caecum, colon, duodenum, eyes, heart, head, ileum, jejunum, kidneys, liver, lung, lymph nodes (mesenteric and mediastinal), mammary gland (right inguinal), oesophagus, ovaries, pancreas, pituitary, prostrate, sciatic nerve, seminal vesicles, skin (with

mammary gland), spinal cord (cervical, lumbar), spleen, stomach, mandibular salivary gland, testes with epididymides, thymus, thyroid/parathyroid, trachea, urinary bladder, uterus.

Statistics
Body weight, food consumption, haematology and clinical chemistry parameters, organ weights and organ/body weight ratios and organ/brain weight ration were analysed. Mean values of all dose groups were compared to control at each time interval.

Statistical evaluation of equality of means was made by the appropriate one way analysis of variance technique, followed by a multiple comparison procedure if needed. First, Bartlett's test was performed to determine if groups had equal variance. If the variances were equal, parametric procedures were used; if not, nonparametric procedures were used. The parametric procedures were the standard one way ANOVA using the F distribution to assess significance. If significant differences among the means were indicated, Dunnett's test was used to determine which means were significantly different from the control. If a nonparametric procedure for testing equality of means was needed, the Kruskal-Wallis test was used, and if differences were indicated a summed rank test (Dunn) was used to determine which treatments differed from control.

A statistical test for trend in the dose levels was also performed. In the parametric case (i.e. equal variance) standard regression techniques with a test for trend and lack of fit were used. In the nonparametric case Jonckheere's test for monotonic trend was used.

The test for equal variance (Bartlett's) was conducted at the 1 %, two-sided risk level. All other statistical tests were conducted at the 5 % and 1 %, two-sided risk level.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
The stability analyses were in the responsibility of the sponsor.

B. MORTALITY
There was no significant difference between the control and treated groups of both sexes with regard to the survival rate during the course of this study. Survival was approximately 80-90 % through Month 20 of the study for all groups. Thereafter, significant reductions in the number of surviving animals occurred in all groups in roughly an equivalent fashion, culminating in the termination of the study at Month 26. At this time, survival had decreased to 30 % in the group I males and the group IV females, requiring that the study be terminated to ensure a sufficient number of animals at the terminal necropsy. At 24 months, survival levels equalled or exceeded 50 %, which is comparable to historical control data for rats of this strain.

Table 5.5-88 A Lifetime Feeding Study of Glyphosate (ROUNDUP® Technical) in Rats ([redacted] 1981): Percentage survival at termination after 26-month dietary exposure to glyphosate

Sex	Dose group (ppm)			
	0	30	100	300
Male	35/50	24/50	34/50	24/50
Female	32/50	27/50	20/50	35/50

Number of dead animals/total number of animals

C. CLINICAL OBSERVATIONS
Physical observations noted during the course of this study included alopecia, excessive lacrimation, nasal discharge and rales. These findings were present in animals in all groups, both male and female, in approximately the same incidence and are common observations in the laboratory rat. Time of appearance and duration was approximately the same in all groups, including the controls. Therefore, it is concluded

that the administration of the test substance did not significantly affect the physical condition of the animals on test in this study.

D. BODY WEIGHT

No statistically significant differences were noted among the mean body weights of the treated males as compared to the group I controls during the course of this study. However, during a portion of the growth period, a slight but consistent trend toward reduced body weights in the treated males was evident. The maximum decrease was approximately 6 % in the group IV males, occurring during Month 16. Thereafter, this difference decreased resulting in little difference in mean body weights between groups at termination. Because this effect was slight and not evident at termination of the study and did not affect survival, it is not considered to be toxicologically relevant.

No statistically significant differences in mean body weights were found among the treated females as compared to the controls through Month 19 of the study. However, for the following 2 months, the treated groups showed statistically significant reductions in mean body weights as compared to the control, although not in a dose-related fashion. The magnitude of the reduction ranged between 10-15 % with the greatest difference evident in groups II and III. Thereafter, the treated females gained weight relative to the control group resulting in nearly identical group mean body weights at termination of the study. This pattern is similar to that evident in the males.

The pattern of increasing body weights for the first 16 months, followed by a plateau and then a slight decline, observed in the males and females in group I is typical for the laboratory rat. In the treated animals, particularly in the group IV males and groups II through IV females, a slight delay in reaching the plateau phase was observed. This effect was not dose-related in the treated females and may be due to biological variation.

Table 5.5-89 A Lifetime Feeding Study of Glyphosate (ROUNDUP® Technical) in Rats ([redacted] 1981): Body weight data

ppm		Males				Females

The number in brackets represents the animal number of the respective dose/timepoint.

E. FOOD CONSUMPTION AND COMPOUND INTAKE

Food consumption values relative to body weight were highest during the early stage of the study, gradually declining through Month 18. Thereafter these values remain essentially unchanged for the duration of the study. This pattern was observed in all groups of both sexes and is typical for long-term rat studies. Occasional statistically significant differences were noted in the treated animals of both sexes relative to their respective controls, but these differences in mean food consumption were slight and occurred sporadically unrelated to dose level. Therefore, it is concluded that the dietary administration of Glyphosate at the doses utilised in this study did not significantly affect food consumption values in either sex.

Test substance intake

During the first week of the study, the test substance was administered at the following dose levels for both sexes: 0, 30, 100 and 300 ppm for groups I through IV, respectively. Based on group mean food consumption, body weight values and nominal dietary concentrations for Week 1, test substance intake was calculated on a mg/kg/day basis. Thereafter, weekly through 14 weeks and biweekly for the duration of the study, the dietary levels of the test substance were adjusted to maintain the test substance intake attained for Week 1. These values were as follows: 0, 3.05, 10.30 and 31.49 mg/kg bw/day for groups I through IV males, respectively and 0, 3.37, 11.22 and 34.02 mg/kg bw/day for groups I through IV females, respectively. These values were maintained within a narrow range throughout the study.

Water consumption

At 18 and 24 months of the study, water consumption was measured for 10 animals/sex/group for two 3-day intervals over a 2-week period. Mean values for both the treated male and female groups were not significantly different from their respective control groups at the intervals studied. As is usual, the females consumed more on a body weight basis as compared to the males. Thee data indicate that the administration of the test substance did not significantly affect water consumption in either sex.

G. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology

Analysis of the group mean haematology data for both sexes indicates no toxicologically significant differences in any of the parameters evaluated. All mean data were within the normal physiological range for the laboratory rat. The few statistically significant differences noted appear to be due to random variation as no consistent treatment-related pattern is evident. On the basis of this data it is concluded that the administration of the test substance did not affect the haematology parameters evaluated.

Clinical Chemistry

Mean clinical chemistry data for all groups of both males and females fall within the normal physiological range for the laboratory rat. Occasional statistically significant differences were noted, but these appear due to random fluctuation, as no treatment-related pattern emerged. Thus, on the basis of this data, the administration of the test substance did not significantly affect any of the clinical biochemistry parameters evaluated during the course of this study.

H. URINALYSIS

No significant differences were noted in the urinalysis data when the control groups were compared to the

treated groups for both sexes. Occasional values outside the normal range were found; however, these values occurred sporadically exhibiting no consistent pattern.

I. NECROPSY

Gross pathology

Gross observations noted at necropsy were similar in incidence between control and treated animals of both sexes. Lesions noted were those commonly found in chronic studies conducted in this laboratory on the same strain of rats.

Organ weights

No statistically significant differences were noted in the terminal organ weights, organ/body weight ratios and organ/brain weight ratios of the treated groups as compared to their respective controls. Slight differences in these parameters were observed in a group by group comparison; however, no consistent pattern related to the administration of the test substance was evident.

Histopathology

Non-neoplastic lesions

In general, a good correlation was found between gross lesions noted at necropsy and microscopic findings of those tissue sections. The incidence and severity of the microscopic findings were similar in the control and treated animals of both sexes. Among the more common findings were changes found in the kidneys and lungs, lesions frequently found in chronic rat studies. Therefore, these findings are considered unrelated to the administration of the test substance.

Neoplastic lesions

A variety of neoplasms were found in both the control and treated animals of both sexes. The most common tumours were found in the pituitary in both sexes. In the females, mammary gland tumours were the next most common neoplasm found. In general, the incidence of all neoplasms observed occurred in the treated and control animals to a similar degree, or occurred infrequently such that a treatment-related association could not be made. The only exception to the above was the incidence of interstitial cell tumours of the testes in male rats. The incidence of this neoplasm in both the scheduled terminal sacrifice animals as well as the total number of animals on test is presented along with recent historical control data for comparison in the table below:

Table 5.5-90 A Lifetime Feeding Study of Glyphosate (ROUNDUP® Technical) in Rats ([redacted] 1981): Neoplastic findings compared to historical control data

	Interstitial cell tumour of the testes			
[ppm]	0	30	100	300
Terminal sacrifice	0/15 (0)	2/26 (8)	1/16 (6)	4/26 (15)
All animals	0/50 (0)	3/50 (6)	1/50 (2)	6/50 (12)

	Recent historical control data					
Study number	I	II	III	IV	V	All Studies
Terminal sacrifice	4/65 (6)	3/11 (27)	3/26 (12)	3/24 (13)	3/40 (8)	16/166 (9.6)
All animals	4/116 (3)	5/75 (7)	4/113 (4)	6/113 (5)	5/118 (4)	24/535 (4.5)

(): incidence [%]

Based on the results in the present study, the data suggest a treatment-related response with regard to the incidence of testicular interstitial cell tumours in male rats. This tumour, as is frequently the case, increases in frequency among older animals as can be seen from comparing the incidence in the animals surviving

until termination to the total incidence. A review of recent control data from animals sacrificed at 12 months suggests an incidence near zero at this age. However, in animals ranging in age from 24-29 months at necropsy, the incidence increases to about 10 %. Therefore, the studies selected for comparison were all terminated within this time interval, as compared to 26 months for the present study.

A comparison of the incidence of interstitial cell tumours in the group IV males to the control data from recent chronic studies suggests that the two incidence are similar. At terminal sacrifice, the incidence in the present study was 15.4 % (4/26), while the range in control animals from 5 concurrent studies was 6.2 % (4/65) to 27.3 % (3/11) with an overall mean value of 9.6 % (16/166). When all animals on test are included, the incidence for the group IV males was 12 % (6/50) compared to a range of 3.4 % (4/116) to 6.7 % (5/75) with a mean of 4.5 % (24/535). Therefore, this comparison suggests an incidence of this tumour in the group I males which is slightly lower (0 %), and an incidence in the group IV males which is slightly higher than recent historical control data. Although an effect on the incidence of this tumour due to the administration of the test substance cannot be ruled out, the data suggest that the incidence in groups II through IV is within the normal biological variation observed for tumours at this site in this strain of rat.

3. Assessment and conclusion

Assessment and conclusion by applicant: In conclusion, glyphosate (ROUNDUP® Technical) was not carcinogenic in Sprague-Dawley rats following continuous dietary exposure of up to 300 ppm for 26 months (corresponding to 31.49 mg/kg bw/day in males and 34.02 mg/kg bw/day in females). The NOAEL for toxicity is 300 ppm (corresponding to 31.49 mg/kg bw/day in males and 34.02 mg/kg bw/day in females), based on the absence of findings in body weight changes, haematology, clinical chemistry, organ weight data or histopathological examinations. Based on the reporting deficiencies and the use of too low dose groups the outcome of the study is not considered reliable for the hazard and risk assessment of glyphosate.

Assessment and conclusion by RMS:

Carcinogenicity studies in the mouse

The most recent 80-Week dietary mouse study was conducted by [redacted] 2009 (CA 5.5/012-015). There were no adverse treatment related effects at the highest dose tested. The NOAEL for this study was 810/1081 mg/kg bw/day in males and females respectively.

A combined toxicity and carcinogenicity study in mice ([redacted] 2001, 5.5/016) demonstrated a slightly higher mortality in the high dose group. Mortality was within the upper end of the historical control range. However, treatment with glyphosate might slightly have affected the mortality at the highest dose of 10000 ppm, above the limit dose of 1000 mg/kg bw/day, and because a relationship to treatment was unclear, a conservative NOAEL for toxicity at the mid dose of 1000 ppm (150.5 mg/kg bw/day for combined sexes) was set for this study. The number of malignant lymphoma, the most common tumour in the mouse, was slightly higher in the high dose group compared to control, but this was considered as incidental variation based on historical control data and was not considered to be related to treatment. A re-evaluation of the statistical analysis of histopathology findings was performed in 2017 (CA 5.5/017). When appropriate statistics are applied to the tumour incidence data, (and the incidence data of malignant lymphoma in particular), no statistically significant increase in tumour incidence is found in this analysis. Moreover, the study was compromised by the presence of non-identified ecto- and endoparasites in a large number of animals and non-identified micro-organisms in single animals. In the absence of any detailed information it must be considered that some of the findings in this study (e.g. dermal lesions) are induced by infectious agents. All this taken together, it can be concluded that Glyphosate Technical (glyphosate acid) is not

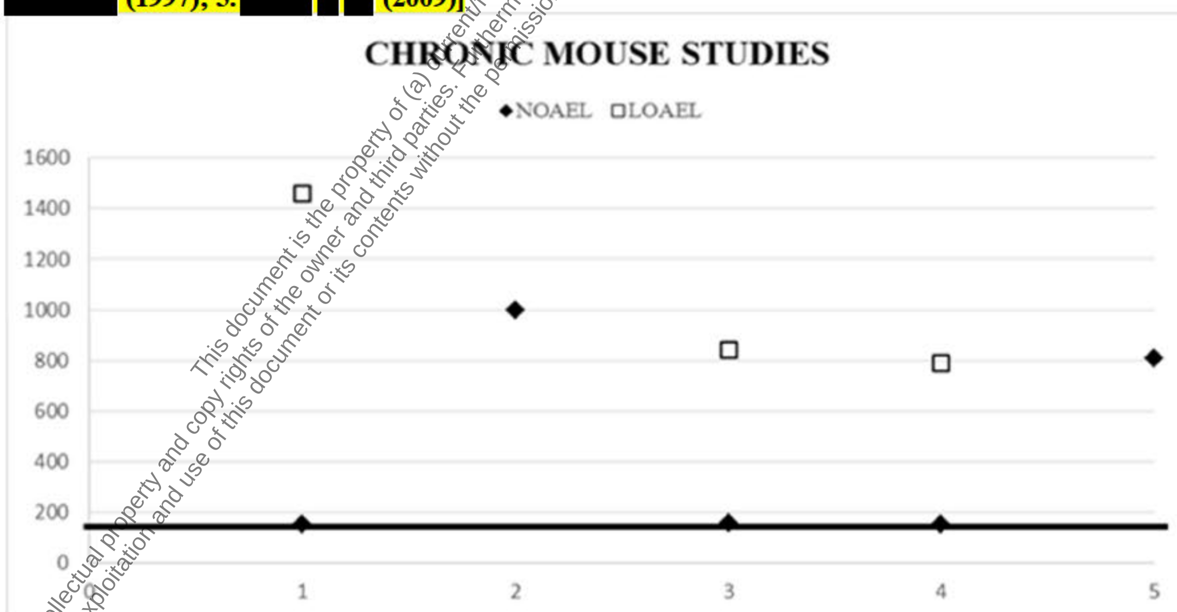
carcinogenic in Swiss albino mice when exposed to dietary concentrations of up to 10000 ppm for a duration of 18 months.

In the study by [redacted] 1997 (CA 5.5/018-018) the low effect level was 8000 ppm (equivalent to 787 mg/kg bw/day) in females only based on a reduction in body weight gain. At the top dose of 40000 ppm (equivalent to 4348/4116 mg/kg bw/day in males and females, respectively) signs of toxicity included loose stools, reduced body weight gain, food consumption and food utilisation, caecum distention and increased absolute and relative caecum weight (without corollary histopathological findings), increased incidence of anal prolapse consistent with histopathological erosion/ulceration of the anus.

A further 2-year oral diet study in mice was performed by [redacted] (1989, CA 5.5/021). In this study glyphosate was found to be not carcinogenic in male and female CD-1 mice following continuous dietary exposure of up to 1000 mg/kg bw/day (the limit dose for this type of study) for 104 weeks. Based on the study results and the lack of toxicological relevance of both the thymus weight findings and increased mineral deposit in the brain observed at 1000 mg/kg bw/day, the NOAEL in mice after chronic exposure to glyphosate technical for 104 weeks is considered to be 1000 mg/kg bw/day.

Two more long-term studies in mice (18-month) were considered not acceptable for reliable assessment of carcinogenicity ([redacted], 1988, CA 5.5/022; [redacted] 1982/1992, CA 5.5/024). Thus, they were not taken into consideration for this re-evaluation. A further study ([redacted], 1983, CA 5.5/023) also concluded that glyphosate technical was not carcinogenic in male and female CD-1 mice following continuous dietary exposure of up to 30000 ppm (equivalent to 5342.4mg/kg bw/day for males and 7045.5 mg/kg bw/day for females) for 104 weeks. Based on the findings of non-neoplastic bladder epithelial effects in male mice at 5000 ppm in diet (891.8 mg/kg bw/day), the NOAEL after chronic exposure to glyphosate for 104 weeks is considered to be 1000 ppm (equivalent to 157 mg/kg bw/day.

Figure 5.5.2-1: Valid chronic mouse NOAEL and LOAEL values, showing an overall NOAEL of 150 mg/kg bw/day [1. [redacted] (2001); 2. [redacted] (1993); 3. [redacted] (1983); 4. [redacted] (1997); 5. [redacted] (2009)]



The overall chronic NOAEL in mice is 150 mg/kg bw/day. No test substance related carcinogenic potential in mice was concluded in all studies.

Table 5.5-91: Summary of long-term toxicity and carcinogenicity studies in mice

Annex Point	Study	Study type	Substance(s)	Reference list-related category§	Result NOAEL (NOAEL)* (mg/kg bw/day)

Report title	Glyphosate Technical: Dietary Carcinogenicity Study in the Mouse
Report No	2060-0011
Document No	NA
Guidelines followed in study	OECD 451 (1981), JMAFF guideline 2-1-15 (2005), US-EPA OPPTS 870.4200 (1996)
Deviations from current test guideline (OECD 451, 2018)	Yes, histopathological examinations of the cervix, coagulating glands and the upper respiratory tract were not performed.
Previous evaluation	Yes, accepted in the RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The carcinogenic potential of Glyphosate technical was assessed in an 18-month feeding study in male and female CD-1 mice. Groups of 51 mice per sex received daily dietary doses of 0, 500, 1500 and 5000 ppm Glyphosate technical (equivalent to an average intake of 84.7, 266.8 and 945.6 mg/kg bw/day). Observations covered clinical signs, body weight, food and water consumption, palpation of masses, organ weights, necropsy and histopathological examination. The latter involved examination of all sampled organ tissues for all control and high dosage group animals killed at termination. In addition, differential white blood cell counts were performed for animals that were killed or died in extremis and for selected animals at twelve and eighteen month of treatment. The dose-levels were chosen based on available toxicity data.

There were no treatment-related deaths or clinical signs in any of the dose-groups. In the carcinogenicity study, survival after 78 weeks of treatment was 76, 80, 76 and 69 % in males and 73, 75, 75 and 78 % in females in the control through high dosage groups, respectively.

There were no treatment-related effects on body weight gain or food and water consumption noted. No significant treatment-related effects were noted on differential white blood cell counts in both sexes. There were no treatment-related trends in the proportion of masses observed, number of mice affected or time to appearance of palpable masses. Gross pathology, organ weight data and histopathological examination revealed no treatment-related effects.

I. MATERIALS AND METHODS

A: Materials

1. Test material: Glyphosate technical

Identification: Glyphosate

Description: White crystalline solid

Lot/Batch #: H05H016A

Purity: 95.7 %

Stability of test compound:	Expiry: 2008-03-25

2. Vehicle and/ or positive control: Diet

3. Test animals:

Species:	Mouse
Strain:	CD-1, Crl:CD-1 (ICR) BR
Source:	[redacted]
Age:	Approx. 5 – 6 weeks
Sex:	Males and females
Weight at dosing:	Males: 22 – 32 g, females: 18 – 28 g
Acclimation period:	At least ten days
Diet/Food:	Rat and Mouse SQC Ground diet No. 1, Special Diet Services Limited, UK), *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	Initially in groups of three per sex in polypropylene solid-floor cages.
Environmental conditions:	Temperature: 21 ± 2 °C Humidity: 55 ± 15 % Air changes: at least 15/hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 2005-10-10 to 2007-11-19

Animal assignment and treatment:
In a carcinogenicity feeding study groups of 51 CD-1 mice per sex received daily dietary doses of 0, 500, 1500 and 5000 ppm (equivalent to mean achieved dose levels of 0, 84.7, 266.8 and 945.6 mg/kg bw/day) Glyphosate technical in diet. Additional 12 mice per sex, designated for veterinary controls, were housed and maintained alongside treated animals. Ten animals per sex from each group were set aside for an interim kill (toxicity assessment), which was carried out on the survivors after 39 weeks of dosing. The remaining 50 mice per sex and dose-level were dosed for a maximum of 79 weeks (carcinogenicity assessment).

Test diets were prepared prior to start of treatment and then weekly by mixing a known amount of the test substance with a small amount of basal diet and blending for 19 minutes. This pre-mix was then added to larger amount of basal diet and blended for further 30 minutes.

The stability and homogeneity of the test material in diet were determined. Samples of each dietary admixture were analysed for achieved concentration monthly for the first six months and then every three months thereafter.

Clinical observations
A check for clinical signs of toxicity, ill health and behavioural changes was made once daily on all mice and recorded weekly. Observations for morbidity, and mortality were made twice daily. Additional unscheduled examinations were performed on animals that showed ill-health.
All surviving animals were palped weekly for size, position and appearance of new or existing masses.

Body weight
Individual body weights were recorded on Day 1 (prior to treatment) and at weekly intervals until the end

of week 13 and every 4 weeks thereafter until termination. Body weights were also determined before sacrifice. Bodyweight data were reported only until Week 77.

Food consumption and compound intake
Food consumption was recorded once weekly for each cage group from Week 1 to Week 13 and subsequently over one week in every 4 weeks until termination. Food consumption data were reported only until Week 77. Food efficiency and compound intake was calculated from the recorded food consumption data.

Water consumption
Water intake was observed daily, for each cage group, by visual inspection of the water bottles for any overt changes.

Haematology
Blood smear samples were collected after 12 months and at termination from all animals, and from mice that were killed in extremis. Differential white cell counts were performed on all control and high-dose animals and on the animals killed in extremis.

Sacrifice and pathology
All animals that died or were killed in extremis during the conduct of the study, and all animals sacrificed t scheduled termination were subjected to a gross pathological examination. Any macroscopic findings were recorded.
The following organ weights were determined from 10 mice per sex per group: adrenals, brain, epididymides, heart, kidneys, liver, lungs, ovaries, spleen and testes.
Tissue samples were taken from the following organs and preserved in buffered formalin: adrenals, aortic (thoracic), bone & bone marrow (sternum and femur (incl. stifle joint)), brain (incl. cerebrum, cerebellum pons), caecum, colon, duodenum, epididymides, eyes (with optic nerve), gross lesions incl. palpable masses, head (incl. pharynx, nasopharynx and paranasal sinuses), heart, Harderian and lacrimal glands, ileum, jejunum, kidneys, larynx, liver and gall bladder, lungs (with bronchi), mammary gland, lymph nodes (cervical and mesenteric), muscle (skeletal), oesophagus, ovaries, pancreas, pituitary, preputial gland, prostrate, rectum, salivary glands, sciatic nerve, seminal vesicles, skin (hind limb), spinal cord (cervical, mid-thoracic and lumbar), spleen, stomach, testes, thymus, thyroid/parathyroid, tongue, trachea, urinary bladder, uterus and vagina.

A detailed histopathological examination was performed on all sampled tissues of the control and high-dose animals, and on animals that died or were killed in extremis. In addition, tissues of the liver, lungs and kidneys, as well as gross macroscopic lesions and palpable masses from low and intermediate dose groups at termination were examined microscopically.

Statistics
All data were summarised in tabular form and analysed by computerised analysis using ProvantisTM Tables and Statistics Module. For each variable the of variance incorporating Student´s t-test and F-test. For each variable the most suitable transformation of data was found, the use of possible covariates checked and the homogeneity of means assessed using ANOVA or ANOVA and Bartlett´s test. The lowest treatment-related significant effects were determined using the Williams Test for parametric data or the Shirley Test for non-parametric data. If no response is found, but the data showed non-homogeneity of means, data were further analysed by a stepwise Dunnet (parametric) or Steel (non-parametric) test to determine significant differences from control. If required, pair-wise tests are performed using Students t-test (parametric) or the Mann-Whitney U test (non-parametric).

The levels of probability chosen as significant were $p < 0.01$** and $p < 0.05$*.

Histopathology data were analysed using Chi squared analysis (differences in the incidence of lesions occurring with an overall frequency of 1 or greater) and the Kruskal-Wallis one-way non-parametric

analysis of variance (comparison of severity grades).

The levels of probability chosen as significant were $p < 0.001$, $p < 0.01$, $p < 0.05$, and $p < 0.1$.

Results

A. ANALYSIS OF DOSE FORMULATIONS

Analyses for homogeneity and stability indicated that the dose preparations were homogeneous and stable for at least six weeks. Analyses for achieved concentration demonstrated that the mean prepared dietary admixture concentrations were within ± 5 % of the nominal concentration for all but 1 sample (500 ppm – level), which was + 10 % of the nominal concentration.

The group mean achieved doses are summarised below.

Table 5.5-92: Glyphosate technical: Dietary Carcinogenicity Study in the Mouse ([redacted] 2009b): Group mean achieved dose levels

Dose group	Dietary concentration (ppm)	Achieved dose level (mg/kg bw/day)*				
		Males		Females		Overall mean
		Mean	Range	Mean	Range	
1 (control)	0					
2 (low)	500	71.4	33 – 104	97.9	55 – 155	84.7
3 (mid)	1500	234.2	101 – 365	299.5	176 – 466	266.8
4 (high)	5000	810	461 - 1143	1081.2	610 - 1728	945.6

* based on actual food intake and body weight data

The results show a higher test material intake for females when compared to males for each dose level. Highest intakes were achieved within the first few treatment weeks, with subsequent decline thereafter. The mean intake for each dose group is therefore 84.7, 266.8 and 945.6 mg/kg bw/day for 500, 1500 and 5000 ppm, respectively.

B. MORTALITY

No treatment-related effects on the deaths occurred during the study, as well as no treatment-related effects on the time of death. From three male mice that were killed in extremis, examination results suggest that the morbidity of these animals was due to fighting between cage mates.

Table 5.5-93: Glyphosate technical: Dietary Carcinogenicity Study in the Mouse ([redacted] 2009b): Cumulated mortalities after 78-week dietary exposure to Glyphosate technical

Sex	Dose group (ppm)			
	0	500	1500	5000
Male	12 (6)	10 (8)	12 (6)	16 (6)
Female	14 (10)	13 (7)	13 (10)	11 (8)

() number of animals killed in extremis

The percentage of survival in each of the dose groups are summarised below.

Table 5.5-94: Glyphosate technical: Dietary Carcinogenicity Study in the Mouse ([redacted] 2009b): Percentage survival at termination after 78-week dietary exposure to Glyphosate technical

Sex	Dose group (ppm)			
	0	500	1500	5000
Male	76	80	76	69
Female	73	75	75	78

C. CLINICAL OBSERVATIONS

There were no significant treatment-related clinical signs of toxicity observed.

There were no trends in the proportion of palpable masses observed during the study period. A significant proportion observed showed evidence for regression before the animal reached the point of death or termination. Based on the results (see **Table 5.5-95**) no treatment-related effect on the development of palpable masses is seen for either sex. The slight increase in the mean number of masses per animal for high-dose females and mid-dose males was considered a coincidence. The median time to appearance of palpable masses was comparable for all dose groups of either sex.

Table 5.5-95: Glyphosate technical: Dietary Carcinogenicity Study in the Mouse ([redacted] 2009b): Group summary of palpable masses

Dose	Total number of animals in group		Number of animals with palpable masses		Total number of masses per group		Mean number of masses per animal		Median time (weeks) to appearance of masses	
	♂	♀	♂	♀	♂	♀	♂	♀	♂	♀
0	51	51	28	23	45	38	0.88	0.75	42.00	45.75
500	51	51	↑32	↑28	↑49	↑49	↑0.96	↑0.96	42.00	↑46.08
1500	51	51	↑39	23	↑60	38	↑1.20	0.75	↑42.43	↓44.83
5000	51	51	↓25	23	↑49	↑51	↑0.96	↑1.00	↓41.67	↓42.50

D. BODY WEIGHT

There were no treatment-related effects on male and female overall body weight gain during the conduct of study.

E. FOOD CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food consumption for either sex noted during the study.

F. WATER CONSUMPTION

There were no treatment-related effects on water consumption for either sex noted during the study.

G. HAEMATOLOGY AND CLINICAL CHEMISTRY

There were no significant treatment related effects on haematology parameters that were consistently observed for animals of both sexes that persisted through the course of the study. Similarly, clinical chemistry did not reveal any consistent changes except ALP activities that were elevated in both sexes and at various time points at the high dose.

At 5000 ppm there was an increase in alkaline phosphatase activity for satellite group males and females compared with controls at 6 and 12 months ($p<0.01$). Main group males were also affected at 18 months ($p < 0.05$). The magnitude of the effect does not appear to increase with age. Furthermore, the lack of a consistent effect for females indicates that this effect is of limited toxicological importance.

Table 5.5-96: Glyphosate technical: Dietary Carcinogenicity Study in the Mouse ([redacted] 2009b): Clinical chemistry findings (group mean values)

ALP [IU/L]	Dose group (mg/kg bw/day)							
	0		500		1500		5000	
	♂	♀	♂	♀	♂	♀	♂	♀
Month 6	88 ± 26	50 ± 18	95 ± 24	63 ± 22	103 ± 31	62 ± 21	129 ± 33**	92 ± 28**

* $p < 0.05$
** $p < 0.01$

H. NECROPSY

Gross pathology

There were no treatment-related macroscopic findings observed for any mice sacrificed at termination or mice that died or were killed in extremis during the study period.

Organ weights

There were no treatment-related findings observed in organ weights or relative organ weights.

Histopathology

There were no treatment-related histopathological findings observed in any dose group of either sex.

3. Assessment and conclusion

Assessment and conclusion by applicant: In conclusion, Glyphosate technical was not carcinogenic in the CD-1 mouse following continuous dietary exposure of up to 945.6 mg/kg bw/day (average for both sexes) for 18 months. The NO(A)EL for toxicity was 810 mg/kg bw/day for male mice and 1081 mg/kg bw/day for female mice, the highest dosage tested.
No non-neoplastic or neoplastic treatment-related findings were observed.
No increases in malignant lymphoma or salivary gland histopathological findings were observed.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/016
Report author	[redacted]
Report year	2001
Report title	Carcinogenicity Study with Glyphosate Technical in Swiss Albino Mice
Report No	Toxi: 1559.CARCI-M
Document No	NA
Guidelines followed in study	OECD 451 (1981)
Deviations from current test guideline (OECD 451, 2018)	Yes, animals were observed for mortality only once per day; food consumption was not measured monthly after the first 13 weeks; histopathological examination of the cervix, Harderian gland, ileum, lacrimal gland, mammary glands, upper respiratory tract and vagina were not performed. The statistical evaluation of incidences of non-neoplastic and neoplastic lesions were evaluated using the Z-test, which is inappropriate for the analysis of tumour incidence data (the Z-test assumes a normal distribution). Peto's incidental tumour analysis was performed without assigning a Petocode to the neoplasms, which is inappropriate for the

	application of this test. The Cochran-Armitage test was only applied to the tumour incidences in the high dose group and the control group, which is inappropriate for a trend test, where all dose levels should be considered. To address these issues, it was decided to re-evaluate the statistical significance of all tumour incidence data, starting from the raw data tables of this report and applying appropriate statistical methods (see CA 5.5-017)
Previous evaluation	Yes, accepted in the RAR (2015).
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

The carcinogenic potential of glyphosate technical was assessed in an 18-month feeding study in male and female Swiss albino mice. Groups of 50 mice per sex received daily dietary doses of 0, 100, 1000 and 10000 ppm glyphosate technical (equivalent to an average intake of 14.7, 150.5 and 1460.3 mg/kg bw/day). Observations covered survival, clinical signs, neurological changes, body weight, food- and water consumption, ophthalmological examinations, masses formation, blood smears with differential count analysis, organ weights, necropsy and histopathological examination. The latter involved examination of all sampled organ tissues and lesions for all control and high dosage group animals died, sacrificed moribund or killed at termination.

The survival after 18-month of treatment was 56, 60, 56 and 46 % in males and 68, 68, 60 and 60 % in females in the control through high dosage groups, respectively. The mortality (combined for both sexes) was slightly increased at the high dose level with 38, 36, 42 and 47 % for the control, low, mid- and high-dose group, respectively. Despite being in the upper range of the historical control data for mortality, the mortality in the high dose is not considered to be mediated by the administration of the test substance. There were no treatment-related effects on clinical signs, behaviour, eyes, body weight, body weight gain, food consumption, and differential white blood cell counts in both sexes. Gross pathology, organ weight data and histopathological examination demonstrated no treatment-related effects. The number of malignant lymphoma, the most common tumour in the mouse, was slightly elevated in the high dose group compared to control, but this was considered as incidental background variation based on historical control data and in agreement with the study director.

I. MATERIALS AND METHODS

A: Materials

1. Test material: Glyphosate technical

Identification: Glyphosate

Description: Solid white, odourless crystals

Lot/Batch #: 01/06/97

Purity: > 95.14 % (w/w)

Stability of test compound:	Expiry: December 1999
2. Vehicle and/ or positive control:	Diet
3. Test animals:	
Species:	Mouse
Strain:	Swiss albino, HsdOla: MF1
Source:	[redacted]
Age:	6 weeks
Sex:	Males and females
Weight at dosing:	Males: 25 – 47 g, females: 21 – 26 g
Acclimation period:	5 days
Diet/Food:	Ssniff rat/mouse powder food maintenance meal – low in germs (M/s Ssniff Spezialdiäten, D-59494 Soest, Germany), *ad libitum*
Water:	Well water passed through activated charcoal filter and exposed to UV rays, *ad libitum*
Housing:	In groups of five per sex in polypropylene mouse cages with stainless steel top grill and steam sterilised clean paddy husk bedding.
Environmental conditions:	Temperature: 19 - 25 °C
	Humidity: 30 - 70 %
	Air changes: 12 - 15/hour
	12 hours light/dark cycle

B: Study design and methods

In life dates: 1997-12-23 to 1999-06-29

Animal assignment and treatment:
In a carcinogenicity feeding study groups of 50 Swiss albino mice per sex received daily dietary doses of 0, 100, 1000 and 10000 ppm (equivalent to mean achieved dose levels of 0, 14.5, 149.7 and 1453 mg/kg bw/day for males, and 0, 15.0, 151.2 and 1466.8 mg/kg bw/day for females) glyphosate technical in diet for 18 month. The dose levels were chosen based on results of a 50-day pre-study in mice. Test diets were prepared prior to start of treatment and then in intervals ranging from 10 to 23 days. Diets were prepared in quantities of 10, 12 or 15 kg. For preparation of 12 kg diet mixtures 1.2 g, 12 g and 120 g for the low-, mid- and high-dose group, respectively, of the test substance was mixed with approximately with 0.5 kg basal diet and blended for 3 minutes. This pre-mix was then mixed manually with approximately 0.5 kg food and then added in portions to the remaining bulk amount of food (approximately 11.0 kg) and blended in a stainless steel ribbon mixer for 20 minutes.

The homogeneity of the test material in diet was determined at beginning of treatment, and at 12 and 18 month. Analyses for achieved concentration were done at three and six month of the study. The stability of glyphosate technical in the diet was determined prior to start of the study for the 100 and 10000 ppm dose levels.

Clinical observations
A detailed veterinary examination of all mice was done before and after grouping and monthly thereafter. A check for clinical signs of toxicity, appearance, behaviour, and neurological changes and mortality was made once daily on all mice. For mice with observed tumours a separate record was maintained with details of the tumour development.

Body weight
Individual body weights were recorded on Day 1 (prior to treatment) and at weekly intervals until the end of week 13 and every 4 weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded once weekly for each cage group from week 1 to week 13 and subsequently at weeks 26, 39, 52, 65 and 78. Food efficiency and compound intake was calculated from the recorded food consumption data.

Haematology
Blood smear samples were collected at 9 month and at termination (18 month) from all surviving animals, and from mice that were killed in extremis. Differential white cell counts were performed on all blood smear samples.

Ophthalmological examination
Ophthalmological examinations were performed on all mice prior to start of treatment at 6, 12 and 18 month of the study. Mydriasis was induced before examination by adding 1 % Tropicamide solution into the eyes. All other grossly visible eye findings were recorded also at the daily observations.

Sacrifice and pathology
All animals that died or were killed in extremis during the conduct of the study, were necropsied immediately or preserved in 10 % buffered neutral formalin until necropsy.

All surviving mice were sacrificed at scheduled termination. A gross pathological examination was performed on all mice. Any macroscopic findings were recorded.

The following organ weights were determined from 10 mice per sex per group: adrenals, kidneys, liver and gall bladder, ovaries and testes.

Tissue samples were taken from each mice from the following organs and preserved in 10 % buffered neutral formalin: adrenals, bone & bone marrow (sternum and femur (incl. joint)), brain (incl. cerebrum, cerebellum pons), caecum, colon, duodenum, epididymides, eyes (with optic nerve), heart, jejunum, kidneys, larynx, liver and gall bladder, lungs, lymph nodes (mandibular, mesenteric, and superficial inguinal), muscle (femoral), oesophagus, ovaries, pancreas, pituitary, prostrate, rectum, salivary glands, sciatic nerve, seminal vesicles and coagulating glands, skin, spinal cord (cervical, mid-thoracic and lumbar), spleen, stomach, testes, thymus, thyroid/parathyroid, trachea, urinary bladder, uterus and all lesions and tumours/masses.
A detailed histopathological examination was performed on all sampled tissues of the control and high-dose animals, and on animals that died or were killed in extremis. In addition, tissues of gross lesions and masses from all mice were examined microscopically.

Statistics
Body weight, body weight gain, food consumption and differential leukocyte counts of different groups were compared by Bartlett´s test for homogeneity of intra group variances. Heterogeneous data were transformed using log transformation. Data with homogeneous intra group variances were subjected to one-way analysis of variance using ANOVA. When "F" values were significant, Dunnetts pair wise comparison of means of treated groups with control means was done individually.

Incidence of gross lesions and non-neoplastic histopathological changes and incidences of benign and malignant neoplasms in the test substance groups were statistically compared with control group by Z-test where necessary. The incidence of neoplasms was analysed by Cochran-Armitage linear trend test, Life table analysis for fatal tumour incidence and Peto´s incidental tumour analysis. When a significant difference over the control group was observed in any of the treatment groups, the dose correlation co-

efficient was estimated and subjected to t-test. All analyses and comparisons were evaluated at the 5 % level and statistically significant differences ($p \leq 0.05$) were indicated

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS

Stability analyses indicated that the dose preparations were stable for up to 30 days with a loss 8.37 % at the 100 ppm level and 6.99 % at the 10000 ppm level, when stored at room temperature in PE bags inside stainless steel drums.

Analyses for homogeneity at the start and at 12 and 18 month of treatment indicated that the dose preparations were homogeneous. Analyses for achieved concentration demonstrated that the mean prepared dietary admixture concentrations were within ± 10 % of the nominal concentration for all diet samples. The overall mean achieved concentrations were 94.0 ± 1.66, 949.5 ± 15.84 and 950.7 ± 142.28 as compared to the nominal concentrations of 100, 1000 and 10000 ppm, respectively.

B. MORTALITY

The cumulated pre-terminal deaths (including moribund sacrifice) are summarised in the table below.

Table 5.5-97: Carcinogenicity Study with Glyphosate Technical in Swiss Albino Mice ([redacted], 2001): Cumulated mortalities after 78-week dietary exposure to glyphosate technical

Sex	Historical control#		Dose group (ppm)**			
	min- max*	Mean ± SD	0	100	1000	10000
Male	11/50 – 27/50	18 ± 5	22 (6)	20 (6)	22 (8)	27 (8)
Female	12/50 – 20/50	16 ± 3	16 (7)	16 (7)	20 (2)	20 (3)
Combined sex	12/100 – 47/100	17 ± 4	38 (13)	36 (13)	42 (10)	47 (11)

\# Derived from the control groups of 9 studies performed in the timeframe embracing the study summarised here
* Number of dead animals / total number of animals
** Total number of animals per group = 50
() number of animals killed in extremis

The percentage of survival in each of the dose groups are summarised below.

Table 5.5-98: Carcinogenicity Study with Glyphosate Technical in Swiss Albino Mice ([redacted], 2001): Percentage survival at termination after 18-month dietary exposure to glyphosate technical

Sex	Dose group (ppm)			
	0	100	1000	10000
Male	56	60	56	46
Female	68	68	60	60
Combined	62	64	58	53

The survival percentage was slightly decreased at the high dose level, but the decrease did not attain statistical significance.

As can be seen from the historical control data, the mortality in the high-dose group is, at the upper end, but within the historical control range. The number of animals that were killed in extremis were comparable or higher in the controls compared to the treated groups.

C. CLINICAL OBSERVATIONS

There were no significant treatment-related clinical signs of toxicity observed.

D. BODY WEIGHT

There were no significant treatment-related effects on male and female body weight and overall body weight gain during the conduct of study.

In males incidences of slightly decreased body weights in week 10 at 100 ppm and in months 7 and 8 at 1000 ppm were considered incidental, since no effects on body weights were observed in the high-dose group.

In females receiving 100 ppm, decreased net body weight gain (85 % of control) was observed in month 18 only. At 1000 and 10000 ppm the body weight gain was 89 % and 99 % of the control. Therefore, this finding was also considered as incidental.

E. FOOD CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food consumption for either sex noted during the study.

The observed slightly lower food consumption observed in males in week 1 at 100 ppm and in weeks 1 and 7 at 10000 ppm was considered incidental, since the changes were minimal and the effects was not consistent during the remaining parts of the study period.

In females lower food consumptions were observed in week 2 for all dose levels, in week 26 at 10000 ppm. Higher food consumption occurred in week 11 at 100 ppm and in weeks 3 and 4 at 10000 ppm. These findings were also considered incidental, since the changes were minimal and food consumption during the remaining parts of the study was comparable with the control group.

The calculated mean daily test substance intake is summarised in the **Table 5.5-99** below.

Table 5.5-99: Carcinogenicity Study with Glyphosate Technical in Swiss Albino Mice ([redacted] 2001): Group mean compound intake levels

Dose group	Dietary concentration (ppm)	Mean daily test substance intake (mg/kg bw/day)*		
		Males	Females	Combined
1 (control)	0	0.0	0.0	0.0
2 (low)	100	14.5	15.0	14.7
3 (mid)	1000	149.7	151.2	150.5
4 (high)	10000	1453.8	1466.8	1460.3

* based on actual food intake and body weight data

F. HAEMATOLOGY

Differential leukocyte counts at 9 and 18 month

There were no significance treatment-related changes in the white blood cell counts for either sex at both 9 and 18 month. Slightly higher neutrophil counts and slightly lower lymphocyte counts in high dose males at 9 month were within the historical control ranges. The slightly higher eosinophil counts, higher neutrophil and monocyte counts, as well as slightly lower lymphocyte counts observed in high dose females at 18 month were comparable with historical control values and therefore considered incidental.

Differential leukocyte counts of moribund sacrificed mice

Although the differential leukocyte count data were not statistically analysed, they appeared to be within the range of biological variation.

G. OPHTHALMOLOGICAL EXAMINATION

There were no treatment-related findings observed at the ophthalmological examinations performed at 6,

12 and 18 month of treatment.

H. NECROPSY

Gross pathology

There were no treatment-related macroscopic findings observed for any mice sacrificed at termination or mice that died or were killed in extremis during the study period.

In animals found dead or sacrificed moribund across control and all dose levels the incidence of enlargement of superficial inguinal lymph nodes and thymus in mid dose females and in the high dose for combined sexes was statistically significant increased. These enlargements were associated with neoplasms of the hemolymphoreticular system. Other changes included enlargement of various lymph nodes, and thymus, both associated with neoplasms of the hemolymphoreticular system, enlargement of the spleen, associated with neoplasia and amyloidosis and increased extramedullary haematopoiesis. The low incidence of observed liver enlargements was associated with neoplasia and amyloidosis. However, none of these findings were dose-dependent.

In mice sacrificed at termination the following changes were observed: Kidney surface rough/uneven in high dose males, discoloration / enlargement of mesenteric lymph nodes in high dose females and discoloration in high dose combined sex, and enlargement of spleens in both sexes combined at the high dose were significantly higher than in control mice. Since none of these changes showed a dose-dependency, and the corresponding histopathological changes were not significantly higher in these groups, the findings were considered incidental.

Organ weights

There were no treatment-related findings observed in organ weights or relative organ weights.

Histopathology

There were no treatment-related histopathological findings observed in any dose group of either sex.

In mice found dead or sacrificed moribund during the study period the following significant histopathological changes were seen. Cystic glands of the stomach were significantly increased in high dose mice of both sexes combined.

There was a more frequent occurrence of cystic glands of the stomach in male mice. The effect becomes more evident when the incidences in animals found dead or moribund and those sacrificed at scheduled termination are combined. The difference between the treated groups is not large and, taking into account the large dose spacing, a clear dose response may be doubted but, according to the study author, the incidence was higher than the historical control data. Unfortunately, this historical control data was notpresented in the report. In contrast, no increase became apparent in females.

	Males				Females				Combined sex			
Finding	**0**	**100**	**1000**	**10000**	**0**	**100**	**1000**	**10000**	**0**	**100**	**1000**	**10000**
from 5 studies)												

Based on the incidences and the statistical significance mentioned for male animals, there was no NOEL in this study because it cannot be excluded that this finding was due to treatment. The clinical relevance of cystic glands of the stomach is not clear. In any case, there was no increase in severity (always minimal to mild) and, more important, the cysts formation did not progress to any other pathological lesion, even at a dose level that was 100 times higher than the lowest. Thus, this finding should not be taken into account when the NOAEL for this study is set.

As can be seen in the tables below, an increase in malignant lymphoma was noted in both the male and female groups receiving the highest dose. The incidence was statistically significantly elevated as compared to the actual control groups in this study, was above the mean values of the (relatively small) historical control and, for males, outside the historical control range. Even though malignant lymphoma is a common tumour in mice (accounting for 54.6 % of all tumours in this study), it cannot be completely excluded that the higher incidence in the top dose groups were somehow related to treatment. The RMS conclusion is that there was limited evidence of a carcinogenic potential of glyphosate in this mouse strain at the very high dose level of 10000 ppm (about 1460 mg/kg bw/day for sexes combined) in this study, with male animals being more affected. The NOAEL should be set at the mid dose level of ca 150 mg/kg bw/day.

Increased haematopoiesis was seen in the bone (femur) of high dose males, mid- and high-dose animals combined sex. Cell debris in tubules of epididymides was increased in mid dose males and the incidence of sub-capsular cell hyperplasia was increased in adrenals of low dose males. In addition, the incidence of kidney nephropathy in mid-dose females, as well as the incidence of lymphocyte infiltration of epididymides in mid dose males was significant decreased. All these findings were also observed at lower doses and/or were not dose dependent. Thus, these findings were also considered incidental.

In mice sacrificed at termination the following more frequent observed changes were observed: Cystic glands of the stomach were significantly increased in low-, mid- and high-dose males. However, this finding was not dose-dependent. Furthermore, high incidences were observed in females of the control group when compared to the HCD data.

Degenerative heart changes were higher in high-dose males and females, and significant higher in combined sex. Since the incidences were similar or slightly higher than historical controls, and no dose-dependency was observed this finding is considered incidental. The number of malignant lymphoma was slightly elevated in the high dose group compared to control. This tumour of the hemolymphoreticular system is one of the most common tumours of mice accounting for the highest percentage of spontaneous tumours in this species. Therefore, the observed tumour incident is considered incidental and not treatment-related. In addition, there was no increase with dose, and the incidences of this tumour varied with sex and fate (i.e. pre-terminal and terminal deaths). In mandibular lymph nodes lymphoid hyperplasia was significantly increase in low and mid-dose males and combined sex, whereas the incidence was significantly lower in high dose females. In addition, extramedullary haematopoiesis was significantly increased in these lymph nodes at the mid-dose level in combined sex. In spleen extramedullary haematopoiesis was significantly increased in females and combined sex at the low dose level. In the absence of any dose-relation these findings, as well as several not statistically significant changes considered incidental (see tables below).

3. Assessment and conclusion

Assessment and conclusion by applicant:
In conclusion, glyphosate technical was not carcinogenic in Swiss albino mice following continuous dietary exposure of up to 1460.3 mg/kg bw/day (average for both sexes) for 18 months. Based on, a more frequent occurrence of cystic glands of the stomach in male mice and an increase in malignant lymphoma was noted in both the male and female groups receiving the highest dose mortality at the upper limit of the historical control range, the NOAEL in mice after chronic exposure to Glyphosate technical for 18 month is conservatively set at 1000 ppm, corresponding to 149.7 mg/kg bw/day for males, 151.2 mg/kg bw/day for females and 150.5 mg/kg bw/day for both sexes combined.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5.017
Report author	[redacted]
Report year	2017
Report title	Statistical Evaluation of Pre-Neoplastic and Neoplastic Lesions from Study: Study No. TOXI: 1559.CARCI-M; Carcinogenicity Study with Glyphosate Technical in Swiss Albino Mice
Report No	11921
Document No	90017583
Guidelines followed in study	No guideline followed
Deviations from current test guideline	Not applicable
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	Not applicable
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

This is a re-evaluation of the statistical analysis of histopathology findings recorded in the [redacted] Study No. TOXI: 1559.CARCI-M, CD-1, [redacted], 2001 (see CA 5.5/016), in which an increased incidence of malignant lymphoma was reported.

Groups of 50 male and 50 female Swiss albino HsdOla:MF1 mice were exposed to glyphosate technical (glyphosate acid) in the diet at 0 (control), 100, 1000 or 10000 ppm for 18 months. The incidences of non-neoplastic and neoplastic lesions were statistically analysed using the Z-test (pair-wise comparisons). The Cochran-Armitage linear trend test, Peto's incidental tumour analysis and life table analysis for fatal tumours were used for the statistical analysis of the neoplastic lesions.

The statistical evaluation performed within the report of [redacted] (2001) has to be considered inadequate and generally lacks clarity.

Non-neoplastic and neoplastic lesions were evaluated using the Z-test, which is inappropriate for the analysis of tumour incidence data (the Z-test assumes a normal distribution). Peto's incidental tumour analysis was performed without assigning a Peto code to the neoplasms, which is inappropriate for the application of this test. The Cochran-Armitage test was only applied to the tumour incidences in the high dose group and the control group, which is inappropriate for a trend test, where all dose levels should be considered.

To address these issues, the statistical significance of all tumour incidence data was re-assessed, starting from the raw data tables of the original report and applying appropriate statistical methods.

When appropriate statistics are applied to the tumour incidence data, (and the incidence data of malignant lymphoma in particular), no statistically significant increase in tumour incidence is found in this analysis. Moreover, the study was compromised by the presence of non-identified ecto- and endoparasites in a large number of animals and non-identified micro-organisms in single animals. In the absence of any detailed information it must be considered that some of the findings in this study (e.g. dermal lesions) are induced by infectious agents.

All this taken together, it can be concluded that Glyphosate Technical (glyphosate acid) is not carcinogenic in Swiss albino mice when exposed to dietary concentrations of up to 10000 ppm for a duration of 18 months.

I. MATERIAL AND METHODS

Data entry and compilation

The animal heading data (animal number, sex, group, first and last day under test) were entered into the Pathdata System Version 6.2e2 (PDS Systems, Switzerland) at AnaPath GmbH, Switzerland, including:

- Groups
- Animal numbers and sex
- The first treatment day (according to study report, December 23, 1997) was entered for all animals.
- The last treatment day was entered according to the study report. In the study report, a list of decedents was provided. A list of interim decedent animals with the respective study day of necropsy is the basis for decedents (Table 10, study report pages 126-127). In this table, the study day of death was specified. The study day was calculated for the correct date. This date was entered as last day under study and as necropsy day for each decedent.
- For terminal sacrifices, no exact data were available. Therefore, the final day under study was calculated for these animals by the last day under treatment (June 29, 1999) (page 14 of study report) + a 14 days necropsy period (July 14, 1999).

- The mode of death (found death, sacrificed moribund, terminal sacrifice) was entered.

Thereafter the following data were entered:

- all neoplastic data
- all pre-neoplastic data insofar they are not related to inflammatory or infectious lesions
- all findings were entered as unilateral findings in bilateral organs
- All findings were entered as unilateral findings in bilateral organs.
- All neoplastic lesions were entered in the PathData system for statistical analysis. Systemic neoplasms (malignant lymphoma, myeloid leukemia and histiocytic sarcoma) were entered under 'Systemic Neoplasms'. In the original report, they were entered under 'Hemolymphoreticular System'. Systemic neoplasms were entered using pathology codes, i.e. ML for malignant lymphoma, MY for myeloid leukemia, HS for histiocytic sarcoma, along with a severity degree (scale 1 to 5). Non-inflammatory tissue infiltrates were given the code "M" for metastasis. A severity grade was not given for metastases because this was not available in the original study report.
- Systemic neoplasms that were originally described under 'bone (femur and joint)' or 'sternum with bone marrow' were separately entered for both organs in this report. Therefore, a 'metastasis' in these organs appears twice, for example for animal no. 1129, the original report states: 'sternum with bone marrow: malignant lymphoma'. Under the re-evaluation, malignant lymphoma is entered as metastasis under sternum and bone marrow.
- Tumours were counted only once per animal, without any consideration of metastases.

Since no Peto codes were assigned to the primary neoplasms in the original study, the following Peto codes were assigned for statistical calculation:

- N0 (malignant neoplasm, no Peto code) in survivors
- N1 (incidental malignant neoplasm) was not applied
- N2 (probably incidental malignant neoplasm) in cases of systemic neoplasms in animals that survived and only one organ was affected
- N3 (probably fatal malignancy) in cases of systemic neoplasms or large squamous cell carcinomas in animals that were sacrificed moribund or survived the course of the study.
- N4 (fatal malignancy) in cases of systemic neoplasms or large squamous cell carcinomas or alveolar-bronchiolar carcinoma in animals that were found dead during the course of the study.
- B0 (benign neoplasm, no PETO code) in survivors
- B1 (incidental benign neoplasm) in Leydig cell tumours,
- B2 (probably incidental benign neoplasm) in cases of small hepatocellular adenoma, renal cell adenoma, adenoma in cecum, haemangioma in tail, and osteoma,
- B3 (probably fatal benign neoplasm) and B4 (fatal benign neoplasm) were not assigned.

The correctness of the transfer of the data from the original report to the PathData system was quality-checked. 100 % of the data have been quality checked of which 20 % under GLP by the local QAU. The microscopic diagnoses were entered directly into the PathData system.

An explanation of Codes and Symbols can be found at the beginning of the Tables section.

Following microscopic data are presented in the Tables:

- NUMBER OF ANIMALS WITH MICROSCOPIC LESIONS BY ORGAN/GROUP/SEX (incidences of non-neoplastic (pre-neoplastic) lesions without gradings)
- OVERALL CHRONOLOGICAL LISTING OF NEOPLASMS BY WEEKLY INTERVALS
- AOFT (Animal Organ Finding Table = table of individual microscopic findings)
- TEXT OF GROSS AND MICROSCOPIC FINDINGS (complete narrative of both the macroscopic and microscopic findings, including Animal Heading Data for each dose group).

Gross lesions were not entered since they are not relevant for the statistical evaluation of microscopical lesions.

Statistical re-evaluation

Neoplastic lesions
Statistical evaluation of all neoplastic lesions was carried out using the Fisher's Exact test and the test for positive trend with respect to dose rates according to Peto *et al*. (1980) with assignment of Peto codes to all neoplasms. For the Fisher's Exact test the one-tailed p-values are given for each pair-wise comparison and for the Peto test the trend and one-tailed p-values are given in the tables in annex to this report. When a neoplasm is marked with a "#", it is considered to be a common tumour.

Non-neoplastic lesions
Statistical evaluation of all non-neoplastic (pre-neoplastic) findings was carried out with the Fisher's Exact test and the trend test over all dose groups according to Armitage (1955), the Cochrane-Armitage linear trend test.

For the Fisher's Exact test the one-tailed p-values are given for each pair-wise comparison and for the Cochran Armitage test the trend and one-tailed p-values are given in the tables in annex to this report.

Assessment of statistical significance
For tumour incidences to be considered as statistically significant according to the "Guidance for Industry: Statistical Aspects of the Design, Analysis, and Interpretation of Chronic Rodent Carcinogenicity Studies of Pharmaceuticals" (CDER 2001) one-tailed p values should be less than 0.025 for rare neoplasms and less than 0.005 for common neoplasms (Haseman 1983, Lin and Rahman 1998). A neoplasm is regarded as rare, if in an assay involving one or two hundred animals there may be no such neoplasm, or at most one or two such neoplasms in animals of one sex and strain. Based on this definition of rare tumors, if only one or two animals have a particular type of neoplasm in a standard assay, a statistically significant result is not relevant. This holds true even if one or two such neoplasms occur in the top dose group and there are none elsewhere in the study. A neoplasm is regarded as common, "if it occurs spontaneously in five or ten or more animals in most experiments performed with animals of one strain" (Peto *et al*. 1980).

II. RESULTS

A: NEOPLASTIC LESIONS

No statistically significant trend was found for systemic neoplasms (including malignant lymphoma) in the Peto test. When the same tumours were analysed using the Fisher's Exact test, no statistically significantly increases were found in pair-wise comparisons of all dose groups with the control group.

B: NON-NEOPLASTIC LESIONS

Non-neoplastic lesions (only pre-neoplastic lesions), including lymphoid hyperplasia's of lymphoid organs were analysed to determine possible early stages of systemic neoplasms such as malignant lymphoma. The only exceptions were the hyperplastic lesions in the skin. In most cases they were diagnosed as being associated with dermal inflammation or the presence of ectoparasites, which were not further specified. No statistically significant trend was found for any of the non-neoplastic lesions when the Armitage trend test was applied. Also, no statistically significant increases were evident in pair-wise comparisons with the control group using the Fisher's Exact test. The only exception was a statistically significant ($p < 0.05$) increase in the incidence of lymphoid hyperplasia in the inguinal lymph node ($p = 0.0269$) in high dose males which was not related to any neoplastic change.

Table 5.5-105: Statistical Evaluation of Pre-Neoplastic and Neoplastic Lesions from Study: Study No. TOXI: 1559.CARCI-M; Carcinogenicity Study with Glyphosate Technical in Swiss Albino Mice ([redacted], 2017): Selected non-neoplastic lesions

3. Assessment and conclusion

Assessment and conclusion by applicant:

It can be concluded that Glyphosate Technical (glyphosate acid) is not carcinogenic in Swiss albino mice when exposed to dietary concentrations of up to 10000 ppm (equivalent to 1460.3 mg/kg bw/day) for a duration of 18 months.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/018 CA 5.5/019
Report author	[redacted]
Report year	1997

Report title	HR-001: 18-Month Oral Oncogenicity Study in Mice
Report No	[redacted] 94-0151
Document No	NA
Guidelines followed in study	Japan MAFF Guidelines 59 NohSan No.4200, 1985 U.S. EPA FIFRA Guidelines Subdivision F, 1984 OECD 451 (1981).
Deviations from current test guideline (OECD 451, 2018)	Yes, mortality was observed only once per day; histopathological examination of the cervix, lacrimal glands and the upper respiratory tract were not performed. No historical control data [Additional Historical control data was submitted from the performing laboratory ([redacted] 2013)].
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

In order to evaluate the oncogenic potential of glyphosate technical in mice, the test substance was administered to SPF ICR mice (Crj:CD-1) by incorporating it into a basal diet at a concentration of 0, 1600, 8000 or 40000 ppm (equivalent to 0, 165.0, 838.1 and 4348 mg/kg bw/day for males and 0, 153.2, 786.8 and 4116 mg/kg bw/day for females) for a period of 18 months (78 weeks). During the treatment period, all animals were observed for clinical signs and measured body weights as well as food consumption. At week 21, urinalysis was carried out on 20 males from all groups. Differential leukocytes counts were determined on the blood smears from 10 males and 10 females of all groups at week 52 and after 78 weeks of treatment, organ weight analysis was conducted on 10 males and 10 females which were served to the determination of differential leukocytes counts. All animals of both sexes were subjected to necropsy and histopathological examinations.

- 40000 ppm group: In clinical observations, the incidence of pale-coloured skin was increased in males. In addition, loose faeces were observed in all cages beginning at week 21 in males and at week 20 in females. Retarded growth was persistently observed during treatment period showing statistically significant differences in weight from week 16 to 36 in males and from week 6 to end of treatment in females. These changes were associated with depressed food consumption and food efficiency. At necropsy, the increased incidences of distention of caecum were noted in males and females at terminal kill and in all animals examined, which were consistent to increase in absolute and relative weights of the caecum. However, no abnormalities were recorded in the caecum histopathologically. In males a significant increase was noted for the overall incidence of anal prolapsed which was correspondent to erosion/ulcer of the anus in histopathology.

- 8000 ppm group: Retarded growth was observed in females with statistically significant decreases in weight at week 6 and weeks 9-24. No treatment related changes were seen in males.

- 1600 ppm group: There were no treatment related changes in either sex in any parameters.

Histopathological examinations failed to show increases of any types of neoplastic lesions in all treatment groups of both sexes.

I. MATERIAL AND METHODS

A: Materials

1. Test material: Glyphosate technical

Identification:	HR-001	
Description:	Solid crystals	
Lot/Batch #:	T-941209	T-950308
Purity:	97.56 %	94.61 %
Stability of test compound:	Not mentioned in the report	

2. Vehicle and/or positive control: Diet

3. Test animals:

Species:	Mouse
Strain:	SPF ICR (Crj:CD-1)
Source:	[redacted]
Age:	5 weeks
Sex:	Males and females
Weight at dosing:	Males: 15 – 25 g, females: 14 – 23 g
Acclimation period:	9 days in males, 7 days in females
Diet/Food:	Certified diet MF Mash (Oriental Yeast Co., Ltd.), *ad libitum*
Water:	Filtered and sterilised water, *ad libitum*
Housing:	In groups of four per sex in aluminium cages with wire mesh floors
Environmental conditions:	Temperature: 24 ± 2 °C
	Humidity: 55 ± 15 %
	Air changes: 15/hour
	12 hours light/dark cycle

B: Study design and methods

In life dates: 1995-02-21 to 1996-09-06

Animal assignment and treatment:
Groups of 50 males and 50 females Specific-Pathogen-Free (SPF) ICR (Crj:CD-1) mice received the test material by incorporating it into the basal diet at a level of 0, 1600, 8000 or 40000 ppm for a period of 18 months.

Clinical observations
All animals were conducted a cage-side observation daily for clinical signs and their deaths during the study. In addition, a detailed examination including palpation of the body was performed at least once a week. Moribund animals showing marked debility were euthanised by exsanguinations under deep ether anaesthesia and necropsied when an unfavourable prognosis was predicted. Dead animals were taken from the cage as soon as possible after discovery in order to minimise the loss of tissues by cannibalism and necropsied. Mortality was expressed as ratios of cumulative number of animals found dead or killed *in extremis* to effective number of animal group.

Body weight
Individual body weights were recorded weekly from week 1 to 13 and every 4 weeks from week 16 to 76. Body weights were also measured at week 78, at the end of treatment, and used for calculation of relative organ weights. Group mean body weights were calculated at each measurement.

Food consumption and compound intake
Food consumption by each cage was recorded for a period of 3 or 4 consecutive days weekly during the first 13 weeks and every 4 weeks from week 16 to 76. Food efficiency and compound intake was calculated from the recorded food consumption data.

Haematology
Blood smear samples were collected at week 52 and at termination (18 month) from all surviving animals, and from mice that were killed *in extremis*. Differential white cell counts were performed on all blood smear samples.

Sacrifice and pathology
All animals that died or were killed *in extremis* during the conduct of the study were necropsied immediately.
All surviving mice were sacrificed at scheduled termination. A gross pathological examination was performed on all mice. Any macroscopic findings were recorded.

The following organ weights were determined from 10 mice per sex per group: brain, adrenals, kidneys, spleen, liver and gall bladder, ovaries, and testes.

Tissue samples were taken from each mice from the following organs and preserved in 10 % buffered neutral formalin: brain, spinal cord, sciatic nerve, pituitary, thymus, thyroids with parathyroids, adrenals, spleen, bone with marrow, tibio-femoral joint, lymph nodes, heart, aorta, salivary glands, oesophagus, stomach, liver with gallblader, pancreas, duodenum, jejunum, ileum, cecum, colon, rectum, head, pharynx, larynx, trachea, lung, kidneys, urinary bladder, testes, prostate, seminal vesicles, epididymides, coagulating glands, ovaries, uterus, vagina, Harderian glands, eyes, skeletal muscle, skin, mammary gland, all gross lesions.

A detailed histopathological examination was performed on all sampled tissues of the control and high-dose animals, and on animals that died or were killed *in extremis*. In addition, tissues of gross lesions and masses from all mice were examined microscopically. The following tissues were examined: brain, spinal cord, sciatic nerve, pituitary, thymus, thyroids with parathyroids, adrenals, spleen, bone with marrow, tibio-femoral joint, lymph nodes, heart, aorta, salivary glands, oesophagus, stomach, liver with gallblader, pancreas, duodenum, jejunum, ileum, cecum, colon, rectum, trachea, lung, kidneys, urinary bladder, testes, prostate, seminal vesicles, epididymides, coagulating glands, ovaries, uterus, vagina, Harderian glands, eyes, skeletal muscle, skin, mammary gland, all gross lesions.

Statistics
Body weight, food consumption and organ weights were evaluated by Bartlett´s test for homogeneity of intra group variances. When group variances were homogenous, a parametric analysis of variance of a one way layout type was conducted to determine if any statistical differences exist among groups. When the analysis of variance was significant, Dunnett's or Scheffe's multiple comparison test was applied. When the group variance were heterogeneous, the data were evaluated by Kruskal-Wallis non-parametric analysis of variance. When significant Dunnett type mean rank test or Scheffe's type mean rank test was applied.

Mortality was assessed by a life table analysis.

Urinalysis were analysed by Mann-Whitney's U test to compare data between the treatment groups and the controls.

Mann-Whitney's U test was used to analyse difference of the differential leukocyte counts between the high dose groups and the controls. For comparison of the data from all groups, Dunnett's and Scheffe's multiple comparison test was applied. The data from males killed *in extremis* during the treatment were examined by Mann-Whitney's U test.

Fisher's exact probability test was used to analyse the data of clinical signs and incidences of gross lesions at necropsy and histopathological lesions.

Results

A. ANALYSIS OF DOSE FORMULATIONS

Stability analyses indicated that the dose preparations were stable for up to 30 days with a loss of 8.37 %. Homogeneity of the test substance in diet was analysed on the samples taken from the top, middle, and bottom portion of the mixer. The coefficient of variation for each test diet was within 5.2 % or less. The results indicated that homogeneity of the test substance in diet was satisfactory in each test diet.

In order to verify concentration of the test substance in test diets, every batch of test diet was analysed during the treatment period. Mean concentration of the test substance in test diet at a nominal level of 1600, 8000 or 40000 ppm was 1561 ± 86.7, 7790 ± 394.4 or 38783 ± 1655.0 ppm (mean ± standard deviation), respectively. The values were within 97-98 % of the target concentrations and satisfied the acceptable limit of concentration for test substance.

B. MORTALITY

No significant differences were noted for mortality between the treated groups and the respective control of either sex. Cumulative mortality of each group of either sex is shown in the following table:

Table 5.5-106: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Final mortality at termination of treatment (%)

Dose group (ppm)	Male	Female
0	24/50 (48)	18/50 (36)
1600	16/50 (32)	14/50 (28)
8000	23/50 (46)	10/50 (20)
40000	21/50 (42)	15/50 (30)

C. CLINICAL OBSERVATIONS

Statistically significant changes in clinical signs observed in the treated groups of either sex are shown in the following table:

Table 5.5-107: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Statistically significant changes in clinical signs

	Male				Female			
	Dose group (ppm)							
	0	1600	8000	40000	0	1600	8000	40000
Number of animals examined	50	50	50	50	50	50	50	50
Perinasal region: tactile hair loss	0	↑3	↑3	↑6*	5	↑13*	↑9	↑8
Anus: mass(es)	0	0	0	↑8**	0	0	0	0
Integument :								
wound	22	↓16	↓20	↓6*	3	↓0	↓0	↓0
Erosion/Ulcer	9	↓5	↑12	↓8	16	↓4**	↓1**	↓2**
Swelling	16	↓6*	↑13	↓9	6	↓2	↓0	↓1
Mass(es)	15	↓13	↓13	↓10	13	↓11	↓9	↓4*
Pale-coloured skin	2	↑3	↑6	↑10*	4	↓2	↑6	↑6

Table 5.5-107: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Statistically significant changes in clinical signs

	Male				Female			
	Dose group (ppm)							
	0	1600	8000	40000	0	1600	8000	40000
Hair loss	11	↑12	↑21*	↑12	22	↑23	↓18	↓14
Wetted fur	11	↓9	↓7	↓4*	1	1	1	1

* $p < 0.05$
** $p<0.01$ (Fisher's exact probability test).

In the 40000 ppm group, males showed increased incidences of tactile hair loss, pale-colored skin, and mass(es) of anus and decreases of wound and wetted fur. In females of this group decreased incidences were observed in ulcer/erosion and mass(es) of skin. Although, in addition to these signs, loose stool was observed in the cages of both sexes beginning at week 21 in males and 20 in females, the group housing failed to identify which animal excreted the loose stool.

In the 8000 ppm group, males showed an increased incidence in hair loss of the skin and females represented decreases in ulcer/erosion and swelling of the skin.

In the 1600 ppm group, males showed a decrease in swelling of the skin and females represented an increase in tactile hair loss as well as a decrease in ulcer/erosion of the skin.

None of the observed effects seems to be dose-related. Whatever the dose tested, females were more sensitive to erosion/ulcer of the integument than males.

D. BODY WEIGHT

In the 40000 ppm group, males and females showed retarded growth during the treatment manifesting significantly lowered weights at weeks 16 to 36 in males and at weeks 6 and thereafter in females compared to the respective control. At the end of treatment, mean average weights were 93 % and 86 % of the respective control in males and females, respectively.

In the 8000 ppm group, females showed significantly decreased weights at week 6 and weeks 9 to 24 compared to the control and the final mean average weight was 92 % of the control at the end of the treatment, while growth rate in males was comparable to the control.
In the 1600 ppm group, males and females showed similar growth curves to the controls during the treatment period.

Effects on the body weight were more important in females than in males. These effects were durable in the 40000 ppm female group whereas they were stopped at week 36 in the male group of the same treatment dose. Sporadic effects were observed in the 8000 ppm female group. No significant effects were seen in the 1600 ppm male and female groups.

Table 5.5-108: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Body weights at week 1, 24, 52 and 78

Week 78		100	104	99	93	100	95	92	86

E. FOOD CONSUMPTION AND COMPOUND INTAKE

In the 40000 ppm group, males showed significant depressions in food consumption at weeks 1 and 68, revealing an overall group mean food consumption at 94 % of the control during the treatment period. Females in this group also showed significantly decreased food consumption at weeks 1, 4, 8, 12, 20, 28, 40, 48 and 68, revealing an overall group mean food consumption at 93 % of the control during the treatment period.

In the 8000 ppm group, females showed significantly lowered food consumption at weeks 28, 40, and 68 compared to the control manifesting an overall group mean food consumption at 96 % of the control. Whereas, food consumption in males was comparable to the control during the treatment period.

No statistically significant effects was observed in the 1600 ppm group either in males or females.

The food consumption depressions were more important in female than in males. They were not time-related.

Overall average chemical intake in each treated group of either sex was calculated from food consumption and nominal concentration as shown in the following table:

Table 5.5-109: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Calculated test substance intake in mg/kg bw/day

Dose level (ppm)	Dose level (mg/kg bw/day) Male	Female
1600	165.0	153.2
8000	838.1	786.8
40000	4348	4116

F. HAEMATOLOGY

Statistically significant changes in differential leucocyte counts observed in the treated group of either sex are shown in the following table.

Table 5.5-110: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted] 1997): Statistically significant changes in haematology parameters

Parameter	Sex	Fate of animals[a]	Dose group (ppm)		
			1600	8000	40000
Lymphocytes	Males	ke	ND[b]	↑139	↑172
	Females	tk	↓ 92	↑131	↑[c]163
Neutrophil (segmented)	Males	ke	ND	↓ 91	↓ 81

Numbers in the above table show values in the treated groups when the corresponding value in the control group is 100.
a: ke, killed *in extremis*; tk, terminal kill; b: ND, not determined; c: Dunnett's or Scheffe's multiple comparison test
↓↑ Mann-Whitney's U test

In the 40000 ppm group, males killed *in extremis* during the treatment period showed an increase of lymphocytes in differential leukocyte counts and a decrease of neutrophil (segmented form). In females of this group, differential count of lymphocytes was significantly increased at week 78.

There were no significant differences in differential leukocyte counts at other intervals of examination in the 40000 ppm group of both sexes, males killed *in extremis* in the 8000 ppm group, and females at week 78 in the 8000 and 1600 ppm groups compared to the controls. No significant treatment-related effects were conceived in morphology of the leukocytes.

G. NECROPSY

Gross pathology

Statistically significant changes in incidence of macroscopic lesions observed in the treated groups of either sex are shown in the following table.

Table 5.5-111: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Statistically significant changes in macroscopic lesions

Tk: Terminal kill; Ke/fd: Killed *in extremis* or found dead; All: All animals examined;
(N=) Number of animals examined
* $p < 0.05$ (Fisher's exact probability test);
** $p<0.01$

In the 40000 ppm group, males and females showed significant increases in incidence of distention of the cecum at terminal kill after 78 weeks of treatment. Significant increases in incidence of the lesion were also noted in all animals examined recording 28 % (14/50) in males and 36 % (18/50) in females. Distended cecum was filled with loose stool-like materials. In addition, males showed an increase in loss of tactile hair and a decrease of cyct(s) in the kidney in those necropsied at terminal kill, and an increase of swelling in the lymph nodes (mesenteric) and a decrease of wound in the skin in those killed *in extremis* or found dead during the treatment period when compared to the controls. Among these, significant differences in incidence were also noted in all animals examined for increases in loss of tactile hair and swelling of the lymph nodes (mesenteric) and a decrease in wound in the skin. Moreover, significant differences in incidence were also noted in all animals examined for an increase in anal prolapse of the anus and decreases in atrophy of the testis, partial amputation of the auricle, and swelling of the skin. Females showed decreases in loss of tactile hair and cyst(s) of the uterus in those necropsied at terminal kill, and an increase in swelling of the lymph nodes (others) and a decrease in ulcer/erosion of the skin in those killed *in extremis* or found dead during the treatment period. Among these, significant differences in incidence were noted in all animals examined for decreases in cyst(s) of the uterus and ulcer/erosion of the skin. Moreover, significant differences in incidence were also noted in all animals examined for decreases in opacity of the eye and loss of hair of the skin.

In the 8000 ppm group, males showed increases in mass(es) of the lung and loss of hair of skin and a decrease in soiled fur on external genital region in those necropsied at terminal kill when compared to the control. An increased incidence was also noted in all animals examined for loss of hair of the skin. Females killed *in extremis* or found dead during the treatment period in this group showed an increase in swelling of the lymph nodes (others) and decreases in coarse surface of the kidney and loss of hair of the skin. Moreover, significant differences in incidence were noted in all animals for an increase in mass(es) of the lung and decreases in swelling of the lymph nodes (cervical) and spleen, pale in colour and coarse surface of the kidney, opacity of the eye, and ulcer/erosion of the skin.

In the 1600 ppm group, males showed decreased incidences in swelling of the spleen in those necropsied at terminal kill and in all animals examined and in swelling of the skin in all animals examined, while

females disclosed a decreased incidence in swelling of the spleen in all animals examined.

Organ weights
In the 40000 ppm group, males and females showed significant increases in absolute and relative weights of the cecum. The percentages of the values to those of the respective control were 173 % in males and 187 % in females for absolute weight, respectively, and 174 % and 212 % for relative weight, respectively. In females, relative weight of the kidney was also increased significantly at a level of 111 % of the control.

Histopathology
Neoplastic lesions
The table below shows neoplastic lesions in the treated groups of either sex with statistically significant differences in incidence from those of the controls.

Table 5.5-112: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Statistically significant changes in histopathology findings: Incidence of malignant lymphoma at terminal sacrifice and over all animals

Sex	Male				Female

Tk Terminal kill;
(N=) Number of animals examined;
* $p < 0.05$ (Fisher's exact probability test)

During the last evaluation historical control data for malignant lymphoma from the performing laboratory ([redacted], 2013; ASB2014-9146) were submitted. A total of 9 long-term studies (no information on actual duration provided) in the same mouse strain was covered that had been performed or at least terminated (perhaps commenced before) between 1993 and 1998, i.e. exactly the time in which the study under review was conducted. In male mice, the total incidence of malignant lymphoma in control groups varied considerably, ranging from ca 4 (actually 3.58) to ca 19 % (19.23). In fact, 8 of 9 studies had a control incidence below 12 % (6 % or lower) as observed now at the top dose level but, in principle, this incidence fell into the historical control range. Thus, the conclusion is that the higher incidence at the exaggerated dose level of 40000 ppm as compared to the control group is a chance findings and cannot be used to support the assumption of a carcinogenic effects of glyphosate in mice that is based on the results of the study by [redacted] (2001, ASB2012-11491).

In female control groups, malignant lymphoma incidence was between 8 and 27 % and, thus, the actual incidences in the control and treated groups were well covered.

As to neoplastic lesions, the incidence of malignant lymphoma was significantly decreased in females of the 1600 ppm group necropsied at terminal kill compared to the control. Neither increases in incidence nor nearly occurrences compared to the controls were noted for neoplastic lesions in the treated groups of both sexes.

Non-neoplastic lesions
Statistically significant changes in incidence of non-neoplastic lesions observed in the treated groups of either sex are shown in the following table.

Statistically significant changes in incidence of non-neoplastic lesions:

Table 5.5-113: HR-001: 18-Month Oral Oncogenicity Study in Mice ([redacted], 1997): Statistically significant changes in non-neoplastic lesions

Tk: Terminal kill; Ke/fd: Killed *in extremis* or found dead; All: All animals examined
(N=): Number of animals examined
* $p < 0.05$;
** $p<0.01$ (Fisher's exact probability test)
c: The number animals examined in the control, 1600, 8000 or 40000 ppm groups were 46, 48, 48 or 46 in males and 48, 48, 50 or 49 in females, respectively.

In the 40000 ppm group, males showed significant decreases in incidence of amyloid deposition in the liver in all animals examined and cyst(s) in the kidney in those necropsied at terminal kill and in all animals examined, when compared to the control. In these males, erosion/ulcer in the anus was observed in a total

of 8 animals including 6 cases killed *in extremis* or found dead during the treatment period and 2 cases necropsied at terminal kill. There was even a large abscess in one case. Among these, regressive hyperplasia of mucous epithelium of the large intestine was seen in 2 cases with severe lesions in the anus. However, as the histopathological examinations were carried out only on the anus which were observed macroscopic lesions, the incidence of erosion/ulcer in the anus was not assessed by a statistical method. In females of this group, statistical significant decreases in incidence were noted in all animals examined as follows; increase haematopoiesis in bone marrow (femur, sternum and vertebra), plasma cell hyperplasia in the lymph nodes (cervical), cyst(s) in the kidney, micro-granuloma in the liver, and amyloid deposition in the spleen, liver, thyroid, and parathyroid. Among these, significant decreases in incidence were also noted for micro-granuloma in the liver in those necropsied at terminal kill and plasma cell hyperplasia in the lymph nodes (cervical) and amyloid deposition in the spleen and liver in those killed *in extremis* or found dead during the treatment period.

In the 8000 ppm group, although males did not show any non-neoplastic lesions with statistically significant differences in incidence from the control, females disclosed significant decreases in incidence of proliferation of cartilageous tissue in the tibio-femoral joint in those necropsied at terminal kill, wound in the skin in those killed *in extremis* or found dead during the treatment period, and subcutaneous abscess in the skin in all animals examined. In addition, significant decreases in incidence, when compared to the control, were observed in all animals examined as follows; increase haematopoiesis in bone marrow (femur, sternum and vertebra), plasma cell hyperplasia in the lymph nodes (cervical), extramedullary haematopoiesis in the spleen, amyloid deposition in the spleen, small intestine, liver, kidney (glomerular amyloidosis), uterus, thyroid, and parathyroid, and cataract in the eye. Among these, the incidences of extramedullary haematopoiesis in the spleen in those necropsied at terminal kill and amyloid deposition in the spleen, liver, thyroid, and parathyroid in those killed *in extremis* or found dead during the treatment period were also decreased significantly.

In the 1600 ppm group, males in all animals examined showed a significant increase in incidence of alveolar epithelial cell hyperplasia in the lung and decreases in incidence of myeloid cell aggregation in the lymph nodes (mesentery) and extramedullary haematopoiesis in the spleen. In females of this group, the incidences in all animals examined were decreased significantly in increased haematopoiesis in bone marrow (femur) and amyloid deposition in the spleen, small intestine, liver, uterus, thyroid, and parathyroid. Among these, significantly decreased incidences were also noted for increased haematopoiesis in bone marrow (femur) and amyloid deposition in the small intestine and thyroid in those killed *in extremis* or found dead during the treatment period.

Study conclusion:

	No-observable effect level	Based on
Males	8000 ppm (838.1 mg/kg/day)	- Increased incidences of tactile hair loss, pale-colored skin and mass(es) of anus at 40000 ppm - Decreased body weight gain at 40000 ppm - Decrease in food consumption at 40000 ppm - Decrease in urinary pH at 8000 and 40000 ppm - Increase of lymphocytes and decrease in neutrophil (segmented form) at 40000 ppm - Increase in mass(es) of the lung and loss of hair of skin at 1600 ppm but not observed at 40000 ppm. - Increase in distension and absolute and relative weight of the cecum at 40000 ppm - Increase in incidence of alveolar epithelial cell hyperplasia in the lung at 1600 ppm but not observed at higher doses.
Females	1600 ppm (153.2 mg/kg/day)	- Decreased body weight gain at 40000 ppm and 8000 ppm - Increase in tactile hair loss at 1600 ppm but not observed in

		higher dose groups - Decrease in food efficiency at 8000 ppm - Increase in swelling of the lymph nodes and in mass(es) of the lung

3. Assessment and conclusion

Assessment and conclusion by applicant: Based on the effects in female mice on food consumption and body weight gain at the mid dose level of 8000 ppm, the lowest dose of 1600 ppm (ca. 153 mg/kg bw/day) is considered the NOAEL in this study. In contrast, the masses in lung mentioned in the dossier were not dose-related and there was no convincing evidence of lymph node swelling. Male mice appeared less vulnerable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/020 CA 5.5/021
Report author	[redacted]
Report year	1989
Report title	Glyphosate: 104-week dietary carcinogenicity study in mice
Report No	7793
Document No	154-GLY
Guidelines followed in study	US-EPA Pesticide Assessment Guidelines Subdivision F, 83-2 (1982); in general compliance with OECD 451
Deviations from current test guideline (OECD 451, 2018)	Yes, histopathological examinations were performed without Harderian gland, cervix, eyes, coagulating glands, gross lesions, lacrimal glands, upper respiratory tract, seminal vesicles and vagina. No historical control data.

2. Full summary

The carcinogenic potential of glyphosate technical was assessed in a 104-week feeding study in male and female CD-1 mice. Groups of 50 mice per sex received daily dietary doses of 0, 100, 300 or 1000 mg/kg

bw/day glyphosate technical for 24 months. Observations covered clinical signs, body weight, food and water consumption, differential blood count, as well as organ weights, necropsy and histopathological examination.

Achieved doses throughout the study period were generally close to nominal. There were no treatment-related deaths or clinical signs in any of the dose-groups. A slight decrease in absolute body weight at Week 40 was evident in the low and high groups of both sexes but this finding was not considered to be treatment-related. Food and water consumption did not differ significantly from the controls. Moreover, there were no treatment-related changes in differential blood count.

At necropsy the incidence of lung masses was slightly higher in the 1000 mg/kg bw/day group. Organ weight data showed increased thymus weights in males at 300 and 1000 mg/kg bw/day after 104 weeks, but not in females. Histopathological examination noted increased mineral deposit in the brain of high dose males. These changes were not considered treatment related. No treatment-related neoplastic lesions were observed at termination.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate technical
Description:	White powder
Lot/Batch #:	206-JaK-25-1
Purity:	97.5 % and 100 %
Stability of test compound:	At least two years at ambient temperature in the dark

2. Vehicle and/or positive control: Diet

3. Test animals:

Species:	Mouse
Strain:	CD-1
Source:	[redacted]
Age:	Approx. 4 weeks upon arrival at testing facility
Sex:	Males and females
Weight at dosing:	Males: 30.9 ± 0.5 g, females: 23.5 ± 0.3 g
Acclimation period:	21 days
Diet/Food:	SQC Expanded (Fine Ground) Rat and Mouse Maintenance Diet No. 1 (Special Diet Services Limited, UK), *ad libitum*
Water:	Tap water, *ad libitum*
Housing:	Either one male or one female in suspended polypropylene cages with stainless steel wire grid tops and bottoms
Environmental conditions:	Temperature: 20 ± 2 °C Humidity: 55 ± 10 % Air changes: 15 – 20 / hour 12 hours light/dark cycle

B: Study design and methods

In life dates: 1989-11-30 to 1991-12-23

Animal assignment and treatment:
In a carcinogenicity study groups of 50 CD-1 mice per sex received daily dietary doses of 0, 100, 300 or 1000 mg/kg bw/day glyphosate technical for 104 weeks. The dose levels were selected based on the results of a 13-week dietary toxicity study in mice.

Test diets were prepared once per week for the first 13 weeks and at least once every two weeks thereafter by direct admixture of the test substance to the plain diet and mixing for 20 minutes.

Analyses for achieved concentrations of the test substance in the diet were conducted from formulated diets or Weeks 1, 4, 8, 12, 15, 23, 30, 38, 46, 54, 62, 76, 83 and 93 of dosing. The stability and homogeneity of the test substance in the diet was determined prior to the start of the study.

Clinical observations
A check for mortality was made twice daily on all animals throughout the study. In addition, all animals were examined for clinical signs during each day. A detailed clinical examination and check for palpable masses were done once each week on every animal.

Body weight
Individual body weights were recorded for each animal before dosing, at weekly intervals until the end of week 13 and approximately every 4 weeks thereafter until termination.

Food and water consumption and compound intake
Food consumption was recorded once weekly for each cage group starting one week before treatment until Week 13 and subsequently every 4 weeks until termination. Water consumption was monitored by visual inspection throughout the study period.
Achieved dosages were calculated from nominal dietary concentration, taking into account actual food consumption and body weight data.

Haematology
During Weeks 52, 77 and 102 of dosing, a blood sample was taken from all surviving animals *via* tail snip without anaesthesia. Differential blood smears were prepared, fixed and stained from all animals. A differential blood count was performed on smears from all surviving Control and High dose animals at each time point.

The following parameters were measured: Differential leukocyte count (neutrophils, lymphocytes, monocytes and eosinophils). Absolute indices were calculated.

Sacrifice and pathology
All surviving animals were sacrificed and necropsied. Method of killing was by carbon dioxide asphyxiation followed by exsanguination. The gross dissections and necropsies were performed under the supervision of a pathologist, with the organs/tissues listed below being weighed and/or fixed.

The following organs were weighed: adrenals, brain, heart, kidneys, liver, lungs, ovaries, pituitary, prostrate, salivary glands (parotid, sublingual and submaxillary), spleen, testes including epididymides, thymus and uterus.

The following organs were examined histopathologically: adrenals, aortic arch, any abnormal tissue, bladder, bone and bone marrow (sternum and rib), brain, intestine (duodenum, jejunum, ileum, caecum, colon, rectum), heart, kidneys, liver with gall bladder, lungs, mammary gland, lymph nodes (mesenteric), muscle (thigh), oesophagus, ovaries, pancreas, parotid salivary glands, pituitary, prostrate, sciatic nerve,

skin, spinal cord (cervical, thoracic and lumbar), spleen, stomach (glandular and non-glandular), sublingual salivary glands, submaxillary salivary glands, testes with epididymis, thymus, thyroid/parathyroid, trachea and uterus.

Statistics
Body weight and organ weight data were statistically analysed for homogeneity of variance using the 'F-max' test. If the group variances appeared homogeneous, a parametric ANOVA was used and pairwise comparison made *via* Students's t-test using Fishers's F protected LSD. If the variances were heterogeneous, log or square root transformations were used in an attempt to stabilise the variances. If the variances remained heterogeneous, then a nonparametric test such as Kruskal-Wallis ANOVA was used.

Organ weights were also analysed conditional on body weight (i.e. analysis of covariance). Differences in survival data between Control and groups receiving Glyphosate were assessed graphically using Kaplan-Meier plots. Histology and tumour data were analysed using Fisher's Exact Probability test.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
Periodic analyses for achieved concentrations showed that the diet preparations of all dose groups were within an acceptable degree of accuracy (± 10 %), with the exception of 2 instances where deviation of the mean from the theoretical concentration exceeded ± 10 % (Group 2♀ - Week 62: +248 % and Group 3♀ - Week 93: -10.1 %).

B. MORTALITY
There were 208 pre-terminal deaths throughout the study. There was no evidence to suggest that any of these deaths were treatment-related.

The numbers of deaths are summarised in the table below.

Table 5.5-114: Glyphosate – 104 week dietary carcinogenicity study in mice ([redacted] 1989): Cumulated mortalities after 104-week dietary exposure to glyphosate technical

Sex	Dose group (mg/kg bw/day)*			
	0	100	300	1000
Male	24/50	25/50	21/50	25/50
Female	29/50	34/50	24/50	26/50

* Number of dead / total number

C. CLINICAL OBSERVATIONS
There were no notable intergroup differences in either sex. The clinical signs seen were distributed equally throughout all groups and included emaciation, a hunched posture, subdued behaviour and exophthalmic eyes. These are considered to be typical for mice of this age and strain in a study of this type and duration.

There were no notable intergroup differences in the incidences of externally palpable masses.

D. BODY WEIGHT
A slight decrease in absolute body weight at Week 40 was evident in all groups of both sexes except control and intermediate dose females. This transient effect is not considered to be attributable to administration of glyphosate. Generally, slight (incidental) increases of body weights were observed in substance treated animals of all dose groups until week 52. The effect was most often observed in high dose males being constantly about 10 % and less often observed in high dose females. Between week 52 and 104 the body weights were comparable within all groups. All groups receiving glyphosate showed a comparable weight gain to that of their respective controls. The mean body weight gain data are summarised in the table below.

Table 5.5-115: Glyphosate – 104 week dietary carcinogenicity study in mice ([redacted] 1989): Body weight development (mean values) after 104-week dietary exposure to glyphosate technical

	Dose group (mg/kg bw/day)							
	0		100		300		1000	
	♂	♀	♂	♀	♂	♀	♂	♀
Weight gain (g) 0-104 weeks	12.8	14.9	↑13.1	↓14.1	↑14.4	↓14.7	↑13.0	↑15.2
% of control	--	--	102	95	113	99	102	102

E. FOOD AND WATER CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food and water consumption for either sex noted during the study.
The overall group mean achieved doses are summarised in table below.

Table 5.5-116: Glyphosate – 104 week dietary carcinogenicity study in mice ([redacted] 1989): Group mean achieved dose levels – oncogenicity study

Dose group	Nominal dose (mg/kg bw/day)	Mean achieved dose level (mg/kg bw/day)		Mean achieved dose level (% of nominal)	
		Males	Females	Males	Females
1 (control)	0	--	--	--	--
2 (low)	100	98 ± 6	102 ± 11	98	102
3 (mid)	300	297 ± 17	298 ± 30	99	99
5 (high)	1000	988 ± 56	1000 ± 113	99	100

Over the entire study duration the mean achieved dosages in all groups were close to the nominal.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Haematology – Differential Blood Counts

There were no notable intergroup differences in either sex at any time point.

H. NECROPSY

Gross pathology

The incidence of lung masses was slightly higher in the male high dose group (18/50) compared to the male control (10/50). There were no other findings in males or females noted at necropsy that could be related to treatment with Glyphosate.

Organ weights

Absolute thymus weight was increased in the male intermediate and high dose groups ($p < 0.01$ and $p < 0.05$, respectively) compared to control. Thymus weight was also increased in the male intermediate and high dose groups ($p < 0.05$ and $p < 0.01$, respectively) after covariance analysis.

There were no other notable intergroup differences in males or females.

Table 5.5-117: Glyphosate – 104 week dietary carcinogenicity study in mice ([redacted] 1989): Absolute thymus weights

Dose group	Nominal dose	absolute Thymus weight (g)

	(mg/kg bw/day)	males	females
control	0	0.02 ± 0.01	0.02 ± 0.01
2 (low)	100	0.02 ± 0.01	0.05 ± 0.05
3 (mid)	300	0.03 ± 0.02**	0.04 ± 0.03
5 (high)	1000	0.03 ± 0.03*	0.06 ± 0.08

* Significantly different from control, $p < 0.05$;
** Significantly different from control, $p < 0.01$

Histopathology
Non-neoplastic changes
The incidence of increased mineral deposits in the brain was higher in the male high dose group (13/50, $p < 0.05$) compared to control (4/49).

All other statistically significant findings in males and females were considered to be typical background changes commonly seen in mice of this age and strain.

Neoplastic findings
There were no statistically significant increases in incidence of any tumour.
The number of animals with tumours, both benign and malignant, was similar between the control and high dose groups of both sexes. However, the number of animals with multiple tumour types was slightly increased in the high dose group of both sexes (males: 16/50 and females: 11/50) compared to control (males: 11/50 and females: 6/50). This led to a slight increase in the total number of tumours in the high dose group of both sexes (males: 60 and females: 43) compared to control (males: 49 and females: 36).

Hemangiosarcoma was evident in 4/50 high dose males, 2/50 low dose females and 1/50 high dose females (not significant) compared to the respective controls (both 0/50).

Histiocytic sarcoma in the lymphoreticular/haemopoietic tissue was evident in 2/50 low and 2/50 high dose males and 3/50 low, 3/50 intermediate and 1/50 high dose females (not significant) compared to the respective Controls (both 0/50).

Other tumours seen were considered to be typical for mice of this age and strain due to the very low incidence of occurrence and were not considered to be due to administration of Glyphosate.

3. Assessment and conclusion

Assessment and conclusion by applicant: In conclusion, glyphosate technical was not carcinogenic in male and female CD-1 mice following continuous dietary exposure of up to 1000 mg/kg bw/day (the limit dose for this type of study) for 104 weeks. Based on the study results and the lack of toxicological relevance of the thymus weight findings, as well as an increase of mineral deposit in the brain observed at 1000 mg/kg bw/day, the NOAEL in rats after chronic exposure to glyphosate technical for 104 weeks is considered to be 1000 mg/kg bw/day.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/022
Report author	[redacted]

Report year	1988
Report title	Carcinogenicity and Chronic Toxicity Study of Glyphosate (Technical) of Excel Industries LTD., Bombay
Report No	Not reported
Document No	Not reported
Guidelines followed in study	No guideline followed; similar to OECD 453 (1981)
Deviations from current test guideline (OECD 453, 2018)	Yes, less than 50 (25) animals/sex/dose were used for the main test and less than 10 (5) animals/sex/dose were used as a satellite group; no ophthalmology performed; haematology was performed without determining mean corpuscular volume, mean corpuscular haemoglobin, mean corpuscular haemoglobin concentration, prothrombin time, activated partial thromboplastin time; clinical chemistry was performed without determining inorganic phosphorous, calcium, chloride, sodium, potassium, cholesterol, AST, any hepatobiliary evaluation, albumin, creatinine, T3, T4, TSH; organ weights of brain, epididymides, spleen, (para)thyroids and uterus were not determined; histopathology was performed without determining bone/bone marrow, caecum, harderian gland, cervix, coagulating gland, epididymides, jejunum, lacrimal gland, upper respiratory tract, rectum, mammary gland, peripheral nerve, prostate, skeletal muscle, spinal cord, trachea, vagina. No historical control data.
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Not reported
Acceptability/Reliability:	Invalid Due to restrictions regarding dose levels, number of animals used and insufficient investigations the study is not considered reliable for hazard and risk assessment. In view of the discussion ongoing on the endpoint carcinogenicity a full summary is provided in order to allow a complete re-evaluation. The test substance (batch reference or purity) was also not clearly defined in the report.
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Glyphosate (Technical) manufactured by Excel Industries Limited, Bombay was administered *via* the diet in concentrations of 75, 150 or 300 ppm (equivalent to mean achieved dose levels of 0, 1.63, 3.35 or 5.87 mg/kg bw/day (males) and 0, 1.65, 3.35 or 5.42 mg/kg bw/day (females)) to 25 Balb/c mice per sex and dose for 80 weeks. In addition 5 animals/sex/dose were used as a satellite group and were treated for 40 month.

Animals were observed for any abnormal toxicity, body weight, food consumption, haematology, clinical chemistry, organ weights, histopathology and occurrence of tumours.

No toxic symptoms were noted during the study. The body weight and the food intake of the high dose animals of both sex was reduced. Haematology and clinical chemistry values of all treated groups were comparable to the control. No significant differences were found in organ weights or histopathological examination and no abnormal rise in tumour occurrence was found in the animals fed with the test material. Glyphosate (Technical) supplied by Excel Industries Ltd., Bombay, did not show any significant increase in tumour formation or toxicological effects when Balb/c mice were fed at the dose of 300 ppm (mixed

with food) for 80 weeks.

B: Study design and methods

In life dates: Not reported

Animal assignment and treatment:
In a combined chronic toxicity and carcinogenicity study groups of 25 Balb/c mice per sex received daily dietary doses of 0, 75, 150 and 300 ppm (equivalent to mean achieved dose levels of 0, 1.63, 3.35 and 5.87 mg/kg bw/day (males) and 0, 1.65, 3.35 and 5.42 mg/kg bw/day (females)) Glyphosate technical for 80 weeks. In addition, for the control and each dose group 5 rats per sex were included for interim sacrifice in month 9 to study blood chemistry and haematology (chronic toxicity study).

Clinical observations
General observations were performed once a day to start with and twice daily later on to prevent death of animals at night. Animals were palpated for occurrence and size of the tumour.

Body weight

Individual body weights were recorded on Day 0, once a week until the end of Week 13 and every 4 weeks thereafter until termination.

Food consumption and compound intake
Food consumption was recorded once weekly for each group from Week 1 to Week 13 and then every 4 weeks.

Haematology and clinical chemistry
The satellite group of 10 animals was sacrificed at the end of 9 months, blood was collected and processed for the following haematological and biochemical studies. All the surviving animals were sacrificed at the end of 18 months, their blood was collected and processed for haematological and biochemical studies.

Haematology
The following parameters were measured: Haemoglobin, total red blood cell count, packed cell volume (PCV), platelets, total white blood cell count and differential white blood cell count.

Blood chemistry
The following parameters were measured: Total serum proteins, alanine transaminase (ALT), blood urea nitrogen and blood glucose.

Sacrifice and pathology
Necropsy was performed on all animals that died during the observation period and all animals at scheduled termination.

The following absolute and relative (percent of body weight) organ weights were determined: adrenals, heart, gonads, kidneys, liver and spleen.

Tissue samples for histopathology were taken from the following organs of all animals: adrenals, aorta, brain, colon, duodenum, eyes, gall bladder, heart, ileum, kidneys, liver, lungs, lymph nodes, oesophagus, ovaries, pancreas, pituitary, salivary glands, seminal vesicles, skin, spleen, stomach, testes, thymus, thyroid, urinary bladder, uterus and tumour.

Statistics
Not reported.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
Analysis of the dose formulation was not performed.

B. MORTALITY
No treatment-related deaths were observed in this study.

The numbers of pre-terminal deaths in the main group are displayed in the below **Table 5.5-118**:

Table 5.5-118: Carcinogenicity and Chronic Toxicity Study of Glyphosate (Technical) of Excel Industries LTD., Bombay ([redacted], 1988): Cumulated mortalities after 80-week dietary exposure to Glyphosate technical

Sex	Dose group (ppm)			
	0	75	150	300
Male	4/25	7/25	5/25	7/25
Female	4/25	5/25	3/25	7/25

C. CLINICAL OBSERVATIONS

None of the animals under treatment exhibited any toxic symptoms during the course of the study.

D. BODY WEIGHT

The gain in body weight of animals treated with Glyphosate (Technical) at two dose levels 75 ppm and 150 ppm was found to be comparable with that of control animals, while that of animals in the higher dose group (i.e. fed with 300 ppm) was found to be reduced.

E. FOOD CONSUMPTION AND COMPOUND INTAKE

Glyphosate (Technical) up to the dose of 150 ppm did not cause any effect on food consumption while the animals in the high group (300 ppm) showed reduction in food intake. The mean intake for each dose group is 1.63, 3.35 and 5.87 mg/kg bw/day (males) and 1.65, 3.35 and 5.42 mg/kg bw/day (females) for 75, 150 and 300 ppm, respectively.

The group mean achieved doses are summarised below.

Table 5.5-120: Carcinogenicity and Chronic Toxicity Study of Glyphosate (Technical) of Excel Industries LTD., Bombay ([redacted], 1988): Group mean achieved dose levels

Dose group	Dietary concentration (ppm)	Mean achieved dose level (mg/kg bw/day)	
		Males	Females
low	75	1.63	1.65
mid	150	3.35	3.35
high	300	5.87	5.42

F. LABORATORY INVESTIGATION

Haematology

The values of haematological parameters in the animals of treated groups (Groups II, III and IV) were found to be comparable to the animals in the control group (Group I) at interim and final sacrifice. There was no significant difference in the values at interim sacrifice and those at final sacrifice.

Numbers of testes weight for male at 75 ppm were not readable properly in the report and may thus not be listed correctly.

Histopathology
Histopathological changes were found at all dose levels including control, hence it is concluded that these are no treatment-related effects.

Table 5.5-125: Carcinogenicity and Chronic Toxicity Study of Glyphosate (Technical) of Excel Industries LTD., Bombay ([redacted], 1988): List of histopathological findings

Organ	Finding
Liver	Degenerative changes, vacuolation of cytoplasm in a few hepatocytes
Lung	Emphysema, perivascular and peribronchiolar lymphoid aggregation
Spleen	Lymphoid hyperplasia, depletion of lymphoid tissue, necrosis
Kidney	Nephrotic changes
Thyroid	Less colloid
Adrenal	Stromal hyperplasia
Uterus	Cystic hyperplasia
Salivary gland	Lymphoid hyperplasia
Ileum	Catarrhal changes
Duodenum	Catarrhal changes

Neoplastic changes
The incidence of tumour finding was comparable in control animals and animals treated at various dose levels.

Table 5.5-126: Carcinogenicity and Chronic Toxicity Study of Glyphosate (Technical) of Excel Industries LTD., Bombay ([redacted], 1988): Neoplastic changes

ppm	Males				Females			
	0	75	150	300	0	75	150	300
Liver: Hepatocellular adenoma	1/25	1/24	0/24	1/24	1/25	0/25	1/25	1/25
Lung: Alveolar adenoma	1/25	1/24	1/24	2/24	1/25	1/25	0/25	1/25

3. Assessment and conclusion

Assessment and conclusion by applicant:
Balb/c mice did not show any significant increase in tumour formation or toxicological effects when given Glyphosate (technical) in the diet at up to 300 ppm (equivalent to 5.87 or 5.42 mg/kg/day in males and females respectively for 80 weeks.
Due to several limitations the study is not considered reliable for hazard and risk assessment.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/023
Report author	[redacted]
Report year	1983
Report title	A chronic feeding study of glyphosate (Roundup® technical) in mice
Report No	77-2061
Document No	M-646425-01-1
Guidelines followed in study	No guideline specified, in general compliance with OECD 451
Deviations from current test guideline (OECD 451, 2018)	Yes, Histopathological examinations were performed without coagulating glands, lacrimal glands, upper respiratory tract, seminal vesicles and vagina. No historical control data.
Previous evaluation	Yes, accepted in the RAR (2015)
GLP/Officially recognised testing facilities	No (pre-GLP; no certificate)
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

This study was designed to assess the oncogenic potential and toxicity of glyphosate (Roundup® Technical) when administered orally, *via* dietary admixture to CD-1 mice (50/sex/group) at dose levels of 1000, 5000 or 30000 ppm (equivalent to 157, 814 and 4841 mg/kg bw/day for males and 190, 955 and 5874 mg/kg bw/day for females) for a period of twenty-four months. Control animals received basal diet.

Detailed physical observations for signs of toxic or pharmacologic effects and palpations for tissue masses were performed weekly throughout the study. Body weight and food consumption measurements were conducted on all animals. Water consumption was measured at month 12 on 10 animals/sex/group and at month 24 on 12 animals/sex/group. Haematology evaluations were conducted on 10 animals/sex/group at months 12 and 18 and 24 and on 12 males/group and all females surviving to the last day of sacrifice. After twenty-four months of treatment, all survivors were sacrificed, selected organs were weighed and organ/body and organ/brain weight ratios were calculated. Complete gross post-mortem examinations and histopathological evaluation of selected tissues were conducted on all animals.

Mean body weights for the high-dose males were generally lower than control; differences from control

were as great as -11 % (at Week 102) and were, for the most part, statistically significant. Mean body weights for the high-dose females and the males and females at the low- and mid-dose levels did not demonstrate a response to treatment.

Other parameters evaluated, i.e. general animal condition, body weight gain. food consumption, feed efficiency, water consumption and haematology revealed no consistent dose- or treatment-related response to administration of glyphosate.
At the terminal sacrifice, the mean absolute and relative (to body and brain weights) weight of the testes were elevated for the high-dose group. Other organ weight differences noted were attributed to differences in body weight or were sporadic and were not considered treatment-related.

Correlation of necropsy observations with microscopic findings revealed no treatment relationship.

Neoplastic findings were those commonly encountered in mice. Bronchioalveolar tumours of the lungs, hepatocellular neoplasms, and tumours of the lymphoreticular system accounted for the majority of those encountered. There were no suspected test substance-associated trends in the incidence of these tumours or in any of the other spontaneously occurring neoplasms. Lymphoreticular tumours tended to be more frequent in treated animals, particularly the females. The numbers were relatively small and differences from the control failed to provide supportive evidence that the neoplasms had a test substance relationship.

The other neoplasms that occurred with any frequency in treated mice only were renal tubule adenomas, which occurred in males. Three were present at the high-dose and one at the mid-dose level; however, the distribution of this benign tumour was considered spurious and unrelated to treatment. All other neoplasms occurred sporadically and were considered to have had no relationship to treatment.

Of the non-neoplastic findings, hepatic central lobular hypertrophy was noted with increased incidence in the high-dose group. This change may represent a hepatocellular adaptation to the metabolism of the test substance. A slight increase in the incidence of slight to mild epithelial hyperplasia was noted in the urinary bladder of the mid- and high-dose males; however, no treatment relationship was suspected.

All other tissue alterations occurred sporadically or were considered to have been spurious in distribution. Most occurred with approximately equal frequency and severity in control and treated mice and were judged to be unrelated to glyphosate administration.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate (Roundup® technical)
Description:	Fine, white clumped powder
Lot/Batch #:	NB 1782608/3 and NB 1782610/7
Purity:	99.7 %
Stability of test compound:	Not reported

2. Vehicle and/or positive control: Diet

3. Test animals:

Species:	Mouse
Strain:	CD-1, COBS (ICR derived)
Source:	[redacted]

Age:	at receipt: 29 days; at treatment: 40 days
Sex:	Males and females
Weight at dosing:	Males: 23 g (16 – 28 g); females: 20 g (15 – 24 g)
Acclimation period:	11 days
Diet/Food:	Purina® Rodent Laboratory Chow #5001, *ad libitum*
Water:	automated watering system (Elizabethtown Water Company), *ad libitum*
Housing:	Animals were doubly housed in elevated stainless steel wire mesh cages during the first week of the acclimation period and individually housed thereafter.
Environmental conditions:	Temperature: 18.3 – 23.9 °C
	Humidity: 30 – 80 %
	Air changes: not reported
	12 hours light/dark cycle

B: Study design and methods

In life dates: 1980-03-31 to 1982-03-14

Animal assignment and treatment:
In a carcinogenicity study groups of 50 CD-1 mice per sex received daily dietary doses of 0, 1000, 5000 or 30000 ppm (equivalent to 157, 814 and 4841 mg/kg bw/day for males and 190, 955 and 5874 mg/kg bw/day for females) glyphosate technical for 104 weeks.

Test diets were prepared once per week. Analyses for achieved concentrations of the test substance in the diet were conducted by the sponsor.

Clinical observations
A check for mortality and for gross signs of toxicology was made twice daily on all animals throughout the study. A detailed clinical examination and check were performed at the beginning of the study and once each week on every animal.

Body weight
Individual body weights were recorded for each animal twice before dosing, at weekly intervals until the end of week 14, biweekly thereafter until termination and at termination.

Food and water consumption and compound intake
Food consumption was recorded once weekly for each cage group starting one week before treatment until Week 14 and subsequently biweekly until termination.

Measured and recorded daily for 10 animals/sex/group at month 12 over one 3-day interval. A second 3-day interval, at month 12, was omitted due to technician error. Due to the high mortality across all groups during month 24, water consumption measurements were initiated on 12 animals/sex/group in an attempt to insure adequate sample size for statistical evaluation. Measurements at month 24 were performed over one 3-day and one 2-day interval.

Achieved dosages were calculated from nominal dietary concentration, taking into account actual food consumption and body weight data.

Haematology
During Month 12, 18 and 24 of dosing, blood was obtained *via* venipuncture of the orbital sinus (retrobulbar

venous plexus) under light ether anaesthesia. Animals were selected randomly; the same animals were used at all intervals when feasible. Mice were fasted overnight prior to blood collections and were not fed until after samples were collected.

Performed on 10 animals/sex/group, evaluations were conducted on 12 males/group (to insure adequate sample size for statistical evaluation) and on all females surviving to the last day of sacrifice (mortality occurring during the water consumption measurement period resulted in haematology evaluations on fewer than 10 animals/group in some groups).

The following parameters were measured: Haemoglobin, haematocrit, erythrocytes, platelets, total and differential leukocytes, erythrocyte morphology.

Sacrifice and pathology
Complete gross post-mortem examination was performed on all animals which died spontaneously, accidentally, or were killed moribund as well as at termination. External surface, all orifices, the cranial cavity, carcass, the external surfaces of the brain and spinal cord, nasal cavity and paranasal sinuses, the thoracic, abdominal and pelvic cavities and their viscera and the cervical tissues and organs were examined for all animals. Animals were fasted prior to the terminal sacrifice.

The following organs were weighed: adrenals, brain (with entire brain stem), heart, kidneys, liver, ovaries, spleen and testes.

The following organs were examined histopathologically: adrenals, abdominal aorta, bladder, bone and bone marrow (costochondral junction), bone marrow smear and blood smear, brain, epididymides, eyes (with optic nerve and contiguous Harderian glands), gross lesions, head, heart, intestine (duodenum, jejunum, ileum, caecum, colon, rectum), kidneys, liver with gall bladder, lungs, mammary gland, lymph nodes (mediastinal and mesenteric), muscle (biceps femoris), oesophagus, ovaries, pancreas, mandibular salivary glands, pituitary, prostrate, sciatic nerve, skin, spinal cord (cervical), spleen, stomach, testes, thymus, thyroid/parathyroid, tissue masses or suspect tumours and regional lymph nodes, trachea and uterus (with cervix).

Statistics
Body weight, body weight gain, food and water consumption, feed efficiency, haematology parameters, terminal organ and body weights, organ/body and organ/brain weight ratios were analysed. Mean values of all dose groups were compared to control at each time interval.

II. RESULTS

A. ANALYSIS OF DOSE FORMULATIONS
Analyses for achieved concentrations of the test substance in the diet were conducted by the sponsor.

B. MORTALITY
The incidence of mortality was low during the first 18 months of study, with survival rates greater than or equal to 62 % and 68 % for the males and females, respectively. The mortality rate increased after 18 months, as would be expected in aging mice. The incidence of mortality was considered to demonstrate no dose- or test substance-related adverse effect of glyphosate administration on survival, i.e. survival was greater than control in the high-dose males and mid- and high-dose females, with the lowest survival in the low-dose females.

The numbers of deaths are summarised in the table below.

Table 5.5-127: A chronic feeding study of glyphosate (Roundup® technical) in mice ([redacted], 1983): Cumulated mortalities after 104-week dietary exposure to glyphosate technical

Sex	Dose group (ppm)[1]			
	0	1000	5000	30000
Male	27/50 (3)	32/50 (2)	32/50 (1)	23/50 (1)
Female	27/50 (3)	38/50 (0)	22/50 (1)	23/50 (4)

[1] Number of dead / total number; accidental deaths are presented in parentheses

C. CLINICAL OBSERVATIONS

The physical observations noted throughout the study were considered common for CD-1 mice under laboratory conditions; these observations included yellow staining of the anogenital area, dermatological abnormalities (scabbing on the ears and alopecia), excessive lacrimation, displacement of the pupils and ocular opacities. These observations occurred with low incidence and did not occur in a pattern suggestive of a relationship to treatment.

D. BODY WEIGHT

Sporadic differences from control were noted in the mean body weight data for the high-dose females, and the males and females at the low- and mid-dose levels. However, these differences from control were slight and failed to demonstrate a consistent pattern with respect to treatment level over time, and were therefore, not considered to reflect a response to treatment.

Body weight gain data exhibited some variability, as is common with mouse studies. No treatment-related trends were apparent in these data for male and female animals.

E. FOOD AND WATER CONSUMPTION AND COMPOUND INTAKE

There were no treatment-related effects on food and water consumption for either sex noted during the study. Test substance intake was calculated from individual body weight and food consumption values and nominal concentrations of 1000, 5000 and 30000 ppm of glyphosate and expressed as milligrams of test substance per kilogram of body weight per day (mg/kg/day).

The overall group mean achieved doses are summarised in the table below.

Table 5.5-4131: A chronic feeding study of glyphosate (Roundup® technical) in mice ([redacted] 1983): Group mean achieved dose levels – oncogenicity study

Dose group	Concentration (ppm)	Mean achieved dose level ranges (mg/kg bw/day)		Mean achieved dose level according to study report (mg/kg bw/day)	
		Males	Females	Males	Females
1 (control)	0	--	--	--	--
2 (low)	1000	110.9 – 249.9	128.9 – 287.8	157	190
3 (mid)	5000	519.3 – 1264.2	689.7 – 1321.5	814	955
4 (high)	30000	3465.0 – 7219.8	4232.4 – 9858.6	4841	5874

Mean water consumption values (expressed in millilitres of water consumed per kilogram of body weight per day) for the treated males at month 12 were lower than control values; however, differences from control were not statistically significant and at month 24, values for the treated males (particularly the high-dose group) were comparable to control values. Water consumption values for the low- and mid-dose females were somewhat elevated at month 12 relative to control, but a similar pattern was not evident at month 24. No consistent test substance-related effects on water consumption were apparent in these data.

F. HAEMATOLOGY AND CLINICAL CHEMISTRY

Although a few statistically significant differences from control were noted for some of the haematology parameters evaluated, these differences occurred sporadically or did not occur in a dose-related pattern and were not consistent over time. Therefore, these slight differences were not considered to be of toxicological significance.

Evaluation of differential leukocytes and erythrocyte morphology revealed no evidence of an effect of glyphosate administration on these parameters.

H. NECROPSY

Gross pathology

Correlation of necropsy observations with microscopic findings revealed no trend indicating a test substance relationship.

Organ weights

Differences in mean absolute or relative (to body or brain weights) organ weights from control for this group were considered reflective of the difference in mean body weight and not of toxicological significance. The exception to this pattern was the increased mean absolute and relative weights of the testes for the high-dose group; although histopathologic evaluation did not reveal any morphologic abnormalities in this tissue. Sporadic organ weight differences were noted at lower dose levels; however, they were not considered toxicologically significant, as no dose response relationship was evident.

The mean absolute and relative (to body and brain weight) ovarian weights for the high-dose females were markedly elevated, although differences from control were not statistically significant. These differences were due to a single animal, whose ovarian weight of 0.213 g was approximately six times the mean ovarian weight for the group when this value was excluded ($\bar{x}$ = 0.033 grams). Differences from control excluding this animal were not considered remarkable. Other organ weight differences were attributed to body weight differences or were sporadic and were not considered to be related to the administration of glyphosate.

Histopathology

Non-neoplastic changes

The only non-neoplastic alteration in the urinary tract that occurred with an increased frequency over controls was slight-to-mild epithelial hyperplasia of the urinary bladder in males. The incidence was 6 %, 6 %, 20 % and 16 % controls through high-dose, respectively. Even though the increase at the mid- and high-dose was present is considered test substance related.

All other tissue alterations occurred sporadically or were considered to have been spurious in their distribution. Most occurred with approximately equal frequency and severity in control and treated animals, and were judged to be unrelated to glyphosate administration.

Neoplastic findings

Neoplastic findings were of the type commonly encountered in mice. Bronchiolar-alveolar tumours of the lungs, hepatocellular neoplasms and tumours of the lymphoreticular system accounted for the majority of those encountered. There were no suspected test substance-associated trends in the incidence of these tumours or of any of the other spontaneously occurring neoplasms.

Lymphoreticular tumours tended to be more frequent in treated animals, particularly the females. The numbers were relatively small and differences from the control population failed to provide any supportive evidence that the neoplasms had a test substance relationship.

The only other neoplasms that occurred with any frequency in treated mice only, were renal tubule adenomas, which occurred in males. Three were present at the high-dose and one at the mid-dose level. The distribution of these benign tumours was considered spurious and unrelated to treatment due to the absence of other renal lesions suggestive of or supportive of an effect on the urinary system.
All other neoplasms occurred sporadically and were considered to have had no treatment relationship.
Non-neoplastic tissue alterations were of the type and severity expected in long term mouse studies. Actually fewer tissue lesions were encountered than anticipated.

The only liver finding which may have been test substance associated was central lobular hepatocyte hypertrophy which occurred in 34 % of high-dose males compared to 18 %, 10 % and 6 % in control through mid-dose males, respectively. This change may have represented a hepatocellular adaptation to metabolism of the test substance.

3. Assessment and conclusion

Assessment and conclusion by applicant: In conclusion, glyphosate technical was not carcinogenic in male and female CD-1 mice following continuous dietary exposure of up to 30000 ppm (equivalent to 4841 mg/kg bw/day for males and 5874 mg/kg bw/day for females) for 104 weeks. Based on non-neoplastic histological changes affecting urinary bladder epithelium in male mice at 5000 ppm glyphosate in diet (814 mg/kg bw/day) and higher, the chronic mouse NOAEL is considered the low dose of 1000 ppm (157 mg/kg bw/day).

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 5.5/024
Report author	[redacted]
Report year	1982 (original report) 1992 (revised translated version)
Report title	18-Month Carcinogenicity Study of Glyphosate in Mice
Report No	8010
Document No	Not reported
Guidelines followed in study	No guideline followed; similar to OECD 451 (1981)
Deviations from current test guideline (OECD 451, 2018)	No data on test item purity provided; animal weight at dosing, acclimatisation period and diet were reported; no in-life dates were reported; only two dose levels were tested; body weight were measured only monthly; the number of animals surviving up to scheduled termination and subjected to pathological examination was too small for meaningful evaluation; the mice which had died inter-currently were not examined and the cause of death is unknown; histopathology was performed without determining cervix, coagulating glands, harderian gland, lacrimal gland, pituitary, thymus and vagina. No historical control data.
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No (pre-GLP)
Acceptability/Reliability:	Invalid Due to several limitations the study is not considered reliable for hazard and risk assessment.
Category study in AIR 5	Category 3b

dossier (L docs)	

2. Full summary

Glyphosate (Technical) was administered to groups of 50 male and female CFLP mice (bred in a facility in [redacted]; 26 - 30 days old at study initiation) per dose at dietary levels of 0, 100 and 300 ppm (equivalent to 0, 12.6 and 37.7 mg/kg bw/day for males and 0, 16.3 and 44.5 mg/kg bw/day for females). The administration period was 18 months.

Animals were kept under continuous observation for behaviour, general condition and lethality. External examinations were performed periodically. Body weight gains were measured monthly and food consumption was measured weekly. All surviving animals were necropsied after the treatment period and examined for gross pathological and histopathological findings.

No toxic symptoms were noted during the study regarding body weight changes and food consumption. Mortality was high in all groups (11-23 of 50 mice). In-life, necropsy and histopathology data excluded the dose-related toxicity of the test item at the applied dose levels. The number of tumours detected partly by gross pathology and identified by histopathology showed a similar distribution in treated and control groups.

This was the case with the number of tumour bearing animals, too. The various kinds of tumours showed a certain difference in their occurrence in treated and control groups without convincing and statistically significant signed of dose dependence. Consequently, the available study data were against the carcinogenicity of glyphosate in mice in the given experimental conditions.

I. MATERIALS AND METHODS

A: Materials

1. Test material:

Identification:	Glyphosate
Description:	No data given in the report
Lot/Batch #:	14/980-03090380
Purity:	No data given in the report
Stability of test compound:	No data given in the report

2. Vehicle and/or positive control:

Diet / none

3. Test animals:

Species:	Mouse
Strain:	CFLP
Source:	[redacted]
Age:	28 ± 2 days
Sex:	Males and females
Weight at dosing:	No data given in the report
Acclimation period:	No data given in the report
Diet/Food:	No data given in the report
Water:	Tap water, *ad libitum*
Housing:	Groups of 10 per sex in OMKER III shoebox type cages

Environmental conditions:	Temperature:	21 ± 3 °C
	Humidity:	50 ± 5 %
	Air changes:	10 times/hour

B: Study design and methods

In life dates: Not reported, but issued in 1982

Animal assignment and treatment:
In a carcinogenicity study groups of 50 CFLP mice per sex received daily dietary doses of 0, 100 or 300 ppm (equivalent to 0, 12.6 or 37.7 mg/kg bw/day for males and 0, 16.3 or 44.5 mg/kg bw/day for females) glyphosate for 18 month.

Clinical observations
Animals were kept under continuous observation for behaviour, general condition and lethality. External examinations were performed periodically.

Body weight
Individual body weights were recorded on monthly.

Food consumption
Food consumption was recorded once weekly.

Sacrifice and pathology
Necropsy was performed on all animals that died during the observation period and all animals at scheduled termination.

Tissue samples for histopathology were taken from the following organs of all animals: adrenals, aorta, bone with bone marrow, brain, duodenum, epididymides, eyes with optic nerve, gall bladder, heart, ileum, jejunum, large intestine, kidneys, lungs, lymph nodes (mesenteric and submandibular), muscle (femoral), oesophagus, ovaries, pancreas, prostate salivary glands, sciatic nerve, seminal vesicles, skin with mammary tissue, spleen, spinal cord, stomach, testes, trachea, thyroid, tongue, tumours, urinary bladder and uterus.

Statistics
For analysing the incidence of tumours and bearing animals χ^2 test was used.

Results

A. ANALYSIS/PREPARATION OF DOSE FORMULATIONS
One week before study initiation, than monthly, three different pre-mixes were prepared from glyphosate substance and soya. Premixes were submitted monthly to [redacted] where they were used for diet preparation. The prepared food samples were given to the animals for one month.

B. MORTALITY
The numbers of pre-terminal deaths in the main group are displayed in Table 5.5-136:

Table 5.5-136: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Mortality

Sex	Dose group [ppm]					
	0		100		300	
	Males	Females	Males	Females	Males	Females
Month 1 – 3	0	1	1	0	0	0

Month 4 – 6	0	2	1	7	0	2
Month 7 – 9	2	7	7	7	3	2
Month 10 – 12	3	7	15	56	5	7
Month 13 – 15	21	7	4	6	4	13
Month 16 – 18	13	12	8	9	15	12
Combined	39/50	36/50	36/50	34/50	37/50	36/50

Both the time dependent incidence and the cumulative values of deaths excluded the negative influence of test substance and dose on the life expectance of mice. The males of the 100 ppm dose group died somewhat earlier, while the survival rate was the highest in the 300 ppm male group with 25/50 overall mortality. Conclusively, test substance exerted no impairment on the health condition of mice as expressed by the mortality values.

C. CLINICAL OBSERVATIONS

Mice had a symptom-free general health condition during the study.

D. BODY WEIGHT

The kinetics of body weight change were of similar pattern in the treated and control groups. Maximal weights were measured mostly between month 6-12 with a slight declination by the end of the study period. The rate of decrease was slightly stronger in 100 and 300 ppm males, but was milder than in the corresponding control, in 100 ppm females.

Table 5.5-137: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Group mean body weights

Time point	Sex	Males			Females

E. FOOD CONSUMPTION AND COMPOUND INTAKE

After the initially higher consumption values a steady state level was formed in all study groups with only minor and temporary deviations. The group mean achieved doses are summarised below.

Table 5.5-138: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Group mean achieved dose levels

Dose group	Dietary concentration [ppm]	Mean achieved dose level [mg/kg bw/day]	
		Males	Females
low	100	12.6	16.3
high	300	37.7	44.5

Table 5.5-139: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Group mean food consumption

Time point	Sex	Males			Females

F. NECROPSY

At terminal sacrifice necropsy findings referred first of all to regular or irregular enlargements in (liver, lung, lymph nodes, uterus and ovary) or on the surface of some organs, like intestines (M+F). Since no distinction was made in respect of their nature (tumor, inflammation, cyst or functional status), therefor, the seemingly dose-related incidence of alterations might refer to, but do not evidence the real treatment dependence of any of the lesions.

Table 5.5-140: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Group mean food consumption

Parameter	Sex	Males/Females		
	Dose [ppm]	0	100	300
	No. of rats	25	30	37
Liver: Focal enlargement		3 (12)	3 (10)	8 (21)
Spleen: Enlargement		2 (8)	2 (7)	6 (16)
Small intestines: round shaped formation		3 (12)	4 (13)	8 (21)
Lymph nodes: Enlargement		6 (24)	5 (17)	6 (16)
Lung: Focal enlargement		7 (28)	6 (20)	9 (24)

() Number in parenthesis are % of the respective group/parameter

Histopathology

Non-neoplastic changes

They were chiefly inflammatory or age related alterations. The inflammatory ones were mostly chronic with acute exacerbations, like in several lungs and some ovaries. In other organs like liver, kidney and glandular organs only focal and mild signs of inflammation were seen.

Liver degeneration of parenchymal or hydropic type was regarded as an age related lesion similarly to focal or multifocal fibrous processes in liver, lung, intestines, etc.

Thymus, and especially female reproductive organs revealed definite signs of atrophy, while the mucosa of the urinary bladder was frequent hypertrophic, in some cases reaching the level of benign papilloma.

Neoplastic changes

The incidence of tumour findings are summarised in the following table:

Table 5.5-141: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted] 1982/1992): Neoplastic lesions

Organ	Tumour
Liver	Hepatoma, haemangioma (benign, malignant, unspecified)
Lung	Bronchial, broncho-alveolar adenoma (benign or malignant)
Lymphoid tissue	Malignant lymphoma (lymphoid or reticular type)
Urinary bladder	Papilloma (always benign)
Uterus	Adenoma, leiomyoma (benign or malignant)
Ovary	Cystoma, cystadenoma, carcinoma
Eye, thyroid, pancreas, skin, muscle, lacrimal gland adenoma, carcinoma, insuloma, dermoid cyst, haemangioma	Only occasionally encountered tumours
Brain, aorta, heart, tongue, oesophagus, stomach, small intestines, large intestines, salivary gland, adrenals, kidneys, testicle, epididymides, seminal vesicles	No tumour observed

Accordingly, and also owing to the relatively low and different number of animals per dose group, some tumours revealed an uneven distribution, while most were seen in similar incidence in dosed and control groups. Percentage frequency was therefore calculated for the most significant tumours, the result of which are as follows:

Table 5.5-142: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Most significant tumours

Parameter	Sex	Males			Females			Combined sex		
	Dose [ppm]	0	100	300	0	100	300	0	100	300
Liver hepatoma		1 (9)	0 (0)	5 (22)	0 (0)	0 (0)	1 (7)	4.5	0	16.2
Pulmonary tumour (adenoma, carcinoma)		1 (9)	1 (7)	4 (17)	4 (29)	4 (25)	2 (14)	22.5	16	16
Malignant lymphoma		1 (9)	1 (7)	1 (4)	1 (7)	2 (12)	1 (7)	8	10	5.4

(): Number in parenthesis are % of the respective group/parameter

Several uteri revealed marked structural transformation by the end of study period. Apart from a few cases of physiological atrophy, many of them showed endometrial cystic-glandular hyperplasia. Very probably this was in close relation with the development of endometrial adenoma and perhaps of leiomyoma, too. In the ovarian tumours the proliferation of both granulosa and transformed epithelial elements was detectable; they were always combined with extensive inflammatory reaction.

Table 5.5-143: 18-Month Carcinogenicity Study of Glyphosate in Mice ([redacted], 1982/1992): Female genital tumours

Parameter	Sex	Females		
	Dose [ppm]	0	100	300
Uterus		2/14 (14)	1/16 (6)	2/14 (14)
Ovary		1/14 (7)	2/16 (12)	1/14 (7)

() Number in parenthesis are % of the respective group/parameter

Owing to the relatively high number and even distribution of most tumours evaluation and concluding seem possible, in spite of the relatively low and different number of animals available per group and sex.

Non-tumorous changes were of partly related to inflammatory-parasitic processes. These were the cause of some focal or extended enlargements described at necropsy in some of the livers, lungs, etc. They were related occasionally to the physiological state of organ, like enlarged Peyer's plaques appearing as focal enlargements in or on the small intestines.

The most frequent tumours were those of the liver, lung and the lymphatic tissue. The combined incidence the three tumours was similar in the three study groups, still, certain tumours showed a higher incidence in one of the groups, like liver tumours in 300 ppm males and lung tumours in 0 ppm females.

It has still to be stated that neither the individual tumours, nor their overall incidence, nor the number of animals with tumour(s) revealed a statistically significant, dose-dependent distribution.

This is valid even if we add to the facts, that certain tumours found only in single animals, occurred in dosed and not in control. This can be regarded as incidental finding, they were taken into account at the overall tumour distribution.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Glyphosate did not show any significant increase in tumour formation or toxicological effects when fed

to CFLP mice up to the highest tested dose of 300 ppm (dietary admix) for 18 months. Consequently the available study data do not reveal the carcinogenicity of glyphosate in mice in the given experimental conditions. The NOAEL in this study is 300 ppm (equivalent to 37.7 mg/kg bw/day for males and 44.5 mg/kg bw/day for females).

Due to several limitations the study is not considered reliable for hazard and risk assessment.

Assessment and conclusion by RMS:

1. Information on the study

2. Summary

Historical control data CRl:CD1 (ICR) mouse already submitted in 2015 are included in this document.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Historical control data CRl:CD1 (ICR) mouse already submitted in 2015 are included in this document.

Assessment and conclusion by RMS:

Epidemiology

Notwithstanding the conclusion of the EU 2001 evaluation, the opinion of the glyphosate renewal task force and of several other recent reviews of Glyphosate (EFSA 2015, ECHA 2016, JMPR/WHO 2016, FSC Japan 2016, PMRA Canada, 2017, U.S. EPA 2019) where it was concluded that glyphosate is not a carcinogen,

in 2015, a review of the scientific evidence by the International Agency for Research on Cancer (IARC) concluded that the evidence for the carcinogenicity of glyphosate was limited in humans but sufficient in experimental animals (rats and mice). IARC further concluded that glyphosate was probably carcinogenic in humans.

The IARC conclusion has triggered a number of experts to investigate why there should be different conclusions from different investigating bodies. Crump *et al* (2020) reports one such investigation.

In his paper Crump points out that the animal carcinogenicity data on glyphosate are unusually extensive (≥15 long term rodent oral bioassays of glyphosate identified by U.S. EPA (2016), EFSA (2016) and IARC (2015). Each bioassay was conducted in both sexes, with each sex potentially having 40-60 unique tumour types, resulting in over 1000 potential statistical tests, which could easily result in many significant ($p \leq 0.05$) tumour increases occurring by chance alone – roughly 5 %. Crump K. *et al* (2020) have assessed the probability of false positives using a modification of the permutation approach of Farrar and Crump (1988 and 1990). The statistical method requires access to individual animal data on histopathological information and tumours, the length of time each animal was on test, and their doses. These criteria were met in 10 bioassays (4 mouse and 6 rat), which included all the bioassays cited by IARC as showing evidence of carcinogenicity.

The present analysis provides new information on the potential carcinogenicity of glyphosate by being the first to provide results from statistical tests with correct false positive rates. These tests found no strong or convincing evidence that glyphosate is an animal carcinogen.

Portier (2020) also provided an additional revised statistical evaluation and trend test analysis. The author asserts that his updated analyses in the publication support the IARC's conclusion of evidence of cancer in experimental animals. Crump (2020), however, determined that statistically a significant number of false positives across the very large glyphosate database supports all previous regulatory reviews around the world, that glyphosate does not demonstrate any carcinogenic potential in rats or mice.

During the last evaluation in 2015, a number of epidemiology studies were evaluated and summaries provided within the dossier. The summaries of these studies (beyond the scope of a 10 year literature search) were additionally included in the dossier in order to allow a comprehensive evaluation (Appendix 1, MCA 5). In order to trace back the publications in the Appendix, the ASB reference numbers are still included in the text below and additionally in the Appendix 1.

A number of epidemiology studies over the last decade have focused on pesticide exposure and associated health outcomes. Publications vary in the scope of their conclusions regarding either pesticides in general, certain classes of pesticides and in some cases individual insecticides, herbicides or fungicides. While some of these publications specifically mention glyphosate, few draw tenable associations with any specific cancer outcome. Publications suggesting glyphosate is associated with any cancer outcome are discussed in Appendix 1.

An essential consideration in both, risk assessment and interpreting the relevance of toxicology data, is exposure assessment. An inherent low level of confidence exists for epidemiological studies where tenuous links to exposure exist. Suggested associations between health outcomes and any possible causative agent are merely speculative if exposure cannot be confirmed and quantified.

The largest epidemiological study of pesticide exposure and health outcomes in the United States was the Agricultural Health Study (AHS) that also addressed and included glyphosate. Dozens of publications have resulted from data generated in this study of approximately 57000 enrolled farmers (applicators). Blair *et al*. (2009, ASB2012-11566) provided an overview of cancer endpoints associated with different agricultural chemicals reported in earlier AHS publications. Glyphosate was not reported to be associated with leukaemia, melanoma, or cancers of the prostate, lung, breast, colon or rectum. De Roos *et al*. (2005, ASB2012-11605) reported AHS data evaluating glyphosate use and multiple cancer endpoints. No

association was noted for glyphosate with all cancers, including cancer of the lung, oral cavity, colon, rectum, pancreas, kidney, bladder, prostate, melanoma, all lymphohematopoietic cancers, non-Hodgkin's lymphoma (NHL) and leukemia. In an earlier publication based on another data set, however, De Roos *et al*. (2003, ASB2012-11606) had reported an association between NHL and glyphosate use. Likewise, McDuffie *et al*. (2001, ASB2011-364) mentioned a non-significant positive association between self-reported glyphosate exposure and NHL in a Canadian study. Blair *et al*. (2009, ASB2012-11566), in contrast, did not report an association between glyphosate use and NHL in the AHS data but a "possible association" between glyphosate use and multiple myeloma was mentioned making reference to a "suggested association" between glyphosate use and multiple myeloma suggested by De Roos *et al*. (2005, ASB2012-11605). However, in this paper, no significant increase in relative risk for multiple myeloma was demonstrated. Both papers by De Roos *et al*. will be discussed in more detail in Appendix 1. Interestingly, a subsequent AHS review paper for the President's Cancer Panel (Freeman, 2009, ASB2012-11623) specifically referenced De Roos *et al*. (2005 ASB2012-11605) to provide no evidence of cancers of any type to be associated with glyphosate. With regards to multiple myeloma Presutti *et al*. (2016) analysed a subset of three NAPP studies (Iowa, Nebraska and Canada) where multiple myeloma (MM) cases were recruited. Self-reported information on pesticide use, farming activities and demographic characteristics was collected and the odds ratios (OR) were calculated for "ever/never" exposure, years of exposure and cumulated lifetime days of exposure to glyphosate with and without exclusion of proxy respondents. The result is that no statistically significant increases in risk of multiple myeloma (MM) associated with self-reported exposure to glyphosate were observed. This publication is considered relevant for glyphosate risk assessment but reliable with restrictions because it concerns pooled case control studies which are subject to recall bias and in which confounding factors could not be ruled out.

Sorahan *et al*. (2015) calculated the relative risk estimates for exposed and non-exposed applicators using Poisson regression and subjects with missing data were not excluded from the main analyses. When using the full dataset adjusted for age and gender the analysis produced a RR close to unity for ever-use of glyphosate. Additional adjustment for lifestyle factors and use of ten other pesticides had little effect. This study found no statistically significant trends of multiple myeloma risk with reported cumulative days of glyphosate use and unexceptional point estimates of risk for ever-use of glyphosate. This was irrespective of whether the analyses had adjustment for a few basic variables (age and gender) or adjustment for many other lifestyle factors or pesticide exposures, as long as data on all available pesticide applicators were used. The suspiciously elevated RRs reported previously in De Roos *et al*. (2005) arose from the use of restricted data sets that were unrepresentative of the study cohort.

Andreotti *et al*. 2018 updated the 2005 AHS publication by DeRoos *et al*. (2005), extending cancer incidence follow-up through 2012 in North Carolina and 2013 in Iowa and incorporating additional exposure information from a follow-up questionnaire. The authors also dealt with missing information through imputation and conducted sensitivity analyses to address the potential for various types of bias in their primary analyses. This 2018 publication includes a total of 7,290 cancers, 3.6 times as many as in the earlier publication. The median lifetime days of glyphosate use for cohort members who reported glyphosate use (83 % of the cohort) was 48 days (interquartile range (IQR) 20 to 166 days). The authors found no evidence of an association between glyphosate use and risk of any solid tumour, NHL (RR 0.87 (95 % CI 0.64, 1.20 in the highest intensity weighted exposure quartile, p_{trend} 0.95), or multiple myeloma (RR 0.87, 95 % CI 0.45, 1.69 highest quartile,, p_{trend} 0.84). They found a stastically non-significant elevated RR for acute myelogenous leukaemia (RR 2.44, 95 % CI 0.94, 6.32, p_{trend} = 011). The lack of stastically significant findings for cancer types were consistent across different exposure metrics, in various sensitivity analyses, and for lagged exposure analyses meant to address cancer induction-latency.

The purpose of the analysis by Crump (2019) was to evaluate the evidence for recall bias in the overall pattern of results in five case control studies and two cohort studies that comprise the main part of the glyphosate-NHL literature. In evaluating the case control studies, Crump reasoned that the percentage of odds ratios > 1 for non-glyphosate exposures should be approximately 50 % if recall bias was not operative and those exposures did not cause NHL. Yet, it turned out that the percentages of ORs >1 for non-glyphosate exposures were 90 % for Hardell *et al*. (2002), 90 % for Erikson *et al*. (2008), 93 % for

McDuffie *et al*. (2001), 76 % for Orsi *et al*. (2009), and 53 % for DeRoos *et al*. (2003). These extreme departures from 50 % for 4 of the 5 case control studies is consistent with recall bias, perhaps augmented by a type of selection bias in the analyses by Hardell *et al*. (2002) and Eriksson *et al*. (2008). In contrast, in the most recent publication from the Agricultural Health Study (Andreotti *et al*. 2018), only 48 % of the relative risks (RR) calculated were >1 – a percentage in the range expected with a true probability of 50 %. While the evaluation of Andreotti *et al*. (2018) concerned glyphosate and other cancer sites and not other exposures and NHL, the principle is the same: under the null hypothesis the proportion of ORs or RRs > 1 should be roughly 50 % absent bias.

Pahwa *et al*. (2019) performed a pooled reanalysis of the data from 2 published non-Hodgkin's lymphoma (NHL) case control studies was conducted: McDuffie *et al*. 2001 and DeRoos *et al*. 2003. The reanalysis sought to evaluate associations for glyphosate use and NHL overall and by histological sub-type. In addition, the pooled analysis implemented more extensive control of confounding factors than in the original publications and considered the impact of excluding pesticide information provided by next-of-kin or proxy respondents. The OR for NHL overall for ever using glyphosate was 1.4 (95 % CI 1.1, 1.8). After adjustment for other pesticides, the OR was reduced to 1.1 (95 % CI 0.8, 1.5). For NHL subtypes, consistent patterns of association across exposure metrics were not seen, with the possible exception of SLL, though SLL findings were not statistically significant. In general, exclusion of proxy respondents reduced ORs to a minor extent with the exception of the analyses for other NHL subtypes. For NHL overall, ever use and analyses that considered duration of use per se or lifetime days of use did not show a relationship with glyphosate. There was a moderate association seen for glyphosate use for the metric > 2 days/year. There was some limited evidence of an association between glyphosate use and SLL across exposure metrics, but the small number of SLL cases resulted in very imprecise OR estimates as evidenced by wide 95 % CIs. The major limitation of the study is likely case recall bias in the reporting of prior pesticide use.

Lee *et al*. (2005, ASB2012-11882) reported a glyphosate association with gliomas, with the odds ratio differing between self-respondents (OR = 0.4) and proxy respondents (OR = 3.1). The authors expressed concern about higher positive associations observed for proxy respondents with glyphosate and several other pesticides. They suggested perhaps more accurate reporting of proxies for cases and underreporting by proxies for controls. Monge *et al*. (2007, ASB2012-11909) investigated associations between parental pesticide exposures and childhood leukaemia in Costa Rica. Results are not interpretable for glyphosate as exposure was estimated with "other pesticides", including paraquat, chlorothalonil and "others". No association was noted for paternal exposures, but elevated incidence of leukaemias was associated with maternal exposures to "other pesticides" during pregnancy.

Some further epidemiological studies have focused on an association between pesticide exposure and Non-Hodgkin`s Lymphoma (NHL). Hardell and Eriksson (1999, ASB2012-11838) investigated in a case-control study the incidence of NHL in relation to pesticide exposure in Sweden. 404 cases and 741 controls have been included. The authors discussed an increased risk for NHL especially for phenoxyacetic acids. Glyphosate was included in the univariate and multi-variate analyses. However, only 7 of 1145 subjects in the study gave exposure histories to this agent. The authors reported a moderately elevated odds ratio (OR) of 2.3 for Glyphosate. This OR was not statistically significant and was based on only 4 "exposed" cases and 3 "exposed" controls. The major limitations of this study were: the reliance on reported pesticide use (not documented exposure) information, the small number of subjects who reported use of specific pesticides, the possibility of recall bias, the reliance on secondary sources (next-of-kin interviews) for approximately 43 % of the pesticide use information, and the difficulty in the controlling for potential confounding factors given the small number of exposed subjects.

A further study was submitted by Hardell *et al*. (2002, ASB2012-11839). This study pools data from the above mentioned publication by Hardell and Eriksson (1999, ASB2012-11838) with data from a previously submitted publication from Nordström *et al*. (1998, TOX1999-687). The authors found increased risks in an uni-variate analysis for subjects exposed to herbicides, insecticides, fungicides and impregnating agents. Among herbicides, significant associations were found for glyphosate and MCPA. However, in multi-variate analyses, the only significantly increased risk was found with a heterogenous category of "other

herbicides" and not for glyphosate. No information is given about exposure duration, exposure concentration, as well as medical history, lifestyle factors (e.g. smoking, use of prescribed drugs etc.). In all, the above mentioned limitations of the publication of Hardell and Eriksson (1999, ASB2012-11838) are also applicable to the publication by Hardell *et al*. (2002, ASB2012-11839).

Fritschi *et al*. (2005, ASB2012-11624) submitted a case-control study with 694 cases of NHL and 694 controls in Australia. Substantial exposure to any pesticide was associated with an increase of NHL. However, no association between NHL and glyphosate can be made on basis of this study. No information was given about exposure duration, used glyphosate products, and application rates. Therefore, the documentation is considered to be insufficient for assessment. Eriksson *et al*. (2008, ASB2012-11614) reported a case-control study which included 910 cases of NHL and 1016 controls living in Sweden. The highest risk was calculated for MCPA. Glyphosate exposure was reported by 29 cases and 18 controls, and the corresponding odds ratio (OR) was 2.02. Results and reliability of the study are discussed in the Appendix 1.

Alavanja *et al*. (2013, ASB2014-9174) reviewed studies on cancer burden among pesticide applicators and others due to pesticide exposure. In this article, the epidemiological, molecular biology, and toxicological evidence emerging from recent literature assessing the link between specific pesticides and several cancers including prostate cancer, NHL, leukaemia, multiple myeloma, and breast cancer were integrated. Glyphosate was reported to be the most commonly used conventional pesticide active substance worldwide. However, the only association between the use of glyphosate and cancer burden mentioned in this review was the observation of Eriksson *et al*. (2008, ASB2012-11614, see above).

The following epidemiological studies did not reveal an association between glyphosate and specific cancer types.

· Alavanja *et al*. (2003, ASB2012-11535) reported on prostate cancer associations with specific pesticide exposures in the AHS; glyphosate did not demonstrate a significant exposure-response association with prostate cancer.

· Multigner *et al*. (2008, ASB2012-11917) also reported a lack of association between glyphosate use and prostate cancer. This data appears to have also been reported by Ndong *et al*. (2009, ASB2012-11922).

· The lack of association between glyphosate use and prostate cancer was also supported recently in an epidemiology study in farmers in British Columbia, Canada, by Band *et al*. (2011, ASB2012-11555).

· Lee *et al*. (2004, ASB2012-11883) reported a lack of association between glyphosate use and stomach and esophageal adenocarcinomas.

· Carreon *et al*. (2005, ASB2012-11585) reported epidemiological data on gliomas and farm pesticide exposure in women; glyphosate had no association with gliomas.

· Engel *et al*. (2005, ASB2012-11613) reported AHS data on breast cancer incidence among farmers' wives, with no association between breast cancer and glyphosate.

· Flower *et al*. (2004, ASB2012-11620) reported AHS data on parental use of specific pesticides and subsequent childhood cancer risk among 17,280 children, with no association between childhood cancer and glyphosate.

· Andreotti *et al*. (2009, ASB2012-11544) reported AHS data where glyphosate was not associated with pancreatic cancer.

· Landgren *et al*. (2009, ASB2012-11875) reported AHS data on monoclonal gammopathy of undetermined significance (MGUS), showing no association with glyphosate use.

· Karunanayake *et al*. (2011, ASB2012-11865) reported a lack of association between glyphosate and Hodgkin's lymphoma.

· Pahwa *et al*. (2011, ASB2012-11987) reported a lack of association between glyphosate and multiple myeloma.

Schinasi and Leon (2014, ASB2014-4819) published the results of epidemiologic research on the relationship between non-Hodgkin lymphoma (NHL) and occupational exposure to pesticides. Phenoxy herbicides, carbamate insecticides, organophosphorus insecticides and lindane were positively associated with NHL. However, no association between NHL an glyphosate was reported.

· Kachuri *et al*. (2013, ASB2014-8030) investigated an association between lifetime use of multiple

pesticides and multiple myeloma in Canadian men. Excess risks of multiple myeloma were observed among men reported using at least one carbamate pesticide, one phenoxy herbicide and ≥ organochlorines. However, no excess risk was observed for glyphosate.
· Cocco *et al*. (2014, ASB2014-7523) investigated the role of occupational exposure to agrochemicals in the aetiology of lymphoma overall, B cell lymphoma and its most prevalent subtypes. No increased CLL risk in relation to glyphosate was evidenced.
· Alavanja and Bonner (2012, ASB2014-9173) reviewed studies on occupational pesticide exposure and cancer risk. Twenty one pesticides identified subsequent to the last IARC review showed significant exposure-response associations in studies of specific cancers. No significant association was observed for glyphosate.
· El-Zaemey and Heyworth (2013, ASB2014-9473) reported a case control study on the association between pesticide spray drift from agricultural pesticide application areas and breast cancer in Western Australia. The findings support the hypothesis that woman who ever noticed spray drift or who first noticed spray drift at a younger age had increased risk of breast cancer. However, it was no possible to examine whether the observed associations are the result of a particular class of pesticides.
· Pahwa *et al*. (2011, ASB2014-9625) investigated the putative association of specific pesticides with soft-tissue sarcoma (STS). A Canadian population-based case-control study conducted in six provinces was used on this analysis. The incidence of STS was associated with insecticides aldrin and diazinon after adjustment for other independent predictors. However, no statistically significant association between STS and exposure to glyphosate or other herbicides was observed.
· Koutros *et al*. (2011, ASB2014-9594) studied associations between pesticide and prostate cancer. No statistically significant positive association between pesticides and prostate cancer were observed. There was suggestive evidence on an increased risk (OR>1.0) with an increasing number of days of use of petroleum oil/petroleum distillate used as herbicide, terbufos, fonofos, phorate and methyl bromide. However, no increased risk (OR>1.0) was observed for glyphosate.

In a comprehensive review of the AHS publications and data, Weichenthal *et al*. (2010, ASB2012-12048) noted that increased rates in the following cancers were not associated with glyphosate use: overall cancer incidence, lung cancer, pancreatic cancer, colon or rectal cancer, lymphohematopoietic cancers, leukaemia, NHL, multiple myeloma, bladder cancer, prostate cancer, melanoma, kidney cancer, childhood cancer, oral cavity cancers, stomach cancer, oesophagus cancer and thyroid cancer.

Mink *et al*. (2012, ASB2014-9617) submitted a comprehensive review of epidemiologic studies of glyphosate and cancer. To examine potential cancer risks in humans they reviewed the epidemiologic literature to evaluate whether exposure to glyphosate is associated causally with cancer risk in humans. They also reviewed relevant methodological and biomonitoring studies of glyphosate. The review found non consistent pattern of positive associations indicating a causal relationship between total cancer (in adults or in children) or any site-specific cancer and exposure to glyphosate.

Literature summaries

A literature search for the active substance glyphosate was performed in accordance to the provisions of the EFSA Guidance "Submission of scientific peer-reviewed open literature for the approval of pesticide active substances under Regulation (EC) 1107/2009" and updated Appendix to this Guidance document. The following publications were found relevant and reliable for this section and the summaries are thus presented below and are part of the general discussion at the beginning of the section.

Table 5.5-144: Overview on literature found relevant for evaluation of glyphosate in section 5.5

Annex Point	Study	Study type	Substance(s)	Reliability & restriction comments	Result
CA 5.5/026	Crump, 2020	Statistical analysis of available bioassays Continuity corrected poly-3 test (a survival-adjusted Cochran-Armitage test)	Not applicable	Reliable without restrictions	No strong or convincing evidence that glyphosate is an animal carcinogen
CA 5.5/027	Portier, 2020	Statistical analysis of available bioassays Use of Cochran-Armitage (C-A) linear trend test	Not applicable	Reliable with restrictions	Sufficient evidence that glyphosate causes cancer in experimental animals
CA 5.5/028	Wozniak, 2020	*In vitro* assay, effect on epigenetic parameters and major cell cycle drivers in PBMCs	Glyphosate (Purity. 95 %)	Reliable without restrictions	No indication of glyphosate to impact the measured parameters was demonstrated
CA 5.5/029	Biserni, 2019	*In vitro*, lipid accumulation in adipocytes	Glyphosate (Purity: ≥ 96 %)	Reliable without restrictions	No lipid accumulation
CA 5.5/030	Crump, 2019	Methodologic evaluation of recall bias in existing studies	Not applicable	Reliable without restrictions	Recall bias not reliable
CA 5.5/031	Duforestel, 2019	*In vitro*, mammary cells (MCF10A)	Glyphosate (Purity not reported)	Reliable with restrictions Glyphosate not sufficiently characterized Only one dose tested, 10^{-11}M	Glyphosate primes mammary cells for tumorigenesis
CA 5.5/032	Hao, 2019	*In vitro*, human A549 cells	Glyphosate isopropylamine salt (Purity: ≥ 95 %)	Reliable with restrictions No positive control Only one dose tested	No activation of the AMPK/mTOR signalling pathway, no role in autophagy
CA 5.5/033	Pahwa, 2019	Reanalysis of case control studies	Not applicable	Reliable with restrictions Recall bias unresolved Missing data	Inconclusive effect of glyphosate to non-Hodgkin

Table 5.5-144: Overview on literature found relevant for evaluation of glyphosate in section 5.5

Annex Point	Study	Study type	Substance(s)	Reliability & restriction comments	Result
					lymphoma
CA 5.5/034	Wang, 2019	*In vivo*, 7-day and 72-week study, mice (C57bl/6 and Vk*MYC)	Glyphosate (Purity not reported)	Reliable with restrictions Glyphosate uncharacterized Only one dose considered in chronic study Insufficient number of animals in acute study and number unreported in chronic study	Glyphosate induces MGUS and promotes disease progression to multiple myeloma
CA 5.5/035	Andreotti, 2018	Epidemiologic evaluation of US Agricultural Health Study (AHS) Data	Glyphosate formulation (no further details)	Reliable with restrictions Dose not known, only frequency of use	No evidence of an association between glyphosate use and risk of any solid tumor, NHL, or multiple myeloma
CA 5.5/036	Presutti, 2016	Epidemiologic evaluation	Glyphosate formulation	Reliable with restrictions Pooled case control studies, thus recall bias with confounding factors	No statistically significant increases in risk of multiple myeloma
CA 5.5/037	Sorahan, 2015	Statistical re-analysis of US Agricultural Health Study (AHS) Data	Glyphosate formulation	Reliable without restrictions	No statistically significant trends of multiple myeloma risk with reported cumulative days of glyphosate use

2. Information on the study

Data point:	CA 5.5/026
Report author	Crump, K. et al.
Report year	2020
Report title	Accounting for Multiple Comparisons in Statistical Analysis of the Extensive Bioassay Data on Glyphosate.
Document No	https://doi.org/10.1093/toxsci/kfaa039
Guidelines followed in study	Not applicable
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Not applicable
Acceptability/Reliability:	-/Reliable without restrictions

6. Full summary of the study according to OECD format

Abstract

Glyphosate is a widely used herbicide worldwide. In 2015, the International Agency for Research on Cancer (IARC) reviewed glyphosate cancer bioassays and human studies and declared that the evidence for carcinogenicity of glyphosate is sufficient in experimental animals. We analyzed ten glyphosate rodent bioassays, including those in which IARC found evidence of carcinogenicity, using a multi-response permutation procedure that adjusts for the large number of tumors eligible for statistical testing and provides valid false-positive probabilities. The test statistics for these permutation tests are functions of p-values from a standard test for dose-response trend applied to each specific type of tumor. We evaluated three permutation tests, using as test statistics the smallest p-value from a standard statistical test for dose-response trend and the number of such tests for which the p-value is less than or equal to 0.05 or 0.01. The false-positive probabilities obtained from two implementations of these three permutation tests are: smallest p-value: 0.26, 0.17, p-values ≤ 0.05: 0.08, 0.12, p-values ≤ 0.01: 0.06, 0.08. In addition, we found more evidence for negative dose-response trends than positive. Thus, we found no strong evidence that glyphosate is an animal carcinogen. The main cause for the discrepancy between IARC's finding and ours appears to be that IARC did not account for the large number of tumor responses analyzed and the increased likelihood that several of these would show statistical significance simply by chance. This work provides a more comprehensive analysis of the animal carcinogenicity data for this important herbicide than previously available.

Materials and methods

Analysis of bioassay data - Of the bioassays identified by U.S. EPA, EFSA, or IARC, 10 glyphosate cancer studies of sufficient quality were selected which allowed the analysis of individual animal data. The characteristics of the selected studies are summarized in Table 1.

Table 5.5-145: Characteristics of the bioassays selected for analysis.

Bioassay	Species	Strain	# Dose Groups	Sex	Animals/Dose	Maximum Dose[a] (mg/kg/d)		Maximum Weeks on test	Sites Where Histopathology was Conducted in All Dose Groups[b]
						Males	Females		
Atkinson et al 1993b[c]	Mouse	CD-1	4	50		988	1000	105	Kidney, Liver, Lung, Vascular System
Knezevich and Hogan 1983[c]	Mouse	CD-1	4	50		4841	5873	102	(all)
Wood et al 2009b	Mouse	CD-1	4	51		810	1081	81	Kidney, Liver and Lung
Sugimoto 1997	Mouse	CD-1-ICR	4	50		4348	4116	78	(all)
Atkinson et al 1993a[c]	Rat	SD[d]	5	50		1007	1018	105	Kidney, Liver, Lung and Salivary Glands: Parotid, Mandibular and Sublingual
Lankas 1981[c]	Rat	SD	4	50		31.49	34.02	111	(all)
Stout and Ruecker 1990[c]	Rat	SD	4	60		940	1183	105	(all)
Brammer 2001[c]	Rat	Wistar	4	64		1214	1498	104	(all)
Suresh 1996	Rat	Wistar	4	50		595.2	886	107	(none)
Wood et al 2009a	Rat	Wistar	4	51		1077	1382	105	Kidney, Liver, Lung and Bone Marrow

[a] All doses in each bioassay are listed in Table 2.
[b] Systemic tumors are assumed to have been searched for if at least one tissue in an animal was given a histopathological examination.
[c] These six studies were evaluated by IARC. IARC (2015) also reviewed two additional studies in which they identified shortcomings, but which they did not claim were "inadequate": Chruscielska et al (2000) and JMPR (2006). No glyphosate-related tumor responses were noted in either of these studies.
[d] SD: Sprague Dawley.

Eight of the 10 studies were assigned a Klimisch code 1 (reliable without restrictions). The Knezevich and Hogan (1983) study was assigned a Klimisch code 2 (reliable with restrictions) mainly because this study

was initiated before the implementation of the OECD test guidelines and GLP, and the study of Lankas (1981) also a pre-GLP and pre-guideline study was assigned a Klimisch code 3 (not reliable) mainly because of the low power of the study due to the low dose range selected.

Statistical tests - The statistical tests applied in the analysis were functions of p-values obtained from conventional continuity-corrected poly-3 tests (survival-adjusted Cochran-Armitage test) for trend applied to each type of tumor or combination of tumor types in each bioassay. In the present analysis, the continuity-corrected version of the poly-3 test used was copied from a key portion of the computer program used by the NTP. Direct comparisons have shown that the author's implementation gives the same results as the version used by the NTP. Throughout this paper, all implementations of the poly-3 test, are one-sided, as are the NTP implementations of the test.

Results from 3 multi-response permutation tests are presented. In the simplest test, referred to as the "min-test", the test statistic is the smallest p-value obtained from applying the poly-3 test to all tumor types in all of the 10 bioassays. In the simplest implementation of this test, animals are randomly reassigned to dose groups (permuted among dose groups) in a Monte Carlo analysis, keeping the total numbers of animals in each dose group equal to the number in the original data. The tumors in each such reassignment are analyzed using the poly-3 test in exactly the same way as in the original data. Males and females are permuted separately. The false positive rate is the proportion of random reassignments that result in a smallest poly-3 p-value that is smaller than or equal to the smallest poly-3 p-value obtained from the original data. In addition to the min-test, two additional permutation tests were computed. The test statistics for these tests were the number of poly-3 tests of tumors in the original data for which the p-value is less than or equal to the critical value of 0.05 (05-test) or 0.01 (01-test). The false positive rates for these tests are the proportion of random permutations of the data for which the number of poly-3 p-values from the permuted data that are less than or equal to the critical value equal or exceed the number from the original data. The min-test could have enhanced power in a situation in which a test agent causes cancer at a single site, whereas the 05-test could have enhanced power when a test agent causes detectable cancer of several types. The permutation tests described above are conditional, not just on the total number of tumors, but also on the patterns of tumors occurring in individual animals.

In addition to conducting conventional poly-3 tests on specific types of tumors, tests were also conducted on combinations of tumor types thought to have a common origin such as liver adenomas and carcinomas. Since including these combinations resulted in the same tumors being present in multiple analyses, it was decided to perform two analyses, one (primary analysis) that included all of the individual tumors and combinations, and one (reduced analysis) in which individual tumors and combinations of tumors were removed from the analysis if they were part of a more inclusive tumor combination (e.g. the individual tumor categories of liver adenoma and liver carcinoma were removed and only the combination was used in the analysis).

For 5 of the glyphosate bioassays, all tissues listed for histopathological examination were scheduled for a histological examination in all animals of all dose groups. In the remaining 5 bioassays, control and high dose animals were all given a complete histopathological examination, along with the animals that died before the final sacrifice in the intermediate dose groups. In addition, certain tissues in all animals were scheduled for a histopathological examination regardless of when they died.

Simple randomization suffers from a potential bias due to dose-related differential survival, and, for studies with incomplete histopathology, a problem of data comparability.

In each of the 10 bioassays, dose-related effects on survival were tested using a Cochran-Armitage test for negative trend on the proportions of animals surviving to final sacrifice in the various dose groups. Regardless of the outcome of this test, to control for potential dose-related differences in survival each randomization of the data maintained the same number of survivors and non-survivors in each group as was seen in the actual data.

For other tissues than the mandatory tissues in the studies with incomplete histopathology, only the non-survivors in the intermediate dosed groups could be used in the trend analyses. For mandatory tissues, the survivors and non-survivors were separately permuted. Mandatory tissues and other tissues had to be separately randomized in studies with incomplete histopathology to make sure that all pathological information routinely collected in this type of studies is included.

In all applications of the poly-3 test, the test is applied only to data from one sex in a single study and the p-values from the poly-3 tests of all the studies are combined to create the "global" tests (min-test, 05-test and 01-test) to give the correct false positive rates. In addition to the randomization procedures for testing for positive dose-response trends in tumor incidence, the same procedures were repeated after reconfiguring the poly-3 test for negative trends.

Results

When the frequency of poly-3 p-values for positive trend computed from all tumors in all 10 bioassays in which at least two tumors occurred are considered there is an excess of large p-values (close to 1.0) compared to small p-values (close to 0.0). Since the version of the poly-3 trend test applied is a one-sided test for a positive trend, p-values close to 1.0 would translate into p-values near 0.0 for one-sided trend tests for anti-carcinogenicity.

Results of tests for a dose-related decrease in survival in each study show that in none of the bioassays analyzed this test was statistically significant. Moreover, 4 of the datasets had p-values in excess of 0.95 which indicates a significant positive trend in survival with increasing dose.

The 24 tumors for which the poly-3 test for a positive dose-related trend was significant at the 0.05 level in the primary analysis are shown in Table 2. Pancreatic islet-cell adenoma in male rats reported in the Stout and Ruecker (1990) study is not listed because it did not have a significant dose-related trend. In an identical analysis with the poly-3 test configured to test for a negative dose-related trend, there were 26 tumors for which the dose-response trend was significantly negative at the 0.05 level.

Table 5.5-146: Tumors with a significant positive trend (poly-3 p ≤ 0.05)

Bioassay	Species/ Sex	Tumor	Summary Tumor Incidence				Poly-3 p-value	Cited by IARC[a]

[a] Indicates tumor responses cited by IARC (2015) as evidence of carcinogenicity. Pancretic islets in male rats in Stout and Ruecker (1990) was also cited by IARC (1/58, 8/57, 5/60 and 7/59) but this response did not give a p-value ≤ 0.05 by the Poly-3 trend test.
[b] IARC (2015) resported tumor responses of 2, 2, 3, 7.

The most significant poly-3 trend in all 10 bioassays was for hemangiosarcoma in male mice in the Atkinson *et al*. (1993) study with a p-value of 0.0013. The actual significance of this smallest p-value, which is the false positive rate for the min-test, was 0.26 based on the primary analysis, rather than the naive value of 0.0013. This means that 26 % of the randomizations of the 10 datasets gave a smallest p-value less than or equal to the smallest p-value obtained from the original data.

The false positive rate for the 05-test was 0.08, which means that 8 % of randomizations of the 10 datasets found at least 24 sites for which the poly-3 p-value was ≤ 0.05. The results from all permutation tests based on the reduced data were similar to those based on the primary data. The false positive rate for the 01-test was 0.06 in the primary analysis and 0.08 in the reduced analysis. Overall, these findings suggest that, after accounting for the number of statistical tests performed, there was no clear evidence of a positive dose-related trend in tumor occurrence.

The evidence for negative trends is greater than that for positive trends in all analyses. The smallest poly-3 p-value for a negative trend was 0.0008 whereas the smallest p-value for a positive trend was 0.0013. The 01-test for a negative trend was highly significant in both the primary and reduced analyses with a p-value of 0.002 for each. These findings suggest stronger evidence for negative rather than positive dose-response trends in tumor occurrence.

Discussion and conclusions

The highest doses given to any animal groups in the 10 bioassays analyzed were 5,873 mg/kg bw/day and 4,841 mg/kg bw/day in female and male mice, respectively. Despite the extremely high doses, there was no evidence of reduced survival in this study. On the contrary, there was a statistically significantly

enhanced survival in male mice in this study, as well as in male animals in several other bioassays. The use of the individual animal data allowed the authors to distinguish between an adenoma and a carcinoma occurring in separate animals and both tumors occurring together in a single animal. Knowledge of the age at death of each individual animal is required for the conduct of the poly-3 test. In addition to the application of the poly-3 test, which is an age-adjusted Cochran-Armitage test, age was also controlled by keeping the numbers of animals surviving to final sacrifice in each dose group the same in all permutations as in the original data.

In the primary analysis of all bioassays 525 poly-3 analyses were conducted of individual tumor responses, of which a total of 174 were on combinations of individual tumor types that may have similar etiologies. In the primary analysis, individual tumors can appear in more than one poly-3 analysis. Since this will happen in the original data and the permuted data with equal frequency, it will not bias the analysis. Also a reduced analysis was conducted in which individual tumors and combinations of tumors were removed from the analysis if they were part of a more inclusive tumor combination. This reduced analysis involved 304 poly-3 analyses. Results from these two analyses were quite similar.

The smallest poly-3 p-value (0.0013) found in the analysis of all the datasets was that for hemangiosarcoma in male mice in the Atkinson *et al*. study. The analysis showed that the actual false positive rate for this finding after accounting for multiple comparisons was 0.26 in the primary analysis and 0.17 in the reduced analysis. Neither the 05-test nor the 01-test gave a false positive rate that was clearly less than 0.05 in the primary and reduced analysis. The statistically significant ($p = 0.0013$) response of 8 % in CD-1 males in the Atkinson *et al*. study resulted from 4 hemangiosarcomas at a dose level of 1,000 mg/kg bw/day, with no hemangiomas or hemangiosarcomas reported at the 3 lower doses. The CD-1 male mice in the Knezevich and Hogan study were exposed to 4,831 mg/kg bw/day, a dose nearly 5 times that used in the Atkinson *et al*. study with no hemangiomas or hemangiosarcomas. Moreover, the incidence of 8 % was still within the historical control range reported for male CD-1 mice by Atkinson *et al*. (0-8 %) and Giknis and Clifford (2005) (0-12 %). The 10 % incidence in hemangioma/ hemangiosarcoma in female CD-1 mice reported in the Sugimoto (1997) study is within the historical control range of 0-12 % of hemangiosarcoma reported by Giknis and Clifford (2005). The lack of a consistent dose response in either males or females suggests that finding significant responses in hemangioma and hemangiosarcoma in both sexes of mice may be attributable to chance, especially considering that this represents the "worst case" of more than 100 tumor sites/types in these bioassays that could have shown evidence of carcinogenicity.

The only other tumor in the mouse studies that the IARC regarded as being clearly related to glyphosate exposure was the marginally significant increase (0/49, 0/49, 1/50, 3/50) in kidney adenoma in male mice observed in the Knezevich and Hogan study. However, additional step sectioning of kidneys in the dosed and control groups revealed one kidney adenoma in the control group, but no additional kidney tumors in the dosed groups. Since the new data provided did not identify this control animal, this additional tumor could not be taken into account in the analysis of this paper. When this tumor-bearing control animal is taken into account in the trend analysis the trend is not anymore statistically significant, adding to the evidence that the tumor increases reported in the glyphosate studies are due to chance.

Comparing the results of negative dose-related trends with those testing for a positive trend, the evidence for an effect was stronger for negative than for positive trends. The smallest p-value for a positive trend was 0.0013 versus 0.0008 for a negative trend, although the corresponding false positive rates after correcting for multiple comparisons were 0.26 and 0.11 demonstrating how adjusting for multiple comparisons can change the interpretation of analyses of individual tumors. The only clearly significant results for any of the 3 permutation tests were the highly significant 01-tests for negative trend in both the primary and reduced analysis.

In all 10 bioassays, the analysis made in this paper identified 24 tumors that exhibited a poly-3 positive trend with a p-value ≤ 0.05. Nevertheless, after accounting for the multitude of statistical tests this analysis did not find that number statistically significant ($p = 0.08$). The statistical analysis of 10 glyphosate bioassays presented in this paper found no strong statistical evidence that glyphosate is carcinogenic. The

main cause for the discrepancy between the analysis made by IARC and that of the authors appears to be that IARC failed to consider the large number of statistical tests performed in the multiple bioassays they reviewed and the resulting multiple comparison problem. IARC and other organizations involved with interpreting results from large data sets to which a large number of statistical tests have been applied should consider applying analyses of the type used in this paper to make informed and reasonable decisions. The present analysis provides new information on the potential carcinogenicity of glyphosate by being the first to provide results from statistical tests with correct false positive rates. These tests found no strong or convincing evidence that glyphosate is an animal carcinogen.

7. Assessment and conclusion

Assessment and conclusion by applicant:

Ten cancer bioassays of sufficient quality and which allowed the analysis of individual animal data was selected for the application of a multi-response permutation procedure that adjusts for the large number of tumors eligible for statistical testing and provides valid false-positive probabilities. The statistical tests applied in the analysis were functions of p-values obtained from conventional continuity-corrected poly-3 tests for trend applied to each type of tumor or combination of tumor types in each bioassay. Results from 3 multi-response permutation tests are reported and discussed: the "min-test", the "05-test" and the "01-test". In the min-test, the test statistic is the smallest p-value obtained from applying the poly-3 test to all tumor types in all bioassays investigated. Animals are randomly reassigned to dose groups in a Monte Carlo analysis, keeping the total numbers of animals in each dose group equal to the number in the original data. The tumors in each such reassignment are analyzed using the poly-3 test in exactly the same way as in the original data. Males and females are permuted separately. The false positive rate is the proportion of random reassignments that result in a smallest poly-3 p-value that is smaller than or equal to the smallest poly-3 p-value obtained from the original data. The test statistics for the 05-test and the 01-test are the number of poly-3 tests of tumors in the original data for which the p-value is less than or equal to the critical value of 0.05 or 0.01, respectively. In all applications of the poly-3 test, the test is applied only to data from one sex in a single study and the p-values from the poly-3 tests of all the studies are combined to create the "global" tests (min-test, 05-test and 01-test) to give the correct false positive rates. In addition to the randomization procedures for testing for positive dose-response trends in tumor incidence, the same procedures were repeated after reconfiguring the poly-3 test for negative trends. When the frequency of poly-3 p-values for positive trend computed from all tumors in all 10 bioassays in which at least two tumors occurred are considered there is an excess of large p-values (close to 1.0) compared to small p-values (close to 0.0). Since the version of the poly-3 trend test applied is a one-sided test for a positive trend, p-values close to 1.0 would translate into p-values near 0.0 for one-sided trend tests for anti-carcinogenicity. Results of tests for a dose-related decrease in survival in each study show that in none of the bioassays analyzed this test was statistically significant. Moreover, 4 of the datasets had p-values in excess of 0.95 which indicates a significant positive trend in survival with increasing dose. The most significant poly-3 trend in all 10 bioassays was found in the Atkinson *et al.* (1993) study for hemangiosarcoma in male mice with a p-value of 0.0013. The actual significance of this smallest p-value, which is the false positive rate for the min-test, was 0.26 based on the primary analysis, rather than the naive value of 0.0013. This means that 26 % of the randomizations of the 10 datasets gave a smallest p-value less than or equal to the smallest p-value obtained from the original data. Besides, the incidence in hemangiosarcomas (8 %) remained within the historical control range and no such tumors were identified in another mouse study at a dose level nearly 5 times of that used in the Atkinson *et al.* (1993) study. Overall, these findings suggest that, after accounting for the number of statistical tests performed, there was no clear evidence of a positive dose-related trend in tumor occurrence. The 01-test for a negative trend was highly significant with a p-value of 0.002. These findings suggest stronger evidence for negative rather than positive dose-response trends in tumor occurrence. In all 10 bioassays investigated, the analysis made in this paper identified 24 tumors that exhibited a poly-3 positive trend with a p-value of less than or equal to 0.05. Nevertheless, after accounting for the multitude of statistical tests this analysis did not find that number statistically significant ($p = 0.08$). The statistical analysis of 10 glyphosate bioassays presented in this paper found no strong statistical evidence that glyphosate is carcinogenic. This publication is considered relevant for

the risk assessment of glyphosate and reliable without restrictions because state-of-the-art statistical methods were employed to a selected set of cancer bioassays to demonstrate false-positive probabilities.

Abstract

Since the introduction of glyphosate-tolerant genetically-modified plants, the global use of glyphosate has increased dramatically making it the most widely used pesticide on the planet. There is considerable controversy concerning the carcinogenicity of glyphosate with scientists and regulatory authorities involved in the review of glyphosate having markedly different opinions. One key aspect of these opinions is the degree to which glyphosate causes cancer in laboratory animals after lifetime exposure. In this review, twenty-one chronic exposure animal carcinogenicity studies of glyphosate are identified from regulatory documents and reviews; 13 studies are of sufficient quality and detail to be reanalyzed in this review using trend tests, historical control tests and pooled analyses. The analyses identify 37 significant tumour findings in these studies and demonstrate consistency across studies in the same sex/species/strain for many of these tumours. Considering analyses of the individual studies, the consistency of the data across studies, the pooled analyses, the historical control data, non-neoplastic lesions, mechanistic evidence and the associated scientific literature, the tumour increases seen in this review are categorized as to the strength of the evidence that glyphosate causes these cancers. The strongest evidence shows that glyphosate causes hemangiosarcomas, kidney tumours and malignant lymphomas in male CD-1 mice, hemangiomas and malignant lymphomas in female CD-1 mice, hemangiomas in female Swiss albino mice, kidney adenomas, liver adenomas, skin keratoacanthomas and skin basal cell tumours in male Sprague-Dawley rats, adrenal cortical carcinomas in female Sprague-Dawley rats and hepatocellular adenomas and skin keratoacanthomas in male Wistar rats.

Materials and methods

Bioassay data - The animal carcinogenicity data analyzed in this publication were derived from the published literature, the EPA review, the addendum to the EFSA review prepared by the German Institute for Risk Analysis, the JMPR review, the review of the carcinogenicity of glyphosate by a panel of scientists on behalf of industry, and full laboratory reports. The 13 cancer bioassays considered acceptable for this

evaluation are presented in Table 1.

Table 5.5-147: Characteristics of the cancer bioassays of glyphosate analyzed in this study

Study Reference	Duration (months)	Strain		Dietary exposure dose levels (mg/kg/day)	Animals per Group	Purity (%)	Comments on survival and weight

[a]Swiss Albino mouse; [b]Sprague-Dawley rat; [c]Wistar rat

For twelve of these studies full study reports were available and most of them were conducted in accordance with the appropriate regulatory guidelines. A full study report was not available for the Takahashi (1999) study but the data on kidney tumours in males and malignant lymphomas in females could be obtained from a JMPR review.

Statistical tests - Individual tumour counts for the individual studies were re-analyzed using the exact Cochran-Armitage one-sided linear trend test in proportions. Re-analyses were conducted on all primary tumours where there were at least 3 tumours in all of the animals in a sex/species/strain combination. In addition, any tumour where a significant positive trend ($p \leq 0.05$) was seen in at least one study was also evaluated in all studies of the same sex/species/strain, regardless of the number of animals with the tumour. When adenomas and carcinomas were observed in the same tissue, a combined analysis of adenomas and carcinomas was also conducted. Pairwise comparisons between individual exposed groups and the control group are conducted using Fisher's exact test. To evaluate the consistency of a tumour finding across multiple studies using the same sex-species-strain combinations, logistic regression with individual background responses and dose trends are fit to the pooled data using maximum likelihood estimation. A common positive trend is seen in the pooled analysis when the null hypothesis that the slope is 0 is rejected (statistical p-value ≤ 0.05 using a likelihood-ratio test) in favor of the alternative that the slope is greater than 0. Heterogeneity is seen in the pooled analysis when the null hypothesis that the slopes are equal is rejected (statistical p-value ≤ 0.05 using a likelihood-ratio test) in favor of the alternative that at least one of the slopes is different. For CD-1 mice analyses were conducted separately for 18 month and 24 month studies and then a combined analysis was performed. Similar grouped analyses were conducted for SD rats with one study of 26 months and 3 studies of 24 months. Only the combined analysis over all study durations is provided. The same methods of analysis were used to evaluate the incidence of non-neoplastic toxicity in tissues where tumours were observed. In cases of rare tumours where the increase in incidence didn't reach statistical significance the test proposed by Tarone (1982) was applied using an appropriate historical control group. All analyses were done using MATLAB, version R2017b.

Results

The purpose of this analysis is to understand the potential of glyphosate to produce tumours across all studies and not one study at a time. Thus, rather than presenting the results of each study separately, this review focuses on the tumours that are seen as positive in any one study and compares the findings across all studies of the same tumour in the same sex/species/strain combination.

Re-analysis of the data from CD-1 mice - From Table 2 it can be derived that a significant ($p \leq 0.05$) positive trend was found in males for kidney adenomas and kidney adenomas/carcinomas in the Takahashi study, malignant lymphomas in the Sugimoto and the Wood studies, hemangiosarcomas in the Atkinson study, and alveolar-bronchiolar carcinomas in the Wood study. When Tarone's test was applied using historical control data then a significant increase was found for kidney adenomas in the Sugimoto study, kidney carcinomas in the Knezevich and Hogan study, kidney adenomas/carcinomas in the Knezevich and Hogan and the Sugimoto study, and hemagiosarcomas in the Sugimoto study. In females a significant ($p \leq 0.05$) positive trend was found for hemangiomas, harderian gland adenomas and adenomas/carcinomas in the Sugimoto study, alveolar-bronchiolar adenomas/carcinomas in the Atkinson study, and malignant lymphomas in the Takahashi study. A significant common trend was found for kidney adenomas, carcinomas and adenomas/carcinomas, hemangiosarcomas in males and hemangiomas and malignant lymphomas in females.

Table 5.5-148: P-values for the exact Cochran-Armitage trend test and pooled logistic regression analysis for tumours with at least one significant trend test ($p \leq 0.05$) or Fisher's exact test ($p \leq 0.05$) in male and female CD-1 mice.

[a] – Study A is Knezevich and Hogan [11] (Additional file 2: Table S1), Study B is Atkinson et al. [12] (Additional file 2: Table S2), Study C is Sugimoto [13] (Additional file 2: Table S3), Study D is Wood [14] (Additional file 2: Table S4), Study E is Takahashi [15] (Additional file 2: Table S5); [b] – three dashes "---" indicates all tumor counts are zero; [c] – ND indicates there is no data available for this tumor in this study; [d] – using historical control data (see text for details) and Tarone's test; [e] – Spleen composite lymphosarcomas (malignant lymphomas) are also significantly increased in female mice in this study (see Additional file 2: Table S1)

Re-analysis of the data from Swiss albino mice - The single study with Swiss albino mice (Kumar, 2001) shows a significant increase in hemangiomas in female mice ($p = 0.004$).

Re-analysis of the data from SD rats - From Table 3 it can be derived that a significant ($p \leq 0.05$) positive trend was found in males for testicular interstitial cell tumours in the Lankas study, hepatocellular adenomas and adenomas/carcinomas in the Stout and Ruecker study, kidney adenomas in the Enemoto study, skin

keratoacanthomas in the Stout and Ruecker, Atkinson and Enemoto studies, and skin basal cell tumours in the Enomoto study. In females a significant (p ≤ 0.05) positive trend was found for thyroid C-cell adenomas in the Stout and Ruecker study, C-cell carcinomas in the Lankas study, and adrenal cortical carcinoma in the Stout and Ruecker study. When Tarone's test was applied using historical control data then a significant increase was found for pancreatic islet cell adenomas in males in the Stout and Ruecker study, and thyroid C-cell adenomas/carcinomas in females in the Lankas study. A significant common trend was found for hepatocellular adenomas, kidney adenomas, skin keratoacanthomas and skin basal cell tumours in males. In females the common trend was statistically significant for adrenal cortical carcinoma.

Table 5.5-149: P-values for the exact Cochran-Armitage trend test and pooled logistic regression analysis for tumours with at least one significant trend test or Fisher's exact test (p ≤ 0.05) in male and female Sprague-Dawley rats

Re-analysis of the data from Wistar rats - From Table 4 it can be derived that a significant (p ≤ 0.05) positive trend was found in males for hepatocellular adenomas and adenomas/carcinomas in the Brammer study, pituitary adenomas in the Wood study, skin keratoacanthomas in the Wood study, and adrenal pheochromocytomas in the Suresh study. In females a significant (p ≤ 0.05) positive trend was found for mammary gland adenocarcinomas and adenomas/adenocarcinomas, pituitary adenomas and adenomas/carcinomas all in the Wood study. A significant common trend was found for hepatocellular adenomas and adenomas/carcinomas and skin keratoacanthomas in males. No statistically significant common trend was found for the tumours in females.

False positive errors - The evaluation of any one animal cancer study involves a large number of statistical tests that could lead to false positives. To evaluate this issue, the probability that all of the results in any sex/species/strain could be due to false positive results is calculated. Overall, a total of 496 evaluations were done for these 13 studies including the few evaluations done against historical controls. There are 41 evaluations at 37 tumour/site combinations with a trend test $p \leq 0.05$. The probability that all of these are due to false positives is 0.001. Similarly, looking at the evaluations resulting in $p \leq 0.01$, the probability that all of the findings are due to false positives is < 0.001. The strongest evidence was found for male CD-1 mice where the probability for 11 positive findings to occur at $p \leq 0.05$ and 8 positive findings at $p \leq 0.01$ are both below 0.001.

Conclusions

Oral exposure of rats and mice to glyphosate *via* the diet in 13 separate carcinogenicity studies demonstrates that glyphosate causes a variety of tumours that differ by sex, species, strain and length of exposure. To summarize the results of the strength-of-evidence analysis, each tumour is placed in any of the following categories: Clear evidence (CE) when there is a causal link between glyphosate exposure and the tumour; Some evidence (SE) when there is a causal link between glyphosate exposure and the tumour but chance, although unlikely, cannot be ruled out; Equivocal evidence (EE) when there is a causal link between glyphosate exposure and the tumour but chance is as likely an explanation for the association as is exposure to glyphosate; No evidence (NE) indicates that any causal link between glyphosate exposure and the tumour is almost certainly due to chance. The factors used to place tumours into these categories include the analyses of the individual studies, the consistency of the data across studies (pooled analyses), the analyses using historical control data, the analyses of non-neoplastic lesions, mechanistic evidence and the associated scientific literature.

The weight-of-evidence analysis conducted in this study indicates that there is clear evidence (CE) that oral exposure to glyphosate *via* the diet produces adrenal cortical carcinoma in the female SD rat, hemangioma in the female mouse (CD-1 and Swiss albino), hemangiosarcoma in the male CD-1 mouse, kidney tumours in the male CD-1 mouse and SD rat, liver adenoma in male rats (SD and Wistar), malignant lymphoma in the male and female CD-1 mouse, skin basal cell tumour in the male SD rat and skin keratoacanthoma in male rats (SD and Wistar). Some evidence (SE) for a causal relationship was found for kidney tumours in

male Swiss albino mice, mammary tumours in female Wistar rats, malignant lymphoma in male and female Swiss albino mice, pituitary adenoma in the male and the female Wistar rat, and testicular interstitial cell tumours in the male SD rat. The results of the analyses conducted in this study are supportive of the conclusions of IARC that there is sufficient evidence to consider glyphosate as a rodent carcinogen.

6. Assessment and conclusion

Assessment and conclusion by applicant:

Thirteen glyphosate cancer bioassays considered acceptable for this re-analysis were selected from the published literature, the EPA review, the review from the German Institute for Risk Analysis, the JMPR review, and full laboratory reports. For twelve of them full study reports were available. Individual tumour counts for the individual studies were re-analyzed using the exact Cochran-Armitage one-sided linear trend test. Re-analyses were conducted on all primary tumours where there were at least 3 tumours in all of the animals in a sex/species/strain combination. In addition, any tumour where a significant positive trend ($p \leq 0.05$) was found in at least one study was also evaluated in all the other studies of the same sex/species/strain combination, regardless of the number of animals with the tumour. Pairwise comparisons between individual exposed groups and the control group were conducted using Fisher's exact test. To evaluate the consistency of a tumour finding across multiple studies using the same sex-species-strain combinations, logistic regression with individual background responses and dose trends are fit to the pooled data using maximum likelihood estimation. The same methods of analysis were used to evaluate the incidence of non-neoplastic lesions in tissues where tumours were observed. In cases of rare tumours where the increase in incidence didn't reach statistical significance the test proposed by Tarone (1982) was applied using an appropriate historical control group. To summarize the results of the strength-of-evidence analysis, each tumour is placed in any of the following categories: Clear evidence (CE), some evidence (SE), equivocal evidence (EE), and no evidence (NE). The factors used to place tumours into these categories include the analyses of the individual studies, the consistency of the data across studies (pooled analyses), the analyses using historical control data, the analyses of non-neoplastic lesions, and mechanistic evidence with the associated scientific literature. The author's weight-of-evidence analysis indicates that there is clear evidence (CE) that oral exposure to glyphosate *via* the diet produces adrenal cortical carcinoma in the female SD rat, hemangioma in the female mouse (CD-1 and Swiss albino), hemangiosarcoma in the male CD-1 mouse, kidney tumours in the male CD-1 mouse and SD rat, liver adenoma in the male rat (SD and Wistar), malignant lymphoma in the male and female CD-1 mouse, skin basal cell tumour in the male SD rat and skin keratoacanthoma in male rats (SD and Wistar). Some evidence (SE) for a causal relationship was put forth for kidney tumours in the male Swiss albino mouse, mammary tumours in the female Wistar rat, malignant lymphoma in the male and female Swiss albino mouse, pituitary adenoma in the male and the female Wistar rat, and testicular interstitial cell tumours in the male SD rat.

After thorough analysis and considering all factors that are important in the interpretation of cancer studies none of the tumours identified by the author as indicating clear evidence (CE) or some evidence (SE) of carcinogenicity were found relevant for reconsideration under the necessary due diligence of the European AIR5 review of glyphosate. Most of the tumours selected by the author were previously dismissed by the EU experts as not relevant even before the last review of glyphosate in 2017, and the applicant believes that there is no solid toxicological evidence for glyphosate exposure related carcinogenicity in the mouse and the rat that warrants any science-based concerns for human health. The discussion of each of the suspect tumours is given below.

Clear evidence (CE) for carcinogenicity:

Adrenal cortical carcinoma in the female SD rat (Stout and Ruecker study):

The tumour incidences were 0/60, 0/60, 0/60, 3/60 at 0, 113, 457, and 1183 mg/kg bw/day, respectively. This tumour has not been considered treatment related by the authors of the study. There is no dose-related increase in adrenal cortical adenoma (1/60, 3/60, 2/60, 1/60), no dose-related increase in pre-neoplastic lesions and this tumour was not found in the males of the same study or in other rat studies. Therefore, this tumour has been considered not relevant for the risk assessment of glyphosate and was

not discussed further in the previous EU review of glyphosate.

Hemangioma in female CD-1 mice (Sugimoto study):
In the Sugimoto study hemangiomas were observed in different tissues:
- In liver with an incidence of 0/50, 0/50, 1/50, 1/50;
- In the ovary with an incidence of 0/50, 0/50, 0/50, 1/50;
- In the uterus with an incidence of 0/50, 0/50, 1/50, 2/50;
- In the spleen with an incidence of 0/50, 0/50, 1/50, 0/50;
- In the abdominal cavity with an incidence of 0/8, 0/9, 0/9, 1/9;

At 0, 153.2, 786.8, and 4116 mg/kg bw/day, respectively. Taken together as systemic tumours a significant positive trend is obtained. However, hemangiomas have also been observed in males (liver and testes) but without any dose-response relationship and the highest incidence found was in the control group (1/50). These tumours have not been confirmed in the other carcinogenicity studies in the CD-1 mouse. Moreover, the dose level (4116 mg/kg bw/day) at which the incidence was statistically significantly increased when compared against the control, is more than 4-fold the limit dose for the testing of carcinogens in rodent species. If that dose is ignored there is no significative positive trend. Therefore, this tumour has been considered not relevant for the risk assessment of glyphosate and was not discussed further in the previous EU review of glyphosate.

Hemangioma in female Swiss albino mice (Kumar study):
In the re-analysis of the tumour data of the Kumar study by K. Weber (report submitted in 2017) no statistically significant trend was found for systemic neoplasms using the Peto test. When analyzed using the Fischer's exact test no statistically significant increase in incidence was found in pair-wise comparisons of all dose groups with the control group. It is important to emphasize that this study was compromised by non-identified ecto-and endoparasites in a large number of animals. Therefore, this tumour has been considered not relevant for the assessment of glyphosate.

Hemangiosarcoma in the male CD-1 mouse (Atkinson study):
The tumour incidences were 0/50, 0/50, 0/50, 4/50 (3 in liver and 1 in prostate) at 0, 98, 297, and 988 mg/kg bw/day, respectively. The incidence at the highest dose (8 %) was still within the historical control range of the test laboratory (0-8 %, 300 male mice in 6 studies up to 1993). This tumour was not confirmed in other mouse studies of which one (Knezevich and Hogan study) with a dose level nearly 5-fold that of the Atkinson study (4841 mg/kg bw/day). Therefore, this tumour has been considered not relevant for the assessment of glyphosate.

Kidney tumours in the male CD-1 mouse (Takahashi study, as reported by JMPR, 2016):
Renal cell adenoma (3/50) and renal cell carcinoma (1/50) were observed in males at 7470 mg/kg bw/day, but, according to the authors, there was no statistically significant difference with the control group. It is of note that the high dose considered in this study for males is extraordinarily high, more than 7-fold the limit dose for the testing of carcinogens in rodent species. If this dose is ignored there is no significant positive trend. These tumours were re-examined by the original study pathologist in 2012 because the Pesticide Expert Panel of the Food Safety Commission of Japan requested more information on historical control data and association with the non-neoplastic renal findings. After re-examination, the incidences for renal cell adenoma were 1/50, 1/50, and 1/50 at 167.6, 685, and 7470 mg/kg bw/day, showing no dose-response relationship. The incidence for renal cell carcinoma was confirmed to be 1/50 at 7470 mg/kg bw/day. The historical control data for the Takahashi study were not available, but the historical control values described in the re-examination document for renal cell carcinoma were 1/725 (0.13 %) in males and 0/725 (0 %) in females and for renal cell adenoma were 3/564 (0.53 %) in males and 0/564 (0 %) in females. The re-examination report also provides reference data of 0-1.8 % in males and 0 % for all doses in females for renal cell carcinoma, and 0-1.8 % in males and females for renal cell adenoma. The results of the re-examination revealed also that the tubular epithelial cell hypertrophy was localized with an incidence in each treatment group that did not significantly differ from that in the control group. There was no association between the tubular epithelial cell hypertrophy and the

development of renal tumours. The renal cell tumours observed in this study are thus not relevant for the human risk assessment of glyphosate because (1) the incidence of renal tumours in males at 7470 mg/kg bw/day did not significantly differ from that in the control group upon re-evaluation; (2) none of the females had neoplastic or non-neoplastic lesions; and (3) the high dose considered in this study for males is more than 7-fold the limit dose for the testing of carcinogens in rodent species. Therefore, this tumour has been considered not relevant for the assessment of glyphosate.

Kidney tumours in the male SD rat (Enemoto study):
The incidences of kidney adenoma were 0/76, 0/75, 0/80, 4/78 at 0, 104, 354, and 1127 mg/kg bw/day. An increasing trend in the incidence of adenomas in the kidney was observed in males of the high dose group (animal 193: killed in extremis at week 92, animal 167: found dead at week 94, animal 159: found dead at week 101, and animal 169: killed by design after 104 weeks of treatment) and this incidence was greater than the historical control range referred to in the study report (0-2.9 %). However, according to the authors of this study, the increase observed was not statistically significant. No kidney tumours were found in the females and nearly all male rats at all dose levels suffered from chronic nephropathy (62/76, 63/75, 56/80, 67/78). This tumour in this study was not considered relevant for the risk assessment of glyphosate and was not discussed further in the previous EU review of glyphosate.

Hepatocellular adenomas in the male SD rat (Stout and Ruecker study):
The tumour incidences for adenomas were 3/60, 2/60, 3/60, 8/60 and of carcinomas were 3/60, 2/60, 1/60, 2/60 at 0, 89, 362, and 940 mg/kg bw/day, respectively. The incidence of adenomas at the high dose (13.3 %) is still within the historical control range of the test laboratory (1.4-18.3 %). Foci of cellular alteration were observed at all dose levels without any dose-response relationship and there were no signs of hepatocellular hypertrophy, a prerequisite for hepatocellular carcinogenesis. Beside the Brammer study no increase in hepatocellular adenomas was noted in the other rat studies. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Hepatocellular adenomas in the male Wistar rat (Brammer study):
The tumour incidences were 0/64, 2/64, 0/64, 5/64 at 0, 121, 361, 1214 mg/kg bw/day, respectively. The positive trend is significant and the incidence at the high dose is significantly different from the control. However, the incidence at the high dose (7.8 %) is still within the historical control range of the test laboratory (0-11.5 %, 26 studies in 1984-2003). There were no histopathological signs of liver enzyme induction or pre-neoplastic lesions. The high dose animals in this study survived longer when compared to the other groups. This may also influence the spontaneous tumour rate. Beside the Stout and Ruecker study no increase in hepatocellular adenomas was noted in the other rat studies. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Malignant lymphoma in the male CD-1 mouse (Sugimoto study):
The tumour incidences were 2/50, 2/50, 0/50, 6/50 at 0, 165, 838, 4348 mg/kg bw/day, respectively. The positive trend is significant but the incidence at the high dose is not significantly different from the control. Moreover, the incidence at the high dose (12 %) is still within the historical control range of the test laboratory (3.6-19.2 %, 458 male mice in 12 studies in 1993-1998). The trend has been found significantly positive because of the elevated incidence at a dose level that is over 4-fold the limit dose for carcinogenicity studies in rodents. If this dose is ignored the trend is not positive. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Malignant lymphoma in the female CD-1 mouse (Takahashi study):
The tumour incidences were 3/50, 1/50, 4/50, 6/50 at 0, 93.2, 909, and 8690 mg/kg bw/day, respectively. The increased incidence of lymphoma at the high dose was statistically significant in the trend test but not in a pairwise comparison. The trend has been found significantly positive because of the elevated incidence at an extraordinarily high dose level, more than 8-fold the limit dose for carcinogenicity studies in rodents. If this dose is ignored the trend is no longer significant. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Skin basal cell tumour in the male SD rat (Enemoto study):
The tumour incidences were 0/78, 0/75, 0/80, 3/78 for adenoma and 0/78, 0/75, 0/80, 1/78 for carcinoma at 0, 104, 354, and 1127 mg/kg bw/day. No increased incidence of this tumour was observed in the females or other rat studies and may be associated with other skin lesions (follicular hyperkeratosis and/or folliculitis/follicular abscess) observed in this study. Although there is a significant positive trend for the adenomas, the increase in incidence at the high dose level was not considered relevant for the risk assessment of glyphosate by the authors of this study. This tumour was not discussed further in the previous EU review of glyphosate.

Skin keratoacanthoma in the male SD rat (Stout and Ruecker study):
The tumour incidences were 1/60, 3/60, 4/60, 5/60 at 0, 89, 362, and 940 mg/kg bw/day. Although there is a significant positive trend the incidence at the high dose was not statistically significantly different from the control and considered not related to treatment. Skin keratoacanthoma is one of the most common spontaneous benign neoplasms in male Sprague Dawley rats. Therefore, this tumour was not considered relevant for the risk assessment of glyphosate by the authors of this study. This tumour was not discussed further in the previous EU review of glyphosate.

Skin keratoacanthoma in the male SD rat (Atkinson study):
The combined incidences of intracutaneous cornifying epithelioma (keratoacanthoma) were 1/50, 2/25, 0/19, 0/21, 5/50 at 0, 11, 112, 320, and 1147 mg/kg bw/day. Although the trend was significant, the incidence at the high dose was not statistically significantly different from the control and considered not related to treatment by the authors of this study. Skin keratoacanthoma is one of the most common spontaneous benign neoplasms in male Sprague Dawley rats. This tumour was not discussed further in the previous EU review of glyphosate.

Skin keratoacanthoma in the male SD rat (Enemoto study):
The incidences of the tumour were 4/76, 3/75, 0/80, 7/78 at 0, 104, 354, and 1127 mg/kg bw/day. The increased incidence of this skin tumour at the high dose may be associated with other skin lesions (follicular hyperkeratosis and/or folliculitis/follicular abscess) observed in this study. Although there is a significant positive trend for this tumour, the increase in incidence at the high dose level was not statistically significantly different from the control. Skin keratoacanthoma is one of the most common spontaneous benign neoplasms in male Sprague Dawley rats and considered by the authors of this study not relevant for the risk assessment of glyphosate. This tumour was not discussed further in the previous EU review of glyphosate.

Skin keratoacanthoma in the male Wistar rat (Wood study):
There were no treatment-related conditions seen in the skin or in subcutaneous tissues, but several spontaneous lesions were observed. Epidermal ulceration and scab formation, inflammatory lesions, abscess formation, focal acanthosis, focal mineralisation, focal dermal thickening, and focal necrosis were seen, occasionally or rarely and without significance. This tumour was not discussed further in the previous EU review of glyphosate.

Some evidence for carcinogenicity (SE)
Kidney tumours in the male Swiss albino mouse (Kumar study):
In the re-analysis of the tumour data of the Kumar study by K. Weber (submitted in 2017) no statistically significant trend was found for systemic neoplasms in the Peto test. When analyzed using the Fischer's exact test no statistically significant increase in incidence was found in pair-wise comparisons of all dose groups with the control group. It is important to emphasize that this study was compromised by non-identified ecto-and endoparasites in a large number of animals. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Mammary tumour in the female Wistar rat (Wood study):
At interim and terminal sacrifice combined mammary neoplasia was seen in 6 female mice. There were no mammary neoplasms in the control group but carcinomas were seen with incidences of 2/51, 3/51,

and 1/51 at 153.2, 786.8, and 4116 mg/kg bw/day, respectively. All neoplasms were adenocarcinomas with the exception of one adenosquamous carcinoma seen in a low dose group animal. No increase in the incidence of these tumours was reported in the females of other rat studies. The authors concluded that there was no effect of treatment upon the incidence of mammary neoplasia in this study. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Malignant lymphoma in the male Swiss albino mouse (Kumar study):
In the re-analysis of the tumour data of the Kumar study by K. Weber (2017) no statistically significant trend was found for systemic neoplasms in the Peto test. When analyzed using the Fischer's exact test no statistically significant increase in incidence was found in pair-wise comparisons of all dose groups with the control group. It is important to emphasize that this study was compromised by non-identified ecto-and endoparasites in a large number of animals. Therefore, this tumour was not considered as relevant for the assessment of glyphosate.

Pituitary adenomas in the male and the female Wistar rat (Wood study):
Pituitary adenomas were only seen in female mice with incidences of 0/51, 1/51, 0/51, 2/52 at 0, 104.5, 348.6, and 1381.9 mg/kg bw/day. The group distribution was unrelated to treatment. Therefore, this tumour was not considered relevant for the assessment of glyphosate.

Testicular interstitial cell tumour in the male SD rat (Lankas study):
The incidences of this tumour were 0/50, 3/50, 1/50, 6/50 at 0, 3.05, 10.30, and 31.49 mg/kg bw/day, respectively. The positive trend is statistically significant and the incidence at the high dose level (12 %) is statistically significantly different from the control and greater that the historical control rate of the test laboratory (3.4-6.6 %). However, there was no dose-response relationship for interstitial cell hyperplasia (1/50, 1/50, 1/50, 0/50). Since the dose range considered in this study (0-31.5 mg/kg bw/day) is approximately at least 30-fold lower than that of all the other studies in rats where no increase of such tumours was found this finding should be considered as spontaneous in nature. Therefore, this tumour was not considered relevant for the risk assessment of glyphosate and was not discussed further in the previous EU review of glyphosate.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because some of the statistical methods employed were not described in sufficient detail. Besides, the results of this study are not in agreement with the findings of Crump *et al*. 2020 in relation to the estimation of false positives and the overall evaluation of the significance of the tumours by the EU regulatory authorities. All the tumours that were identified by the author as providing clear evidence for the carcinogenicity of glyphosate have been previously dismissed in the EU regulatory process.

2. Full summary of the study according to OECD format

The effect of glyphosate on selected epigenetic parameters and major cell cycle drivers in human peripheral blood mononuclear cells (PBMCs) was determined. The cells were incubated with glyphosate at 0.5, 10 and 100 µM. The analysis included: global DNA methylation, methylation in the promoter regions of tumor suppressor genes (P16, P21, TP53) and proto-oncogenes (BCL2, CCND1) by the Real-Time PCR and the expression profile of the indicated genes by Real-Time PCR. The obtained results have revealed significant reduction of global DNA methylation level in PBMCs exposed to glyphosate. Tested compound changed methylation pattern of the P21 and TP53 suppressor gene promoters, but in case of other analysed genes: P16, BCL2 and CCND1 we did not identify any statistically significant changes. Gene profiling showed that glyphosate changed the expression of genes involved in the regulation of cell cycle and apoptosis. Glyphosate decreased expression of P16 and TP53 as well as an increase in the expression of BCl2, CCND1 and P21. Summing up, our results have shown a potential disturbance in methylation processes and gene expression in human PBMCs exposed to glyphosate, but the observed changes do not prejudge about the final metabolic effects, which are depended on many other factors.

Materials and methods

Chemicals; N-(phosphonomethyl)glycine (glyphosate) (purity 95 %), fetal bovine serum (FBS), penicillin – streptomycin, TRIzol™ and using primers were bought from Sigma-Aldrich, (USA). RPMI 1640 medium with L-glutamine and lymphocyte separation medium (LSM) (1.077 g/cm^3) were purchased in Cytogen (Germany). Invisorb Spin Tissue Mini Kit was bought in Stratec (Germany). Methylated DNA Quantification Kit was bought in Abcam (United Kingdom). Transcriptor First Strand cDNA Synthesis Kit and FastStart Essential DNA Green Master was purchased from Roche (Basel, Switzerland). EZ DNA Methylation™ Kit was bought from Zymo Research (USA). Methyl Primer Express®, v.1.0 was obtained from Life Technologies. TRIzol™ Reagent was purchased from Thermo Fischer Scientific, Waltham, MA, USA. Other chemicals were from Roth (Germany) and POCh (Poland) and were of analytical grade.

Cells isolation; PBMCs were isolated from leucocyte-buffy coat obtained from blood purchased in Blood Bank in Lodz, Poland. Blood was obtained from four healthy volunteers (aged 18–55), who showed no signs of infection disease symptoms at the time the blood samples were collected. The investigation was approved by the Bioethics Committee of the University of Lodz No. 1/KBBN-UŁ/II/2017. Cells isolation was determined. The final PBMCs density used in the experiments (after addition of glyphosate) was 1 × 10^6 cells/mL.

Cells treatment; Glyphosate was dissolved in PBS, pH 7.4. The concentrations of glyphosate were from 0.5 to 100 µM (0.085–17 mg/L). In a previous study, no changes in cell viability after treatment of PBMCs with glyphosate were observed at the above mentioned concentrations. The cells were incubated with investigated xenobiotic for 24 h in four independent experiments (four blood donors). During incubation, the cells were resuspended in RPMI supplemented with 10 % FBS and penicillin/streptomycin solution (50 U/mL and 50 µg/mL, respectively) at 37 °C, 5 % CO_2. After incubation, the cells were centrifuged, glyphosate was discarded, and the cells were resuspended in RPMI medium.

Methylation levels

Global DNA methylation; Genomic DNA from human PBMCs was isolated using Invisorb Spin Tissue Mini Kit (Stratec Molecular GmbH, Berlin, Germany). Global DNA methylation was determined by colorimetric measurement of 5-methylcytosine in DNA using Methylated DNA Quantification Kit (Abcam). For global DNA methylation analysis, 100 ng of genomic DNA was used, following the protocol provided by the manufacturer. Methylation levels were calculated relatively to the methylated control DNA

(included in the kit) and expressed as a percentage of total methylated DNA using the following formula:

$$5-\mathrm{mC}\% = \frac{(\text{Sample OD}-\text{Negative Control OD}) \div \mathrm{S})}{\text{Positive Control OD}-\text{Negative Control OD}) \times 2 \div \mathrm{P}} \times 100\%$$

where:

S – the amount of input sample DNA in ng; P – the amount of input positive control in ng; 2 – a factor to normalize 5-mC in the positive control to 100 %, as the positive control contains only 50 % of 5-mC.

Methylation at promoter regions of tumor suppressor genes (P16, P21, TP53) and proto-oncogenes (BCL2, CCND1); Chemical modification of 500 ng of genomic DNA was analysed using EZ DNA Methylation™ Kit (Zymo Research, Irvine, CA, US), according to manufacturer's instruction. For methylation analysis, methylation-specific real-time PCR assay (MSP-PCR) was conducted with FastStart SYBR Green Master (Roche, Basel Switzerland). Bioinformatic analysis of the potential methylation sites within the promoter regions of the proto-oncogens BCL2 and CCND1 as well as methylated and unmethylated primers were designed by utilizing of Methyl Primer Express®, v.1.0 (Life Technologies, Carlsbad, CA, US). The DNA sequences around the transcription start sites (from -1000 to 300 bp) of both genes, were obtained from the DBTSS. The primer list is presented in Supplementary Table 1. All samples were amplified in duplicate and in the presence of positive control (CpG methylated Jurkat genomic DNA, fully methylated), negative control (5-Azadc-treated Jurkat genomic DNA) (NEB, Ipswich, MA, US) and blank control (water). The methylation status of a particular gene is expressed as methylation index (MI):

$$\Delta\mathrm{Ct} = \mathrm{CtU} - \mathrm{CtM}$$

$$MI = \frac{1}{1 + 2^{-\Delta\mathrm{Ct}}} \times 100\%$$

where: MI - methylation index [%]; Ct values of the methylated gene (M) were compared with the Ct values of the unmethylated gene (U).

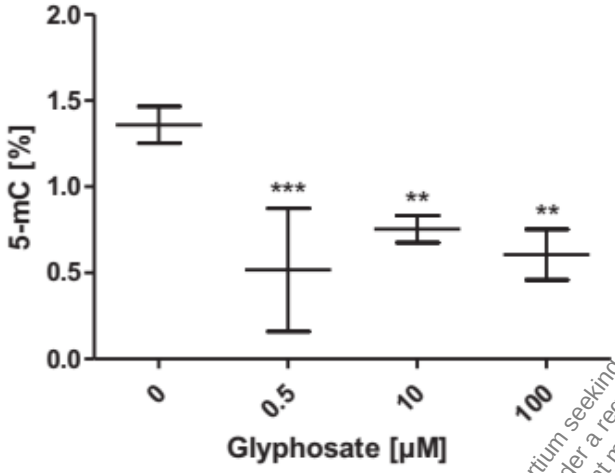
Gene expression: RNA was extracted with TRIzol™ Reagent (Thermo Fischer Scientific, Waltham, MA, USA). RNA samples with a 260/280 nm ratio in the range of 1.8–2.0 were used for further analysis. cDNA synthesis was performed using Transcriptor First Strand cDNA Synthesis Kit (Roche, Basel Switzerland). The cDNA was quantified by real-time PCR using FastStart SYBR Green Master (Roche, Basel Switzerland). Gene expression was normalized to the mean expression of all three housekeeping genes (GAPDH, RPL13, RPLP0) and was presented as a relative gene expression. The 2ΔCt (Ctgene–Ct mean from GAPDH, RPL13, RPLP0) method was used to calculate the expression levels of studied genes. The $2^{-\Delta Ct} \times 100$ values were re-calculated into relative copy number values.

Statistical analysis; The statistical analysis was performed with STATISTICA 13.1 data analysis software (2000 Stat-Soft, Inc., Tulsa, USA). Statistical analysis was conducted using the one-way analysis of variance (ANOVA) followed by Tukey's post hoc multiple comparisons procedure. The difference was considered to be significant for $P < .05$. The individual analysis was performed on blood from four donors, while each experiment (conducted for blood from one donor) was repeated twice or three times depending on the method.

Results

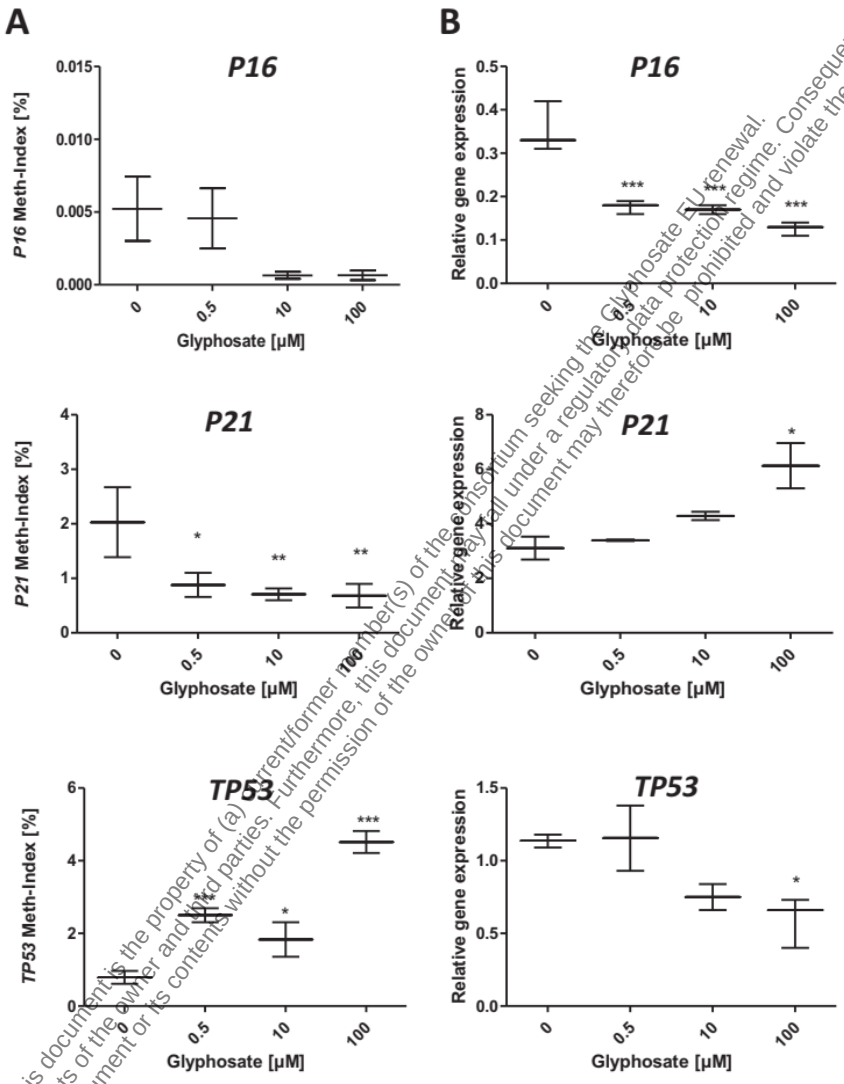
Analysis of global DNA methylation level; Statistically significant changes in 5-mC level were observed in PBMCs treated with glyphosate (see figure below). As compared to control cells, the level of global DNA methylation was significantly decreased after glyphosate treatment at all concentrations tested: 0.5 µM, 10 µM and 100 µM.

Figure 5.5.2-2: 5-methylcytosine (%) in human PBMCs incubated with glyphosate (0.5-100 µM) for 24 h. Mean ± SD was calculated for four individual experiments. Statistically different from control at **p < 0.01; * < 0.0001. Statistical analysis was conducted using one-way ANOVA and a posteriori Tukey test.**



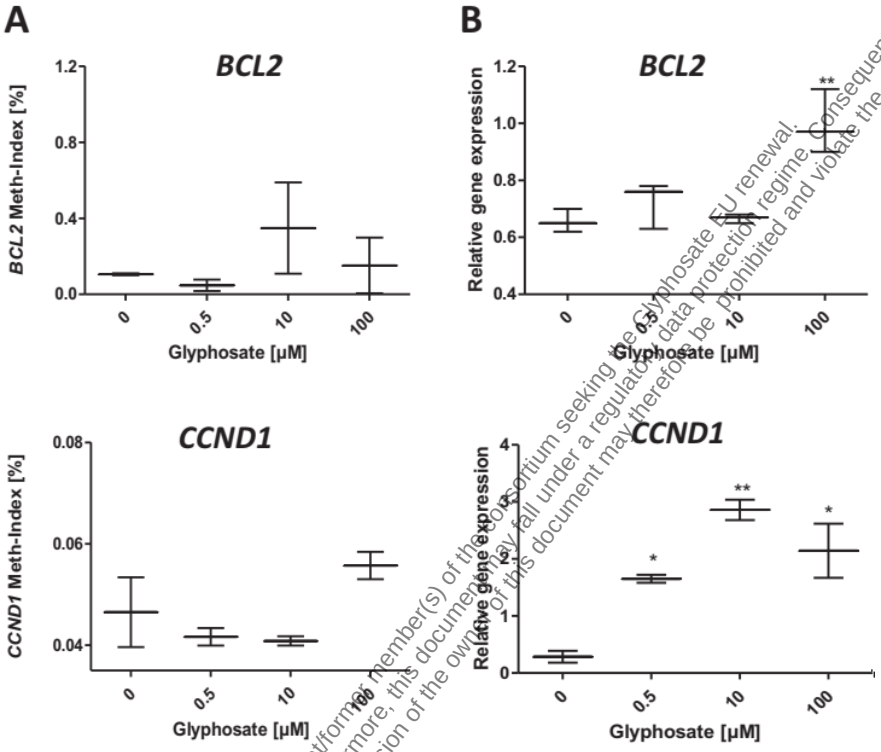
Analysis of methylation at promoter regions of the selected tumor suppressor genes (P16, P21, TP53) and proto-oncogenes (BCL2, CCND1); Statistically significant (p <.05, one-way ANOVA) decrease of methylation within P21 gene promoter was found in PMBCs treated with glyphosate from its lowest concentration of 0.5 µM (Figure 5.5.2-3A). The opposite response to the investigated xenobiotic (0.5 µM) such as hypermethylation of gene promoter, was observed on TP53 tumor suppressor gene (Figure 5.5.2-3A). In the case of other analyzed genes: P16, BCL2 and CCND1 we did not determine statistically significant changes in gene promoter methylation level (Figure 5.5.2-3A and Figure 5.5.2-4A).

Figure 5.5.2-3: Methylation (A) and expression (B) of suppressor genes (P16, P21 and TP53) in human PBMCs incubated with and glyphosate (0.5-100 µM) for 24 h. Mean ± SD was calculated for four individual experiments. Statistically different from control at *p < 0.05, **p < 0.01; *** < 0.0001. Statistical analysis was conducted using one-way ANOVA and a posteriori Tukey test.



Analysis of gene expression of the selected tumor suppressor genes (P16, P21, TP53) and proto-oncogenes (BCL2, CCND1): The analysis of methylation of the selected gene promoters using Real-Time PCR let us assess their expression at the transcript level. A statistically significant decrease of P16 expression in PBMCs treated with all concentrations of glyphosate were identified (Figure 5.5.2-3B). Glyphosate induced significant decrease in TP53 expression only at the highest concentration of 100 µM (p <.05, one-way ANOVA). Expression of other cell cycle drivers like P21 demonstrated a significant increase only at the highest concentration of glyphosate (p <.05, one-way ANOVA; Figure 5.5.2-4B), which was also effective in increasing of BCL2 expression (Figure 5.5.2-4B). Expression of the cyclin was significantly increased by two tested concentrations (10 µM and 100 µM) of glyphosate (p <.05, oneway ANOVA) (Figure 5.5.2-4B).

Figure 5.5.2-4: Methylation (A) and expression (B) of proto-oncogenes (BCL2 and CCND1) in human PBMCs incubated with and glyphosate (0.5-100 µM) for 24 h. Mean ± SD was calculated for four individual experiments. Statistically different from control at *p < 0.05, **p < 0.01. Statistical analysis was conducted using one-way ANOVA and a posteriori Tukey test.



Discussion

The knowledge that pollutants may influence the epigenome raises grave concerns concerning their long-term effects on chronic diseases development. A study showed that glyphosate can predispose breast cells to tumorigenesis *via* epigenetic reprogramming, which occur through TET3-mediated global and local DNA hypomethylation. Just recently, changes in the DNA methylation machinery due to glyphosate treatment were also identified in the fish model of Japanese medaka (Oryzias latipes), where upregulation of DNMT1, DNMT3a, Tet1 and Tet3 gene expression was shown. The current results have shown that treatment of PBMCs with glyphosate changed global DNA methylation profile. Decreased 5-mC level in PBMCs treated with low concentration of glyphosate that is comparable to that determined in human body after environmental exposure (0.5 µM) were found. Moreover, the obtained results are in agreement with previous findings, showing that glyphosate at high concentrations (determined in blood during glyphosate acute poisoning at 250–500 µM), reduces total DNA methylation in PBMCs. Recently, a study observed that glyphosate causes global DNA hypomethylation in non-neoplastic mammary epithelial MCF10A cells and triggers tumorigenesis in a "two-hit oncogenic model". Also a specific DNA hypomethylation signature of genes (i.e. local DNA hypomethylation), which was linked to the TET3 pathway that potentially can be used as an epimark to glyphosate exposure, was identified. Similar findings i.e. global hypomethylation of DNA were found in blood cells of tobacco farmers (n = 40) using pesticides and other xenobiotics during plant cultivation. However, literature data regarding potential epigenetic effects exerted by herbicides became contradictory. Recent epidemiological studies point to an increase of DNA methylation level under the combined effects of various pesticides, including glyphosate. It was found that long-term exposure of farmers (n = 137), employed at growing soybeans cultivation, to complex mixtures of pesticides, resulted in DNA hypermethylation and micronuclei formation in their blood cells probably due to impairment of

DNA repair mechanisms. Nevertheless, the farmers were exposed to the mixture of different pesticides and heavy metals that are known to induce DNA hypermethylation and to disturb the cell cycle progression. These findings were confirmed in a study on children living in an industrial areas. In blood samples of young subjects exposed to increased heavy metals and polycyclic aromatic hydrocarbons concentrations, DNA hypermethylation was observed. Detailed analysis of selected genes promoters involved in cellular metabolism regulation including cell cycle, i.e. TP53, P21, P16, CCND1 or BCL2, revealed significant changes in their methylation profiles. Beside global DNA hypomethylation we have found an increased methylation within the CpG islands of the TP53 gene promoter in PBMCs treated with glyphosate in all range of concentrations. The lowest concentration (0.5 μM) of glyphosate induced 5-mC methylation of the TP53 gene promoter. This result is in agreement with previous studies, where observed statistically significant increase of CpG islands methylation within the TP53 gene promoter after treatment of PBMCs with 250 μM and 500 μM glyphosate were identified. TP53 is known to be genome guard and tumor suppressor gene. It has been shown that hypermethylation of CpG islands within its promoter results in the silencing of gene transcription, but it is not clear-cut relationship in this case. Glyphosate reduced TP53 expression only from the concentration of 100 μM. Changes in TP53 expression and identified functions of p53 protein in the regulation of cell cycle directed us towards the findings of an author, who have shown that only Roundup but not glyphosate changed cell cycle of sea urchin embryonic cells due to delayed activation of the CDK1/cyclin B complex, acting downstream from p53. The effect of glyphosate on cell cycle was also excluded in the experiments on human lymphocytes, however the tested concentrations range of this compound was between 0.0125 and 0.5 μg/mL (0.07–2.9 μM), while the current study showed that glyphosate at 100 μM caused downregulation of TP53 expression in PBMCs. Beside hypermethylation of TP53 gene promoter and down regulation of its transcript level in PMBCs treated with glyphosate (100 μM), hypomethylation within P21 gene promoter was detected for all glyphosate concentrations. Changes in methylation of the P21 gene promoter were correlated with increased expression of the cell cycle regulator at 100 μM of glyphosate, that would suggest inhibition of PBMCs cycling in G0/G1 phase. Further analysis of molecular drivers of the cell cycle revealed a decreased expression of the P16 gene encoding the cell cycle inhibitor in glyphosate-treated cells, staring from its lowest concentration comparable to that occurring during environmental exposure. However, the analysis carried out did not show any changes in the methylation level within the P16 gene promoter region in PBMCs due to glyphosate treatment. These results correlate with previous findings, in which higher concentrations of glyphosate (250 μM and 500 μM) also did not cause any changes in methylation of P16 gene promoter. The protein product of P16 gene, p16, is an inhibitor of cyclin D. Literature data suggests that low expression of P16 may result in overexpression of cyclin D1 (CCND1), activation of its complexes with CDK4 and CDK6 complexes (cyclin D1/CDK4, cyclinD1/CDK6) and overcoming the G0/G1 checkpoint of the cell cycle. In the tested experimental conditions, an increased expression of the CCND1 due to glyphosate treatment at its whole tested range of the concentrations (0.5–100 μM) was identified, but no statistically significant changes in the methylation level of the gene promoter has been shown. Beside of changes in the expression level of the major cell cycle regulators and/or methylation pattern within their gene promoters, significant upregulation of the BCL2 expression at the mRNA level at the highest tested concentration of glyphosate (100 μM) was also identified. Therefore, this data may suggest a disturbance of apoptosis induction, due to sustained antiapoptotic abilities of BCL2. In contrast, *in vitro* studies on the effect of glyphosate on apoptosis in mature rat testicular cells and PBMCs showed that glyphosate only at very high concentrations (29.57 mM/0.5 mM, in rat testicular cells and PBMCs; respectively) induced apoptosis. Thus, the obtained data may not result in specific metabolic effects until the exposure to high doses or cumulative long-term exposure of humans to glyphosate will be preceded.

Conclusion

This study has attempted to assess epigenetic mechanisms of action of glyphosate in human PBMCs, which has been poorly studied in cellular models including blood cells. The conducted analysis have shown that glyphosate significantly affected global DNA methylation of PBMCs as well as methylation in the promoter regions of selected tumor suppressors (P21 and TP53) as well as expression of major cell cycle and apoptosis drivers (P16, TP53, BCl2, CCND1 and P21). Changes in the DNA methylation profile were minimally correlated with gene expression level, however, regulation of transcription process is performed at many different levels and further and more global analysis (genome-wide based on) are necessary to give

clear answer about epigenetic-transcriptomic changes induced by glyphosate. It should be noted that glyphosate induced changes in concentrations corresponding to environmental or occupational exposure. Conducting of further *in vitro* studies on various epigenetic modifications caused by glyphosate with different target cell cultures is still warranted.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The objective was to assess epigenetic mechanisms of action of glyphosate in human PBMCs, which has been poorly studied in cellular models including blood cells. The study was conducted using an *in vitro* test system. The ability of glyphosate to impact the measured parameters was demonstrated (global DNA methylation of PBMCs, methylation in the promoter regions of selected tumor suppressors (P21 and TP53), and expression of major cell cycle and apoptosis drivers (P16, TP53, BCl2, CCND1 and P21). However, a positive control was not used, and a clear dose-response was not established for all of the measured parameters. Additionally, the measured effects *in vitro* are not clearly linked to an adverse outcome *in vivo*. While it is stated that the concentrations used are comparable to environmental exposure, external exposure was not linked to a corresponding internal concentration. Therefore, it is not possible to calculate a dose for risk assessment purposes. The study is useful for supplemental information on *in vitro* effects resulting from glyphosate exposure, but, is not appropriate for derivation of an endpoint in human health risk assessment.

This publication is considered relevant and reliable without restrictions because the assays conducted comply in general with the quality criteria for *in vitro* testing.

2. Full summary of the study according to OECD format

In this study glyphosate, among other pesticide active substances, was investigated for its effect on lipid accumulation in differentiated adipocytes *in vitro* at concentrations ranging from 0.1 to 1000 µM. The results indicated that at the concentrations tested glyphosate scored negative for lipid accumulation.

Materials and methods

Chemicals – Glyphosate (purity ≥ 96 %) purchased from Sigma-Aldrich, Gillingham, UK. Stock solutions of glyphosate were prepared in serum-free medium and adjusted to pH 7.2.

Cell culture - The murine fibroblast 3T3-L1 cell line was purchased from ZenBio (Cambridge Bioscience, Cambridge, UK) and was not used past passage 10. Undifferentiated 3T3-L1 cells were grown at 37 °C under 5 % CO_2 in a maintenance medium composed of phenol red free Dulbecco's Modified Eagle Medium (DMEM), 10 % newborn calf serum, 2 mM glutamine and 10 µg/mL penicillin/streptomycin. Cells were released from the flask substratum using 0.05 % trypsin-EDTA and counted using a hemocytometer prior to seeding.

Adipocyte differentiation - For the differentiation of murine 3T3-L1 cell cultures to adipocytes, cells were seeded into 96-well plates at a density of 20,000 cells per well in 100 µL maintenance medium. Following a 2-day stabilization period, cells were switched to differentiation medium consisting of DMEM, 2 mM glutamine, 10 µg/mL penicillin/streptomycin, 10 % fetal bovine calf serum, 500 µM 3-isobutyl-1-methyl-xanthine and 100 nM insulin from bovine pancreas. After a further 2 days of culture, the medium was refreshed to start the incubation with concentrations of glyphosate ranging from 0.1 to 1000 µM.

Dexamethasone was used as a positive control. Media were replenished every 2 days for a further 6 days. Lipid accumulation was visualized on day 8 using fluorescent Nile Red staining in accordance with the manufacturer's instructions and quantified using a microplate reader. The fluorescence was measured with a filter giving an excitation at 490 nm and emission at 510-570 nm. The adipogenic effect was expressed as a fold change in emission signal intensity between untreated differentiated and treated differentiated 3T3-L1 cells.

Cell viability assay - Cell viability was assessed using a colorimetric 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) assay, which indirectly measures cell number by testing for activity of mitochondrial succinate dehydrogenase. The 3T3-L1 cells were seeded into 96-well plates and differentiated as described above for 8 days. Cells were then incubated with 100 mL of MTT solution (1 mg/mL) for 2 hours and the test terminated by adding 100 µL DMSO. As a measure of cell number, the optical density of the cell lysate was determined at 570 nm using a GloMax Multi Microplate Multimode Reader. The number of cells was directly proportional to the intensity of the signal. Cell viability was expressed as a percentage of the control samples.

Intracellular lipid staining - The 3T3-L1 cells were seeded into 96-well clear bottom black tissue culture treated plates and differentiated as described above for 8 days. Medium was then removed and cells fixed by addition of 100 µL 4 % paraformaldehyde. Cells were then stained for intracellular lipid accumulation by adding 50 µL of 1 mg/mL Nile Red and 1 µg/mL 4',6-diamidino-2-phenylindole (DAPI) in 0.2 % Triton X-100-PBS for 15 minutes in the dark. Nile Red staining for lipid droplets and DAPI staining for cell nuclei were imaged at 530 and 405 nm, respectively, using fluorescence imaging on a Nikon Eclipse Ts2 microscope at 40 x.

Statistical analysis - The statistical analysis of the dose-response results from the adipogenesis assay was performed by ANOVA. Pair-wise comparisons were made using a Mann-Whitney test. Nonlinear regression analysis was performed using 5-parameter logistic dose-response curve models. These statistical analyses were performed using GraphPad Prism version 7.00 for MAC OS X.

Results

With dexamethasone as the positive control the adipogenic assay using murine 3T3-L1 cells to undergo differentiation to adipocytes was shown to be a sensitive assay system causing a maximum of 21-fold increase in lipid accumulation when compared to untreated differentiated cells. The dose response relationship of dexamethasone was used to determine the concentration that caused a 50 % response (EC_{50}). The EC_{50} for dexamethasone was 9.4 pM and some of the tested compounds showed an effect on lipid accumulation with different dose response patterns. Treatment with glyphosate scored negative.

Discussion

Commonly used herbicide active substances were tested in an adipogenesis assay to evaluate their obesogenic potential. Using the 3T3-L1 cell assay system, which measures lipid accumulation following differentiation to adipocytes, glyphosate scored negative at all concentrations tested. This study uses the well-established murine 3T3-L1 cell line model system for obesogenic screening. However, this cell line can only address a limited number of possible modes of action. The 3T3-L1 cells consist of unipotent pre-adipocytes, which can only differentiate into mature adipocytes. Another important limitation of 3T3-L1 cells is that they are of murine origin, and may not fully be representative of human metabolism. In addition, stocks of 3T3-L1 cells from different sources can have different metabolic capabilities.

Conclusion

Amongst the pesticide active substances tested for effects on lipid accumulation in differentiated adipocytes glyphosate scored negative.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In this study glyphosate, among other pesticide active substances, were investigated for their effect on lipid accumulation in differentiated adipocytes *in vitro* at concentrations ranging from 0.1 to 1000 µM. The results indicated that at the concentrations tested, glyphosate scored negative for lipid accumulation. This publication is considered relevant for the risk assessment of glyphosate and reliable without restrictions.

Assessment and conclusion by RMS:

Reliability criteria for *in vitro* toxicology studies

Publication: Biserni *et al*., 2019	**Criteria met? Y/N/?**	**Comments**

2. Full summary of the study according to OECD format

The principal human data for glyphosate and non-Hodgkin's lymphoma (NHL) come from five case–control studies and two (related) cohort studies. The case–control studies are at risk of recall bias resulting from information on exposure to pesticides being collected from cases and controls based on their memories; cases being deemed likely by textbook authors to have a greater motivation than controls for remembering or reporting past exposures. In addition, two of the case–control studies are additionally at risk of a form of selection bias that can exacerbate the effect of recall bias. Both biases are in the direction of making glyphosate appear carcinogenic (viz. causing odds ratios (ORs) to be >1 in the absence of a true causal relationship). If ORs are not biased and a pesticide plays no role in causing NHL, the probability that an OR for that pesticide is greater than 1.0 is approximately 0.5. The fractions of ORs for pesticides other than glyphosate that are greater than 1.0 in the five case–control studies are 0.90 (n = 92), 0.90 (n = 152), 0.93 (n = 59), 0.76 (n = 140), and 0.53 (n = 54), the first two from studies that are at risk for both types of bias. In the two cohort studies, which are not subject to these biases, the comparable fractions for relative risks for all cancers are 0.51 (n = 70) and 0.48 (n = 158). Thus, this analysis provides evidence that at least four of the five case–control studies of glyphosate exposure and NHL are contaminated by statistical bias, likely stemming in the main from recall bias, exacerbated by selection bias in two of the studies. This suggests that these case control studies of glyphosate are not reliable evidence for a relationship between glyphosate and NHL.

Materials and methods

Two of the case–control studies exclude from some analyses of glyphosate (as well as analyses of other pesticides) the unexposed cases and controls who report exposures to pesticides not the subject of the analysis, which raises the possibility of selection bias if recall bias is also operating. The potential effect of selection bias in the presence of recall bias on ORs is illustrated by simulating sets of case–control data in which increasing amounts of recall bias are introduced, and the effects of adding selection bias to these analyses are noted. Each simulation involves 500 cases and 1,500 controls. Controls are randomly assigned exposure to pesticides according to the percentages of controls reporting exposure to nine pesticides reported by McDuffie *et al.* (2001) (Table II). Cases are randomly assigned exposures in the same way

except the exposed percentages are multiplied by increasing factors in different simulations, which introduces increasing amounts of recall bias. In each of six simulations, 10,000 sets of data are simulated and the 10,000 simulated ORs for glyphosate are averaged, (1): using all data so that recall bias but not selection bias is present and (2): after removing from the unexposed group both cases and controls that are exposed to any pesticide other than glyphosate (so that both recall bias and selection bias are present). In interpreting this simulation study, it needs to be understood that the McDuffie data and glyphosate are used only to make the simulations more realistic, and that the simulations say nothing about the McDuffie study or about the risk from glyphosate exposure, as any such data or a herbicide other than glyphosate could have been used to illustrate the same points. The likelihood that statistical bias (from any source) may be responsible for the elevated ORs for glyphosate is evaluated by tabulating ORs and RRs from the studies and cross-classifying them by pesticide groups and the fraction that exceed 1.0. If all types of pesticides have an elevated percentage of ORs greater than 1.0, this suggests that bias may be the cause of the elevations rather than any carcinogenic effect of the pesticides. The ORs and RRs included in the tabulations were selected from the original papers according to the following rules:

(1) In some instances, the exact same OR calculation is reported in two or more separate tables (e.g. the category "herbicide" in tables I, II, and V of Hardell *et al*., 2002). Only one of the identical calculations is tabulated.

(2) Similarly, some tables contain two sets of OR or RR calculations for testing the same hypotheses, but using different statistical methods (e.g. controlling for different sets of potential confounders). In these instances, only one set of calculations is tabulated, namely the set of ORs or RRs whose method of calculation agrees most closely with methods used in in the remainder of the article or in other articles. For example, De Roos *et al*. (2003) reported ORs calculated using both logistic regression and hierarchical regression. The ORs computed using logistic regression were selected for tabulation because this was the only study that employed hierarchical regression and logistic regression was the most common method used in the remaining studies.

(3) In De Roos *et al*. (2003), the category "potentially carcinogenic pesticides" apparently was formed post hoc and included those pesticides that gave greatest evidence of a carcinogenic effect in initial analyses. Such an approach would almost guarantee an OR greater than 1. In fact, the three ORs from this category were all greater than 1. ORs from this analysis were not included in order to avoid biasing the tabulation. (This does not imply that De Roos *et al*. erred in computing these ORs, only that they were not suitable for inclusion in our analysis.)

(4) Otherwise, all OR or RR calculations reported in the publications were tabulated. A complete listing of the ORs from each study contained in the tabulation is provided in the Supporting Information. The results of these tabulations are summarized in graphs and in tabular form.

Results
Specific results part not given in this article. Results and discussion are merged.

Discussion
Results of the simulation exercise to demonstrate the effect of selection bias are shown in Table I. The first row in the table verifies that, as expected, selection bias does not affect the expected OR in the absence of recall bias. The remaining rows assume increasing amounts of recall bias as indicated in the first column. The effect of that recall bias on the expected ORs for glyphosate are shown in the second column. The third column shows the expected ORs when selection bias is added to the recall bias present by removing from the unexposed (to glyphosate) groups cases and controls exposed to any herbicide other than glyphosate, just as was done in Hardell *et al*. (2002) and Eriksson *et al*. (2008).

Table I. Results of Simulations[a] to Demonstrate the Effect of Recall Bias[b] Alone and with Selection Bias[c] on Average OR

Recall Bias[b]	Average OR for Glyphosate with Recall Bias Only	Average OR for Glyphosate with Both Recall Bias and Selection Bias
0	1.01	1.01
0.05	1.07	1.10
0.1	1.12	1.18
0.3	1.35	1.59
0.5	1.59	2.10
1	2.24	3.95

[a]10,000 simulations, 500 cases, 1,500 controls, each row. Herbicides assumed present and the percentage of controls assumed to report exposure: (glyphosate, 8%), (2,4-D, 19%), (mecoprop, 5.4%), (MCPA, 3.1%), (diclofopmethyl, 1.7%), (thiocarbamates, 3.3%), (bromoxynil, 3.2%), (dicamba, 8.7%), (dinitroaniline, 2.1%). Thus, for example, the probability that a particular control claimed exposure to MCPA was 0.031. Exposures to different herbicides are assumed to occur independently.

[b]Recall bias is introduced into each simulation by computing the prevalence of each herbicide exposure among cases as [prevalence among controls] × [1+ Recall bias].

[c]Selection bias is introduced by eliminating from OR calculations both unexposed (to glyphosate) cases and controls exposed to herbicides other than glyphosate.

Crump notes that the effect of selection bias increases with the increase in recall bias. This simulation demonstrates that selection bias can cause ORs to be inflated by important amounts above that due solely to recall bias when recall bias is also present. Fig. 1 shows plots of the tabulated ORs or RRs by study, with the pesticide groupings upon which the ORs are based (including ORs derived for both individual pesticides and groups of pesticides), classified as to fungicides, herbicides not containing glyphosate, impregnating agents, insecticides, and pesticide groupings that include glyphosate. The individual pesticides and groupings for each study are listed in the footnote to Table II. The tabulated RRs from the two cohort studies are similarly classified into cancer groupings not containing NHL and groupings containing NHL. Since the logarithms of ORs are plotted, the focus is on the proportion of log-transformed ORs that are greater than 0.0 (equal to the proportion of untransformed ORs greater than 1.0). These figures show that ORs in McDuffie *et al*. (2001), Hardell *et al*. (2002), and Eriksson *et al*. (2008) are nearly all greater than 1.0.

Table II. Counts of ORs and RRs Categorized by Study, Pesticide, and Whether Greater than 1.0

[a]ORs for NHL and hairy cell leukemia computed for herbicides; phenoxyacetic acids; MCPA; 2,4,5-T + 2,4-D; glyphosate; other herbicides; insecticides; DDT; mercurial seed dressing; pyrethrins; fungicides; impregnating agents; chlorophenols; pentachlorophenol; arsenic; creosote; other impregnating agents; organic solvents.

[b]ORs for NHL, including subtypes, as well as several subcategories of NHL were computed for herbicides, total; phenoxyacetic acids; MCPA; 2,4,5-T and/or 2,4-D; other phenoxyacetic acids; herbicides except phenoxyacetic acids; glyphosate; other herbicides; insecticides, total; DDT; mercurial seed dressing; pyretrine; permetrine; other insecticides; fungicides; impregnating agents; chlorophenols; arsenic; creosote; tar; other impregnating agents; rodenticides.

[c]ORs for NHL computed for phenoxyherbicides; 2,4-D; mecoprop; MCPA; diclofopmethyl; phosphonic acid; glyphosate (Roundup); thiocarbamates; diallate; phenols: bromoxynil; dicamba; dicamba (Banvel or Target); dinitroaniline; trifluralin; carbamates; carbaryl; carbofuran; methomyl; organochlorine; chlordane; lindane; aldrin; organochlorine diphenylchlorides; DDT; organophosphorus; malathion; dimethoate; diazinon; amide; captan; phaval; aldehyde; formaldehyde; mercury containing; mercury dust; mercury liquid; sulfur compounds.

[d]ORs for NHL, including subtypes, and other categories of lymphoid neoplasms computed for occupational pesticide use, insecticides, organochlorine, organophosphate, pyrethrin, fungicides, carbamates, imide, triazole, herbicides, phenoline, phenoxy, picoline, triazine, amide, urea, quaternary ammonium, glyphosate, garden pesticide use, insecticides, fungicides, herbicides, domestic insecticide use.

[e]ORs for NHL computed for aldrin; bufencarb; carbaryl; carbofuran; chlordane; copper acetoarsenite; coumaphos; DDT; diazinon; dichlorvos; dieldrin; dimethoate; ethoprop; famphur; fly, lice, or tick spray; fonofos; heptachlor; lead; arsenate; lindane; malathion; methoxychlor; nicotine; phorate; pyrethrins; rotenone; tetrachlorvinphos; toxaphene; terbufos; alachlor; atrazine; bentazon; butylate; chloramben; cyanazine; 2,4-D; dicamba; EPTC (protectant; glyphosate; linuron; MCPA; metolachlor; metribuzen; paraquat; propachlor; sodium; chlorate; 2,4,5-T; trifluralin; any pesticide; any insecticide; any herbicide; chlordane and DDT; carbofuran and atrazine; diazinon and atrazine; alachlor and atrazine; atrazine and dicamba.

[f]RRs computed for glyphosate exposure in relation to the following cancers: all cancer, lung, oral cavity, rectum, pancreas, kidney, bladder, prostate, melanoma, lymphohematopoietic cancer, NHL, lukemia, and multiple myeloma.

[g]RRs computed for glyphosate exposure in relation to the following cancers: all cancer; oral cavity; colon; rectum; pancreas; lung; melanoma; prostate; testicular; bladder; kidney; lymphohematopoietic; Hodgkin lymphoma; non-Hodgkin lymphoma; non-Hodgkin lymphoma B cell; chronic lymphocytic lymphoma or small lymphocytic leukemia; diffuse large B cell lymphoma; marginal-zone lymphoma; follicular lymphoma; multiple myeloma and non-Hodgkin lymphoma T cell.

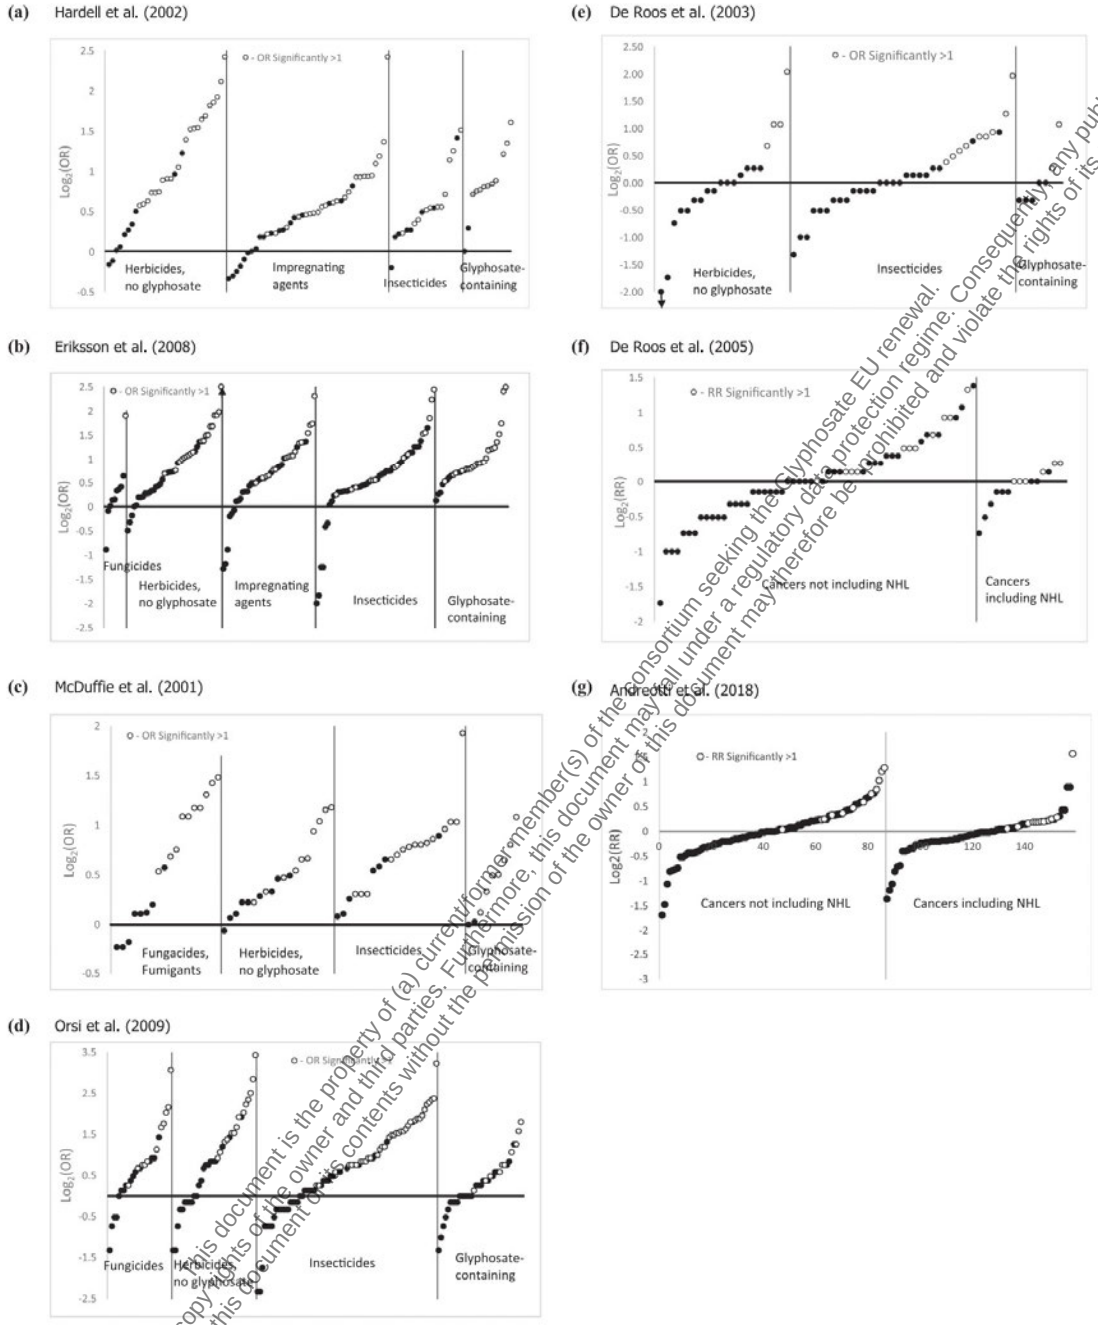

Fig. 1. Graphs of tabulated ORs and RRs. (a) Hardell et al. (2002), (b) Eriksson et al. (2008), (c) McDuffie et al. (2001), (d) Orsi et al. (2009), (e) De Roos et al. (2003), (f) De Roos et al. (2005), (g) Andreotti et al. (2018).

Also, there is an excess of ORs greater than 1.0 in Orsi *et al*. (2009). These excesses of ORs greater than 1.0 occur in all categories of pesticides considered in these studies. On the other hand, there appears to be roughly a balance between the numbers of ORs greater than and less than 1.0 in all categories of pesticides in the case–control study of De Roos *et al*. (2003). Similarly, in both cohort studies (Andreotti *et al*., 2018; De Roos *et al*., 2005), there seems to be roughly an equal number of RRs greater than and less than 1.0, both for cancer groupings that include NHL and those that do not. These graphs also display those ORs and RRs that are statistically significantly greater than 1.0, with statistical significance defined by the lower bound on the 95 % confidence interval being greater than or equal to 0.8 (apparently the decision rule used in De Roos *et al*., 2003 to define "potentially carcinogenic pesticides.") This shows that many statistically

significantly elevated ORs occur in every pesticide category with little notable difference between categories that contain glyphosate and those that do not. Table II, which summarizes the tabulated ORs and RRs, provides confirmation of the impressions obtained from the graphs. In this table OR and RR reported in the original papers as equal to 1.0 (which are mostly due to roundoff in reported values) each contribute 0.5 to the counts of ORs and RRs greater than 1.0. In the case–control studies of Hardell *et al.* (2002), Eriksson *et al*. (2008), and McDuffie *et al*. (2001), 90 % or more of all ORs from pesticide groups not containing glyphosate are greater than 1.0. In these three studies, the percentage of ORs greater than 1.0 exceeds 80 % in all pesticide groupings (fungicides, herbicides not including glyphosate, impregnating agents, and insecticides, as well as groupings that contain glyphosate). The percentages of ORs from Orsi *et al*. (2009) that exceed 1.0 are also elevated, although not to the same extent as in the other three studies. By contrast, the percentages of ORs from the case–control study of De Roos *et al.* (2003) that are greater than 1.0 are all fairly close to 50 % in all pesticide categories (52.8 % in categories combined than do not include glyphosate and 51.6 % if glyphosate-containing categories are included). Thus, of the five case control studies, the study of De Roos *et al*. (2003) presents considerably less evidence of recall bias resulting from an excess of ORs greater than 1.0. In the two cohort studies, the percentages of RRs greater than 1.0 in cancer groupings not containing NHL in both studies are 54 %, and overall, with NHL included, are 49.5 % (Table II). Thus, these results from the two cohort studies, which are not subject to recall bias or selection bias, are reasonably consistent with what would be expected if these studies are free of statistical bias and glyphosate has no effect upon cancer rates. If the ORs are not biased, the results in Table II pertaining to the case–control studies suggest that all types of pesticides investigated in these studies are having a role in causing NHL, including fungicides, herbicides other than glyphosate, impregnating agents and insecticides. It should also be kept in mind that the category NHL contains many types of lymphoma, not all of which are likely to share common risk factors. Thus, it seems unlikely (at least to this investigator) that pesticides within each of these types of pesticides would be causing NHL, and particularly to an extent to be responsible for the evidence seen in Table II. It seems much more likely that the preponderance of ORs greater than 1.0 seen in all pesticide categories in most of the case–control studies is simply the result of recall bias, which is a well-known problem with these types of case–control studies, possibly augmented in two studies by selection bias. Such a conclusion is further supported by the fact that in the two cohort studies, which are not subject to these biases, the overall percentage of RRs greater than 1.0 is 49.6 % that is in excellent agreement with the theoretical value of 0.5, assuming no bias and no effect of glyphosate on any cancer. Given this evidence, one could reasonably conclude that at least four of the case–control studies of glyphosate and NHL are contaminated by statistical bias, and consequently are not suitable for reaching conclusions about the potential ability of glyphosate to cause NHL.The potential for case–control studies to be affected by recall bias is well known and has been discussed in many publications. The potential for the case–control studies of glyphosate, in particular, to be subject to recall bias, along with concerns about glyphosate studies not controlling for exposure to farm animals, and for the use of proxy respondents were discussed previously. These same issues were raised by some panelists in an EPA FIFRA scientific advisory panel.

Conclusion

In summary, the potential for these types of case–control studies to be contaminated by bias from the use of exposure information based on the memories of both cases and controls (recall bias) is well known. This article provides evidence that at least four of the five case–control studies of glyphosate exposure and NHL are contaminated by statistical bias, likely stemming in the main from recall bias, exacerbated by selection bias in two of the studies. This suggests that the case control studies of glyphosate are not reliable for determining whether glyphosate is carcinogenic. However, the two cohort studies (Andreotti *et al*., 2018; De Roos *et al*., 2005) do not present evidence of bias. If further study of the potential relationship between glyphosate exposure and NHL is needed, it would best come from cohort or other studies that are not at risk of recall bias resulting from quantifying exposures by questioning subjects. Of course, cohort studies have other potential problems that must be evaluated, including incomplete follow-up, the healthy worker effect and poor information on exposures. The potential for recall bias identified herein could affect, not just case–control studies of the potential carcinogenicity of glyphosate, but any such study that involves quantifying exposures occurring in the distant past based on participant’s memories.

3. Assessment and conclusion

Assessment and conclusion by applicant:

It is well known that recall bias is a potentially important bias in cancer case control studies where study participants are asked to recall their past exposures. In an ideal study, information about exposures for cases and controls would be collected under exactly the same circumstances. However, circumstances are quite different for cases and controls. Cancer cases have suffered a grievous illness and it is only natural for them to be deeply introspective about what might have caused their cancers. Controls have no such motivation that would augment their recall (or reporting). So, the concern expressed in many textbooks is that recall bias tends to produce false positive results. The purpose of this analysis by Crump was to evaluate the evidence for recall bias in the overall pattern of results in five case control studies and two cohort studies that comprise the main part of the glyphosate-NHL literature.

In evaluating the case control studies, Crump reasoned that the percentage of odds ratios > 1 for non-glyphosate exposures should be approximately 50 % if recall bias was not operative and those exposures did not cause NHL. Yet, it turned out that the percentages of ORs >1 for non-glyphosate exposures were 90 % for Hardell *et al*. (2002), 90 % for Erikson *et al*. (2008), 93 % for McDuffie *et al*. (2001), 76 % for Orsi *et al*. (2009), and 53 % for DeRoos *et al*. (2003). These extreme departures from 50 % for 4 of the 5 case control studies is consistent with recall bias, perhaps augmented by a type of selection bias in the analyses by Hardell *et al*. (2002) and Eriksson *et al*. (2008). In contrast, in the most recent publication from the Agricultural Health Study (Andreotti *et al*. 2018), only 48 % of the relative risks (RR) calculated were >1 – a percentage in the range expected with a true probability of 50 %. While the evaluation of Andreotti *et al*. (2018) concerned glyphosate and other cancer sites and not other exposures and NHL, the principle is the same: under the null hypothesis the proportion of ORs or RRs > 1 should be roughly 50 % absent bias.

We agree with Crump's conclusion that the 4 case-control studies with a high proportion of ORs > 1 are "contaminated" by statistical bias and are not reliable as evidence of a relationship between glyphosate and NHL. Of course, there are also other types of bias that may contribute to the high proportion of positive ORs (e.g. lack of control for confounding, lower participation for controls than cases (traditional selection bias), proxy respondents, etc.) (see Acquavella *et al*. 2016). Nonetheless, Crump's point is well taken that ORs for glyphosate in 4 of the 5 case control studies should be interpreted as unreliable because the vast majority of ORs for other exposures are >1.

Assessment and conclusion by RMS:

Reliability Criteria: Epidemiology studies

Publication: Crump K., 2019	**Criteria met? Y/N/?**	**Comments**
Study Design		
Adequate study design given study objectives	Yes	For a methodologic evaluation of recall bias in existing studies
Appropriate study population to address potential glyphosate-related health outcomes	Not applicable	

Publication: Crump K., 2019	**Criteria met? Y/N/?**	**Comments**
Exposure studied		
Exposure to formulations with glyphosate as a.s.	Yes	
Exposure to formulations with other a.s.	Yes	
Exposure to other farm exposures	Yes	
Study Conduct/analysis		
Adequate description of study population	Not applicable	
Adequate description of exposure circumstances	Not applicable	
Comparable participation by groups being compared	Not applicable	
Information provided by proxy respondents	Not applicable	
Adequate statistical analysis	Yes	To illustrate bias
Adequate consideration of personal confounding factors	Not applicable	
Adequate consideration of potentially confounding exposures	Not applicable	
Overall assessment		
Reliable without restrictions	Yes	As methodologic work. Clearly illustrates recall bias in the glyphosate case control studies.
Reliable with restrictions	No	
Not reliable	No

2. Full summary of the study according to OECD format

The herbicide glyphosate has been scrutinized for an impact on cancer incidence, but reports demonstrate the difficulty of linking estimates of exposure and response analysis. An approach to better apprehend a potential risk impact for cancer is to follow a synergistic approach, as cancer rarely occurs in response to one risk factor. The known influence of glyphosate on estrogen-regulated pathway makes it a logical target of investigation in breast cancer research. In this study, non-neoplastic MCF10A cells in a repeated glyphosate exposure pattern over 21 days were used. Glyphosate triggered a significant reduction in DNA methylation, as shown by the level of 5-methylcytosine DNA; however, in contrast to strong demethylating agent and cancer promoter UP peptide, glyphosate-treated cells did not lead to tumor development. Whereas UP acts through a DNMT1/PCNA/UHRF1 pathway, glyphosate triggered increased activity of ten-eleven translocation (TET)3. Combining glyphosate with enhanced expression of microRNA (miR) 182-5p associated with breast cancer induced tumor development in 50 % of mice. Culture of primary cells from resected tumors revealed a luminal B (ER+/PR-/HER2-) phenotype in response to glyphosate-miR182-5p exposure with sensitivity to tamoxifen and invasive and migratory potentials. Tumor development could be prevented either by specifically inhibiting miR 182-5p or by treating glyphosate-miR 182-5p-cells with dimethyloxallyl glycine, an inhibitor of TET pathway. Looking for potential epigenetic marks of TET-mediated gene regulation under glyphosate exposure, we identified MTRNR2L2 and DUX4 genes, the hypomethylation of which was sustained even after stopping glyphosate exposure for 6 weeks. The findings reveal that low pressure but sustained DNA hypomethylation occurring *via* the TET pathway primes cells for oncogenic response in the presence of another potential risk factor. These results warrant further investigation of glyphosate-mediated breast cancer risk.

Materials and methods

Cell Culture and Transfection; MCF10A cells were cultured in DMEM/F12 supplemented with 5 % horse serum (Invitrogen, Cergy Pontoise, France), 500 ng/ml hydrocortisone (Sigma-Aldrich, France), 100 ng/ml cholera toxin (Sigma-Aldrich, France), 10 µg/ml insulin (TermoFisher, France) and 20 ng/ml epidermal growth factor (EGF, SigmaAldrich, France), penicillin (100 U/ml), and 2 mmol/L L-glutamine. MCF7 and MDA-MB-231 cells were cultured in DMEM medium (Invitrogen) all supplemented with 5 % FCS and 2 mM l-glutamine. Glyphosate (CAS 1071-83-6, sc-211568) was purchased from Santa-Cruz (France), and a 10^{-8}-M stock solution was prepared in DMSO every week. Glyphosate was diluted directly in fresh cell culture medium and was fed to the cells at the time points indicated in the results section. For the transfection of RNAs, we used miRCury LNA miR mimics for the has-miR-146a, has-miR-182-5p, has-miR-27a, has-miR-500a-5p, has-miR-30a, and has-miR-495 (Qiagen, France), siRNA for siRNA-T ET3 (sc94636) and control siRNA-A (sc94636) and HIPerfect Transfection Reagent (Qiagen, France). All miRs showed similar transfection efficiency (10- to 15-fold change, as measured by RTqPCR).

DNA Extraction, 5mC ELISA, and qMSRE; A QIAcube automate and QIAmp DNA Mini QiaCube kit (Qiagen, France) were used to isolate DNA. The quantification of 5mC was performed using the 5mC DNA ELISA Kit (Zymo Research-Euromodex, France) according to the manufacturer's instructions. The 5mC DNA ELISA Kit estimates the number of 5mC on DNA without distinction of localization; therefore, the term of global DNA methylation level when referring to results obtained *via* this mode of quantification was used. Next, DNA methylation was quantified by qMSRE. Digestions were performed with adequate restriction enzymes, HpaII and AciI (NEB, France). Typically, 1 ng of genomic DNA was digested with 40 U of enzymes at 37 °C for 2 h in 50 µl of reaction. Control samples were treated in the same way but without addition of the enzyme. Five microliters of digestion mixture were used for qPCR. The QuantiFast SYBR Green PCR Kit and Rotor-Gene Q (Qiagen, France) were used to perform the qPCR. Primers were MSH3: TTTCTCCAG GGCTGGGACTTTG and CCCGACTGGATTCCCCTTTTCT; DHFR: AAACCTCAGCGCTTCACCCAAT and TGATAGG GCTGGAGGAGGAAG; DUX4: CGACACCCTCGGACAGCA and TCAAAGCAGGCTCGCAG; COL23A1: TCTCCAGG CCAGAAACAGTCTT and ATTTAGAGAGGCAGGGTC GAGA; and MTRNR2L2: ACCCCACCTGTTTACCAA and GCTACCTTTGCACGGTTAGGG.

Tumor Xenografts in Nude Mice; Cells were harvested by trypsinization, washed and resuspended in saline buffer. Cell suspensions were injected subcutaneously into the flank of 7 to 8-week-old mice (Janvier, France) in 100 µl of sterile PBS. Tumor volume based on caliper measurements was calculated using the

modifed ellipsoidal formula [Tumor volume = 1/2 (length × width^2)] according to previously published work. At the end of the observation period, the mice with xenograf tumors were euthanized, and the tumor tissues were removed for analysis. The experimental procedures with animals were in accordance with the guidelines of Institutional Animal Care and the French National Committee of Ethics. In addition, all experiments were conducted according to the Regulations for Animal Experimentation at the Plateforme Animalerie in the Institut de Recherche en Santé de l'Université de Nantes (IRS-UN) and approved by the French National Committee of Ethics. The number of mice was restricted to four per condition to limit the number of animals to the necessary minimum as in previous studies based on the fact that we anticipated to detect a highly frequent tumorigenic event (frequency superior to one to four for tumorigenesis).

Establishment of Tumor Cells; From Xenografts (PCTCdX); PCTCdX (here named Glypho-iBPCTC) were obtained after mechanical dissociation. Briefly, resected tumor tissue from mice was cut into pieces of 1–5 mm^3 and plated in a 60-mm^2 tissue culture dish with DMEM containing 10 % FBS and antibiotics. Minced pieces of tumor were incubated with 200 U/ml collagenase I (Sigma) and 500 U/ml DNaseI (Sigma) in PBS for 1 h at 37 °C with vigorous constant agitation. The single cell suspension was filtered through a 70-mm cell strainer (BD Falcon), washed with PBS, and then placed in DMEM-10 % FBS. Cell cultures were split 1:5 when confluent.

Migration Assay; Cells (3×10^5) were seeded in six-well plates, cultured until they reached 80–90 % confluence, and treated with 10 µg/ml of mitomycin C (Sigma, France) for 2 h (to prevent cell proliferation). The monolayer of cells was scratched using a two-well silicone insert (Ibidi, Germany). Cell migration was monitored by microscopy (Incellis Cell Imager, Bertin, France). The images acquired at different time points (0, 4, 8, 24, 28, 32, and 48 h) for each sample were analyzed quantitatively. For each image, distances between one side of the wound and the other side were measured with ImageJ software; the mean value of 10 measurements all along the wound was recorded. The average migration speed was obtained by calculating the ratio distance/time along the time course.

Invasion Assay; All of the procedures were performed according to the manufacturer's instructions (QCM 24-Well Collagen-Based Cell Invasion Assay, Millipore, France). In brief, 200 µl of serum-free medium containing 2×10^5 cells were added into the invasion chamber, with the bottom well of the 24-well plate containing 500 µl of complete medium. After 72 h of incubation at 37 °C, the medium was removed, and the cells were stained by placing the chamber in staining solution for 20 min at room temperature. Cells that did not invade were carefully removed from the top side of the chamber using a cotton swab. The stained chamber was inserted into a clean well containing 200 µl of extraction buffer for 15 min at room temperature. A total of 100 µl of extracted (stained) solution from the chamber was transferred into a 96-well plate, and the optical density was measured 570 nm using a spectrophotometer.

Viability Assay: MTT and XTT Tests; A cell suspension containing 105 cells was prepared, and 100 µl was distributed in sixplicates in a 96-well plate. After 24 h of incubation at 37 °C and 5 % CO_2, cells were exposed to tamoxifen for 48 h. Tamoxifen was first diluted 10 times in dimethyl sulfoxide (DMSO) and then further diluted in DMEM containing 4.5 g/L glucose, 1 % SVF, 1 % glutamine, 1 % penicillin-streptomycin at the desired concentrations. Following treatment, 10 µl of MTT (10 µg/ml) (VWR Chemicals, France) was added in each well, and the cells were incubated for 3 h. Finally, the medium containing MTT was removed, and 200 µl/well of DMSO was added to measure the optical density at 570 nm using a spectrophotometer. For the XTT test, the XTT Assay Kit was used (ab232856, Abcam, France) according to the manufacturer's instructions. Briefly, 10^5 cells were seeded in 100 µl of culture medium in each well of a 96-well plate. After 24 h of incubation at 37 °C and 5 % CO_2, cells were treated with adequate drugs. Then, 10 µl/well of XTT mixture was added for an incubation of 2 h at 37 °C and 5 % CO_2. Finally, absorbance was measured at 450 nm.

Breast Tissue and Urine Samples; Human samples were collected from the Réseau des tumorothèques du Cancéropole Grand-Ouest and Institut de Cancérologie de l'Ouest. In accordance with regulations, all subjects signed a specifc informed consent form for this biocollection approved by an Ethics Committee (CPP OUEST IV, n °18/16), the French State Department for National Education, Higher Education and

Research (Ministère de l'Education Nationale, de l'Enseignement Supérieur et de la Recherche, N ° DC-2015-2457) and the Commission Nationale de l'Informatique et des Libertés (CNIL) (compliance commitment to MR 001). The glyphosate concentration in urine samples was obtained using Glyphosate kit (Novakits, France).

mMTase and TET Activities; TET activity was determined using the Epigenase 5mC-Hydroxylase TET Activity/Inhibition Assay Kit (Colorimetric; Epigentek/Euromedex, France) according to the manufacturer's instructions. Dnmts-magnetic beads (DMB) assays were performed to estimate mMTase, such as initially described. Briefly, a typical methylation reaction required 50 µg of nuclear extract (Nuclear extract kit, Active Motif, France), 125 nM DNA oligonucleotides (probes), and 900 nM tritium-labeled AdoMet (1 mCi/ml; #NET155V001MC; PerkinElmer, France) in reaction buffer (50 mM Tris, pH 8.0, 5 mM EDTA, 10 % glycerol, 0.5 mM phenylmethylsulfonyl fluoride). After incubation at 37 °C for 1 h, reactions were quenched with an equal volume of magnetic beads suspension and incubated for 15 min at room temperature. Next, the beads were magnetically isolated from the reaction mix, and tritium incorporation was measured by scintillation counting.

In-Cell ELISA; In-cell ELISA was performed using the In-Cell ELISA Kit (Abcam, France) according to the manufacturer's instructions and after a fixation step performed with 4 % of paraformaldehyde solution (10 min at room temperature). Primary antibodies were incubated overnight at 4 °C. Adequate HRP-conjugated secondary antibodies were incubated for 1 h at room temperature. Detection was performed at 450 nm. After the washes, cells in each well were incubated with 1X Janus Green Stain for 5 min at room temperature, according to the manufacturer's instructions. Data were expressed in normalized unit, according to the following calculation: (HRPsignal 'minus' HRPsignal in absence of primary antibody)/(Janus Green signal 'minus' Janus Green signal in absence of cells). Antibodies used were anti-TET1 (sc163446, Santa Cruz, France), anti-TET2 (sc398535, Santa Cruz), anti-TET3 (sc139186, Santa Cruz), anti-ERα (sc8002, Santa Cruz), anti-PR (sc130071, Santa Cruz), and anti-HER2 (sc-393712, Santa Cruz).

ChIP Analyses; ChIP was performed using the ChIP-IT Express kit (Active Motif, France) according to the manufacturer's instructions. The cross-linking step was performed by treating the cells with 37 % formaldehyde solution for 15 min at room temperature. Sonication was performed with the Bioruptor Plus (eight cycles 30 s on/90 s off) (Diagenode, France). The QuantiFast SYBR Green PCR Kit and Rotor-Gene Q (Qiagen, France) were used to perform the qPCR. Antibodies used were Anti-IgG (Abcam, AB2410) and anti-TET3 (sc139186, Santa Cruz).

Statistical Analysis; All experiments were done at least in biological triplicates. Differences in means were assessed using Student t test, and the degree of correlation between two parameters was calculated using Pearson's test. $P < 0.05$ was considered significant.

Results

Exposure to Glyphosate Promotes TET3-Mediated Global DNA Hypomethylation in MCF10A Cells; DNA hypomethylation has been shown to play a determining role in cancer development. To verify the impact of glyphosate exposure on the global level of DNA methylation, non-neoplastic breast epithelial MCF10A cells were treated with a low dose (10-11 M) of this herbicide every three to four days over 21 days, covering three passage numbers; whereas control cultures were treated with vehicle DMSO (Figure 1A). Several articles analyzing the effect of glyphosate on human cells have reported using 10-11 M. Indeed, 90 % of MCF10A cells were viable as measured by XTT (2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-5-carboxanilide) assay at this concentration. Importantly, glyphosate 10-11 M is below the concentration detected in biological fluids (milk, serum, urine). As a control performed in parallel, MCF10A cells were exposed to carcinogenic UP peptide (0.5 µM) previously described to promote global DNA hypomethylation *via* the disruption of the DNMT1/PCNA/UHRF1 complex. As expected, there was a decrease in the level of 5mC-DNA in MCF10A cells treated with the UP peptide (Figure 1B). There was also a reduction in 5mC content in cells treated with glyphosate (Figure 1B), hence suggesting that

glyphosate promotes a global DNA hypomethylation as per the definition given in the introduction. The origin of glyphosate-mediated decrease in DNA methylation was assessed by measuring the levels of activity of maintenance methyltransferase (mMTase) and Ten-eleven translocation (TET), since a decrease of mMTase activity and an increase of TET activity are both causes of DNA hypomethylation. The mMTase activity remained unchanged in MCF10A cells treated with glyphosate (Figure 1C) while TET activity significantly increased in these cells (Figure 1D). Specifically, an ELISA-based assessment of the amount of the three TET family members, TET1, TET2 and TET3, revealed an overexpression of TET3 in MCF10A cells following exposure to glyphosate (Figure 1E). To confrm that glyphosate promotes TET3-mediated global DNA hypomethylation in MCF10A cells, we analysed the level of DNA methylation in MCF10A cells with siRNAmediated TET3 down-regulation. ELISA results show that the presence of siRNA-TET3 abrogates TET3 overexpression and prevents DNA hypomethylation in cells exposed to glyphosate (Figure 1F).

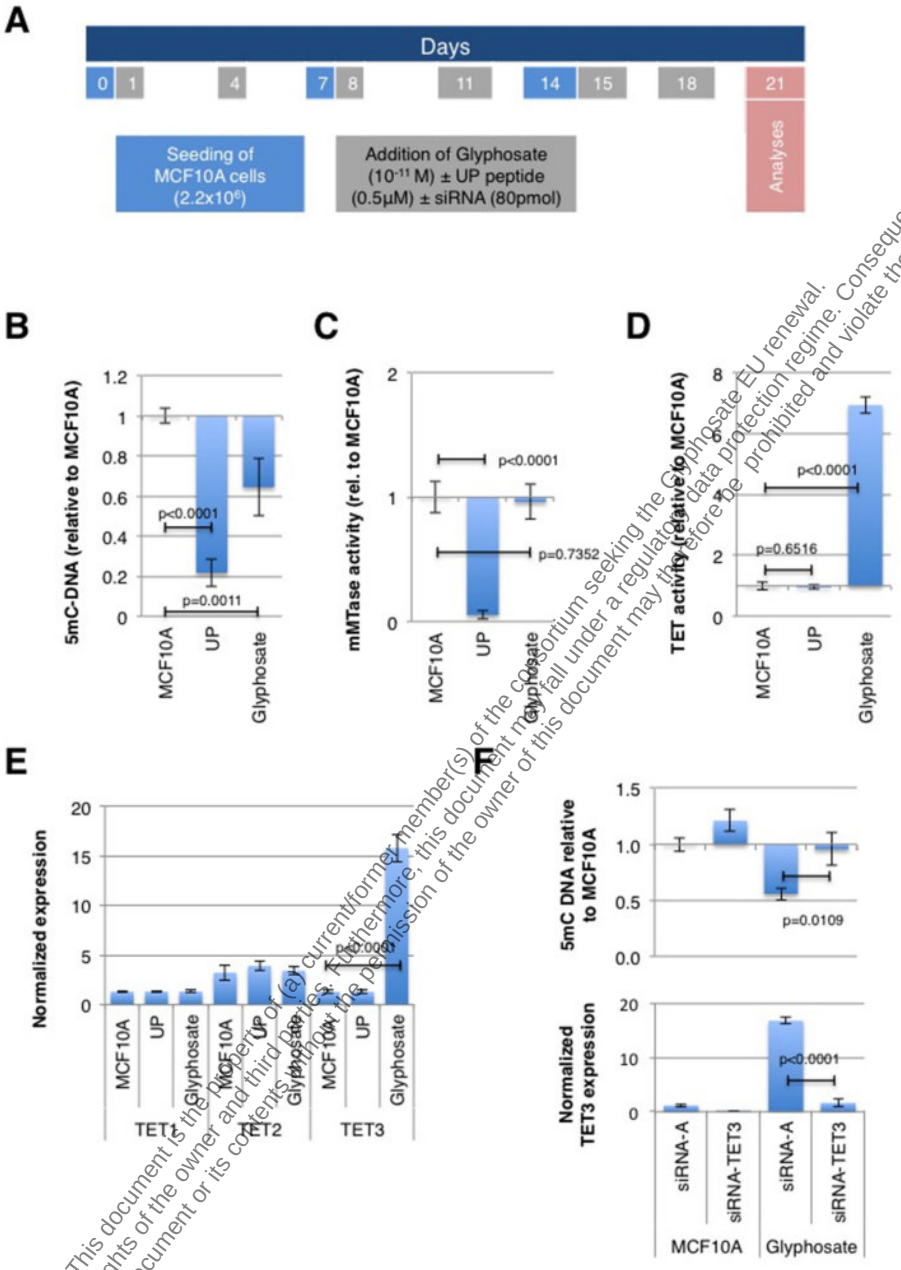

FIGURE 1 | Glyphosate exposure promotes a TET3-mediated global DNA hypomethylation. MCF10A cells were treated according to a timetable shown in **(A)** and analyzed on day 21 of culture. Explanations for color-coded days are located in corresponding color rectangles underneath the timeline. UP peptide promotes DNMT1/PCNA/UHRF1 disruption). **(B)** ELISA was used to measure the level of 5-methylcytosine (5-mC). **(C)** DMB assay was used to measure maintenance methyltransferase (mMTase). **(D)** TET assay. **(E)** In-Cell ELISA was used to quantify TET proteins. **(F)** MCF10A cells were transfected either with siRNA for TET3 or with control siRNA (siRNA-A) and treated with glyphosate (Glyphosate) or vehicle DMSO (MCF10A) according to a timetable shown in **(A)**. ELISA was used to measure the level of 5mC, and TET3 levels were determined by In-Cell ELISA and normalized to Janus Green staining intensity to account for differences in cell seeding density. For all assays, the bar graph displays the average ± standard deviation values of three independent experiments.

Glyphosate Exposure Is Tumorigenic for MCF10A Cells in a Two-Factor Hit Model; Global DNA hypomethylation is potentially tumorigenic. Therefore, MCF10A cells exposed to glyphosate were injected subcutaneously in Swiss nude mice. No tumors developed, whereas the control experiment with MCF10A cells exposed to the UP peptide led to visible tumor growth within 21 days in 100 % of the mice (Figure 2A). The Knudson's hypothesis for cancer initiation suggests that several oncogenic hits cooperate to promote cancer. This hypothesis initially based on mutations can be transposed to risk factors beyond

genetic alterations. Indeed, several microRNAs (miR) have been associated with cancer either as oncomiR (one hit) or suspected to promote cancer phenotype in light of their overexpression in cancers. To investigate the possibility of a two factor hit oncogenic impact with glyphosate, six miRs associated with poor prognosis of breast cancer [miR-182-5p, miR-27a, miR-500a-5p, miR-30a, miR-495, and miR-146a] were transfected individually in MCF10A cells. For this purpose, miRs mimics were used, and their increased expression was confirmed by RTqPCR. Tumor nodules were observed in two out of the four mice with subcutaneous injection of glyphosate-exposed MCF10A overexpressing miR-182-5p, whereas none of the other five miRs were associated with tumor formation (Figure 2B). Moreover, no tumor nodules were observed with subcutaneous injection of glyphosate/miR-182-5p/siRNA-TET3-exposed MCF10A, confirming that TET3 is implicated in glyphosate-mediated tumorigenic pathway (Figure 2C). The use of the Pan-cancer RNA-seq data available from the KM plotter database revealed that although TET3 overexpression is associated with a favorable overall survival in head and neck squamous cell carcinoma, thymoma, and thyroid carcinoma, it is associated with an unfavorable overall survival in breast cancer, as well as cervical squamous cell carcinoma, kidney renal papillary cell carcinoma, liver hepatocellular carcinoma, pheochromocytoma, paraganglioma, and uterine corpus endometrial carcinoma. We next compared several molecular signatures and phenotypic traits of primary cultures of tumor cells (PCTC) from glyphosate-induced breast tumors (Glypho-iBPCTC) with the ones of luminal A (MCF-7) and triple negative (MDA-MB-231) breast cancer cells. Only one of the two tumors led to viable Glypho-iBPCTC. In-cell ELISA confirmed that MCF7 and MDA-MB-231 cells were ERα+/PR+/HER2- (luminal A) and ERα-/PR-/HER2- (triple negative), respectively, and revealed that Glypho-iBPCTC were ERα+/PR-/HER2-, hence corresponding to a luminal B type of breast cancer with poorer outcome compared to ER+/PR+/HER2-subtype (Figure 3A). Tamoxifen/IC50 in MCF-7 and Glypho-iBPCTC were similar (Figure 3B). The QCM™ 24-Well Collagen-based cell invasion assay revealed that all cell strains had similar invasion capacity (Figure 3C), although scratch test indicated that Glypho-iBPCTC had the lowest migration ability compared to MCF-7 ($p = 0.0137$) and MDA-MB-231 cells ($p = 0.0002$) (Figure 3D). These results confirm that Glypho-iBPCTC display phenotypic traits associated with breast cancer cells *in vitro*.

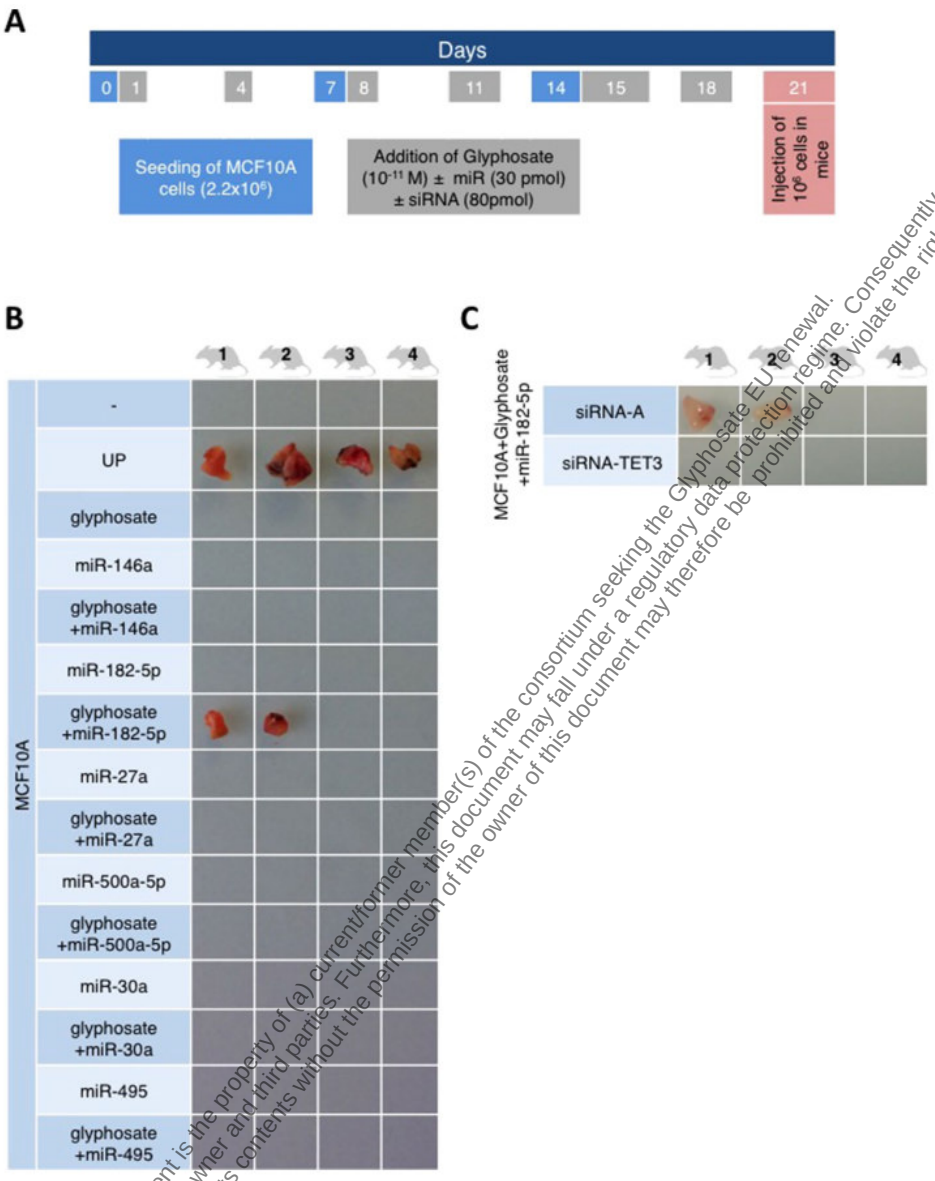

FIGURE 2 | The combination of glyphosate exposure and miR-182 overexpression is tumorigenic for MCF10A cells in a two-factor hit model. **(A)** The timetable illustrates the experiment design. Explanations for color-coded days are located in corresponding color rectangles underneath the timeline. **(B** and **C)** Four mice were injected per condition. miRCury LNA miR mimics and siRNA for TET3 were used to overexpress miRs or siRNA in MCF10A cells. Mice were euthanized 21 days after the injection of cells, and the tumors were resected. The pictures show the resected tumors.

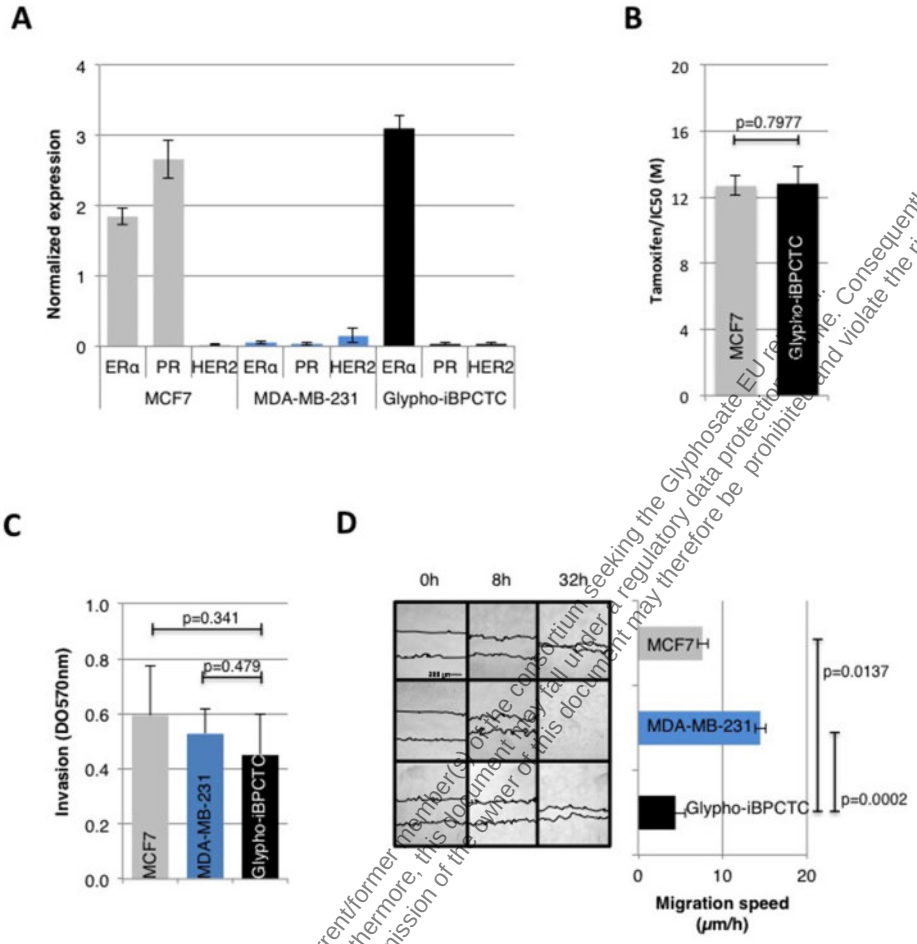

FIGURE 3 | Primary cells from glyphosate-induced breast tumor display characteristics of malignant cells. **(A)** The expression levels of ERα, PR, and HER2 were estimated in MCF7 cells, MDA-MB-231 cells, and Glypho-iBPCTC primary cells using In-Cell ELISA. Normalization to Janus Green staining intensity was performed to account for differences in cell seeding density. The bar graph displays the average ± standard deviation values of three independent experiments. **(B)** Bar graph of the viability of MCF-7 and Glypho-iBPCTC cells treated with increasing doses of tamoxifen (0, 2, 4, 6, 8, 10, 16, 19, 22 µM). Viability was measured by an MTT test, and the results represent the average ± standard deviation values of six independent experiments. The IC50 for each cell type was calculated using the IC50 Calculator (ATT Bioquest). **(C)** Bar graph showing the invasion capacity of MCF-7, MDA-MB-231, and Glypho-iBPCTC cells measured by optical density (absorbance at 570 nm). n = 3. **(D)** Confluent cultures of MCF-7, MDA-MB-231, and Glypho-iBPCTC cells were subjected to the wound healing test. The average migration speed was obtained by calculating the ratio distance/time between each acquisition time. Left: Pictures were acquired immediately after seeding (0 h) and after 8 and 32 h of culture. The bar graph represents the average ± standard deviation values of three independent experiments.

DMOG, a TET Inhibitor, Prevents Tumor Formation in Glyphosate-Challenged Cells; Some of the nutraceuticals/alicaments currently available target epigenetic pathways involved in normal homeostasis, notably those controlling DNA methylation. Like established epigenetic drugs, these sources of epigenetic modifiers offer great potentials to help determine the epigenetic path targeted by environmental factors and possibly revert the risk of tumorigenesis. MCF10A cells were transfected with miR-182-5p and exposed to 10-11 M of glyphosate (MCF10Aglyphosate/miR-182-5p) every 3 to 4 days over a 21-day period. They were also simultaneously treated with 40 µg/ml folate, a promoter of DNA methylation, or with 250 µM ascorbic acid, an activator of TET, 24 h after every glyphosate +/-miR treatment (Figure 4A). MCF10Aglyphosate/miR-182-5p cells were also treated in a similar manner with two therapeutic agents, an anti-miR-182-5p (50 nM) and dimethyloxallyl glycine (DMOG, 1 mM), a compound that blocks TET enzymatic activity (Figure 4A). For all of these conditions, the global level of DNA methylation and tumor incidence compared to untreated MCF10Aglyphosate/miR-182-5p cells (control) at the end of the 21-day treatment sequence was measured. As expected, folate and DMOG prevented glyphosate-induced DNA demethylation, whereas ascorbic acid further reduced DNA methylation in MCF10Aglyphosate/miR-182-5p cells, as shown by the level of 5mC (Figure 4B). Treatment with anti-miR-182-5p did not modify

significantly the level of 5mC compared to control. Both folate and DMOG treatments were confirmed to indeed induce hypermethylation in several cell lines. Of the two hypermethylating agents, DMOG and folate, only DMOG prevented tumor formation; there was no difference between folate and control treatments (50 % of the mice displayed tumors). Ascorbic acid and glyphosate acting synergistically on DNA hypomethylation led to a 50 % increase in tumor incidence. In contrast, although without an obvious impact on glyphosate-induced DNA hypomethylation, anti-miR-182-5p was able to prevent tumor formation (Figure 4C). These results confirm that both DNA demethylation and miR-182-5p are necessary for tumor onset. Importantly, the extent of DNA demethylation appears to set a threshold for tumor onset (i.e. the more hypomethylated, the higher the risk for tumor development).

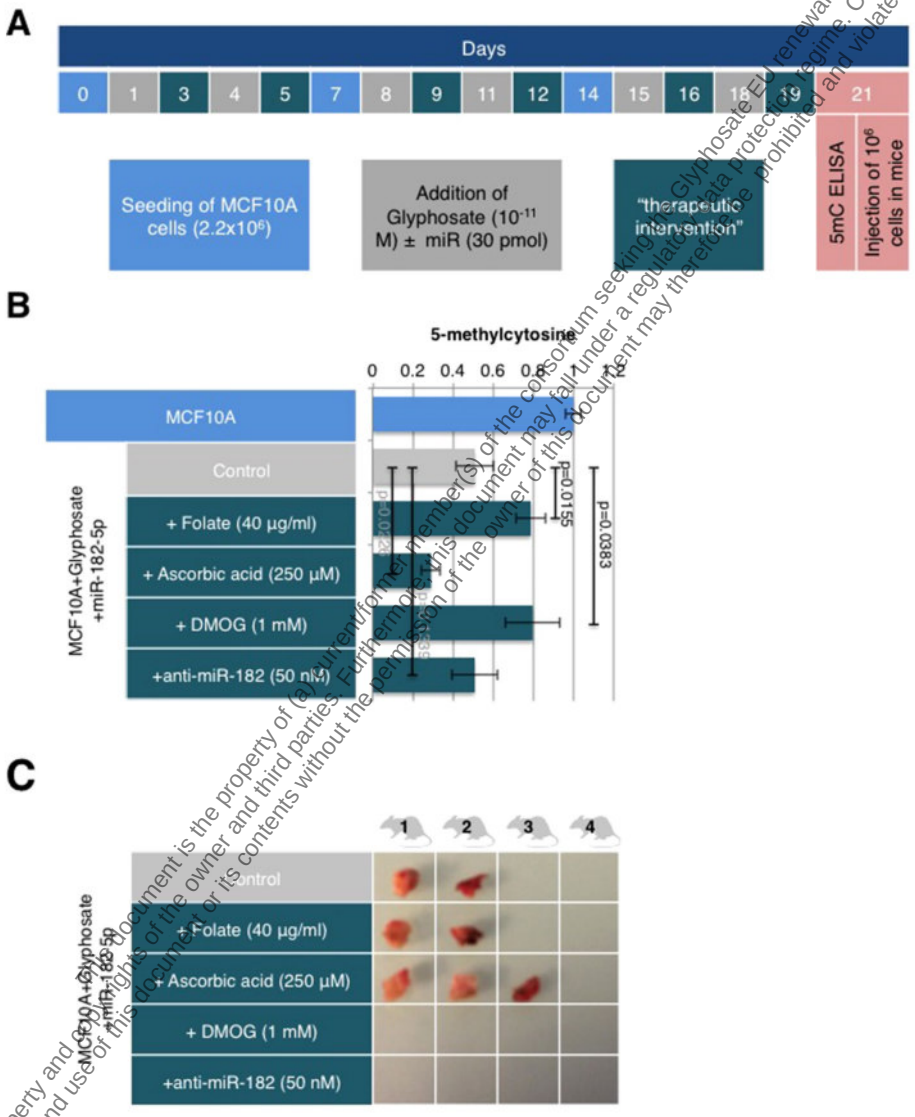

FIGURE 4 | DMOG and anti-miR-182 prevent tumor onset but differentially impact 5-meC level. **(A)** The timetable illustrating the experiment design. Explanations for color-coded days are located in corresponding color rectangles underneath the timeline. Therapeutic interventions on MCF10A cells treated with glyphosate and miR as indicated, were performed on days 3, 5, 9, 12, 16, and 19 with folate (40 µg/ml), ascorbic acid (250 µM), DMOG (1 mM), or anti-miR-182 (50 nM). **(B)** MCF10A cells were treated as shown in schedule A. DNA was extracted at day 21 and used in 5mC ELISA. The bar graph illustrates the levels of 5mC for the different conditions. **(C)** Mice were injected with the cells following the treatment schedule A and euthanized 21 days later. Shown are pictures of the resected tumors.

Glyphosate Exposure Induces Sustained TET3-Mediated Gene Demethylation; The hypomethylation induced by glyphosate treatment is sufficient for tumor onset when using a two-factor hit model with induced overexpression of miR-182-5p. Therefore, the possibility that an epimark of hypomethylation

might be imprinted in the DNA was investigated. It was postulated that the putative epimark induced by glyphosate might be the hypomethylation of TET3-targeted genes because TET3 mediates glyphosate-induced DNA hypomethylation. The chromatin immunoprecipitation (ChIP) atlas database identifies MTRNR2L2, COL23A1, MSH3, DHFR, and DUX4 as the most frequently present in TET3-ChIP hits. According to this predictive finding, ChIP experiments using anti-TET3 antibody were performed for chromatin obtained from MCF10A cells treated or not with glyphosate for 21 days, such as described in Figure 1A. Interestingly, only MTRNRL2 and DUX4 genes were immunoprecipitated by TET3 in MCF10A cells treated with glyphosate. COL23A1, MSH3, and DHFR genes were not immunoprecipitated in both untreated and treated MCF10A cells. Thus, the prediction made by the ChIP atlas database was validated for MTRNRL2 and DUX4 genes and not for the COL23A1, MSH3, and DHFR genes, suggesting a context-dependent accessibility for this set of TET3-controled genes. Accordingly, quantitative methylation-sensitive restriction enzyme (qMSRE) revealed that MTRNRL2 and DUX4 genes were strongly methylated in control cells and became hypomethylated in MCF10A cells exposed to glyphosate (Figure 5A). The involvement of TET3 in the glyphosate-induced hypomethylation of DUX4 and MTRNR2L2 was confirmed by the abrogation with siRNA-TET3 of the glyphosate-induced hypomethylation of these genes (Figure 5B). Preliminary investigation of available breast tissue from breast cancer-free women confirmed the demethylation of DUX4 and MTRNR2L2 in a woman showing glyphosate exposure based on urinary test. However, the methylation status of the five genes immunoprecipitated by TET3, MTRNR2L2, DUX4COL23A1, MSH3, and DHFR, should be kept in consideration in the future because a woman with low glyphosate exposure displayed methylation on the five genes, hence suggesting that an epimark should consider the methylation status of all these genes in future investigations (Supplementary Figure S5). The stability of epigenetic changes is an important factor for long-term risk determination. MCF10A cells were exposed to glyphosate for 21 days (as previously described; Figure 1A) and then cultured without glyphosate for 1 and 6 weeks. The DUX4 and MTRNRL2 hypomethylations remained stable, as shown by qMSRE, even after exposure to glyphosate has seized (Figure 5C). bc-GenExMiner and KM plotter indicated that a high expression of DUX4 is associated with a poor prognosis, suggesting that genes controlled by TET3 might deserve additional scrutiny in breast cancer pathogenesis.

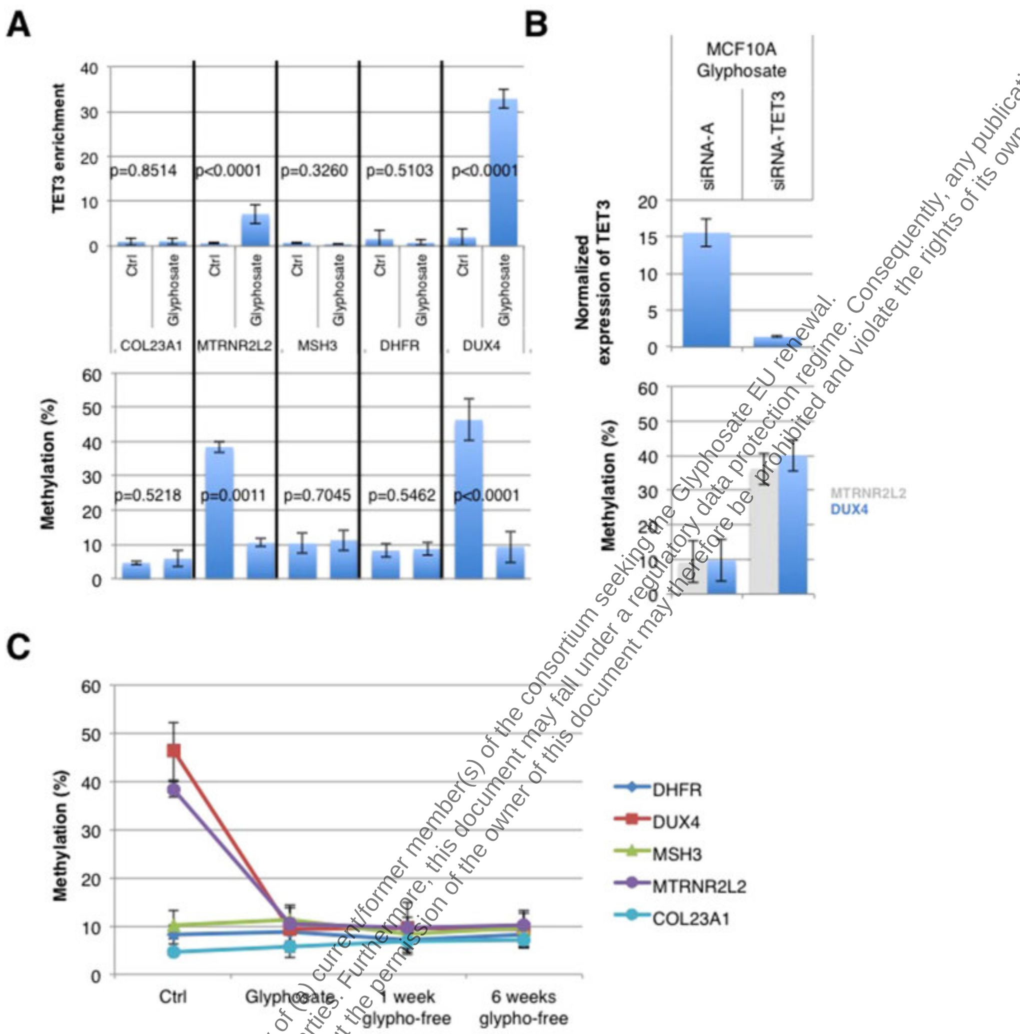

FIGURE 5 | Glyphosate-induced TET3-mediated demethylation affects *MTRNR2L2* and *DUX4* genes. **(A)** MCF10A cells were treated with glyphosate for 21 days as in the schedule shown in **Figure 2**. The graphs illustrate TET3 enrichment (top) following chromatin immunoprecipitation (ChIP) and the methylation level measured by qMSRE (bottom) of five genes defined by the ChIP atlas as being TET3-targeted genes. **(B)** MCF10A cells were treated with glyphosate for 21 days (according to the timetable of **Figure 2**), with siRNA added concomitantly to glyphosate. Bar graph (top) of TET3 expression measured with In-Cell ELISA after treatment with siRNA-TET3 (sc94636) or control siRNA-A (sc94636). Normalization to Janus Green staining intensity was performed to account for differences in cell seeding density. Bar graph (bottom) of methylation levels of *DUX4* and *MTRNR2L2* genes as measured by qMSRE. **(C)** MCF10A cells were treated with glyphosate for 21 days (glyphosate) according to the schedule shown in **Figure 1** and then cultured in glyphosate-free medium for another 1 (1 week glypho-free) or 6 (6 weeks glypho-free) weeks. Shown is the graph of the methylation level of five TET3-dependent genes. "Ctrl" represents MCF10A cells without glyphosate exposure.

Discussion

The impact of glyphosate on human health has been analysed and discussed for several years now. Recently, glyphosate exposure was correlated with shortened gestational lengths, and the level of glyphosate excretion was associated with steatohepatitis and advanced liver fibrosis in patients with fatty liver disease. However, the multiple research studies that investigated the tumorigenic effect of glyphosate as the sole risk factor had not led to convincing evidence of its implication. It is assumed that only 5–10 % of cancers are directly caused by inherited genetic abnormalities. The remaining 90 % of cancers are linked to environmental factors that directly or indirectly affect DNA, possibly triggering genetic defects or aberrations in the reading and/or expression of DNA. Environmental and lifestyle factors are pleiotropic and include diet, tobacco, infections, obesity, alcohol, radiation, stress, physical activity, exposure to heavy metals and other pollutants, such as glyphosate. This study is reporting that glyphosate exposure is not oncogenic by itself, but it acts as an oncogenic hit factor that, combined with another oncogenic hit, promotes the development of mammary tumors. At the molecular level, these findings demonstrate that glyphosate exposure can predispose breast cells to tumorigenesis *via* epigenetic reprogramming occurring

via TET3-mediated global and local DNA hypomethylation. this study and others have identified that global DNA hypomethylation promoting tumorigenesis may be caused by a deficiency of the DNMT1/PCNA/UHRF1 complex or of DNMT1 expression as shown in astrocytes, pulmonary fibroblasts, mesothelial cells, and breast cells. This study shows that glyphosate-mediated DNA hypomethylation is associated with TET3 overexpression instead of the DNMT1 pathway. The lower degree of DNA hypomethylation reached *via* the glyphosate TET3 path compared to that reached *via* UP peptide-DNMT1 path that is capable of inducing tumor onset suggests that a great intensity of global DNA hypomethylation could act as an oncogenic event, while a moderate intensity of global DNA hypomethylation might be considered a predisposing factor to cancer. The fact that active DNA demethylation orchestrated by TET can occur in resting (non-dividing) cells representing the majority of breast cells (in contrast to DNMT activity that requires cell proliferation) confers to TET-mediated mechanism a potentially higher degree of danger for cancer development. The implication of TET proteins in breast cancer growth and metastasis has been strongly documented, and the level of hypomethylation of triple-negative breast cancer has been associated with TET1 DNA demethylase activity. In the latter article, it is proposed but not shown that TET1 might act as an oncogene by leading to aberrant hypomethylation. These findings demonstrate that the hypothesis of an involvement of TET-mediated DNA hypomethylation in cancer onset was correct. Notably, siRNA-TET3 abolished the presence of glyphosate-induced global and local DUX4 and MTRNR2L2 hypomethylation, as well as tumorigenesis. The data from this study feed the ongoing debate regarding whether TET3 exerts an oncogenic role or a tumor suppressor role. For the latter role, TET3 might act by inhibiting epithelial-to-mesenchymal transition in ovarian and melanoma cancers. But the current analysis with KM plotter database revealed a potentially unfavorable outcome for breast cancers when TET3 is overexpressed. This work shows that two epigenetic events (global DNA hypomethylation and overexpression of a miR) cooperate to promote breast cancer. Other epigenetic events described to be involved in breast cancer development include the reduction of H3K9 acetylation *via* TIP60 downregulation that promotes ER-negative tumors. Histone acetyltransferase p300 activity and BIM1- mediated histone H2A ubiquitination that remodel chromatin are also two epigenetic events described as promoters for the development of aggressive breast tumors. A body of literature reports that miRs also play a crucial role in mammary tumorigenesis. In addition to oncogenic miRs, there are also miRs acting as tumor suppressors. For example, loss of miR-10b delays oncogene-induced mammary tumorigenesis overexpression of miR-489 inhibits HER2/neu-induced mammary tumorigenesis. Since the expression of miR depends on epigenetic control, it seems that either an extensive global hypomethylation of DNA (like with UP peptide) or a less extensive global hypomethylation associated with local epigenetic alterations affecting a miR might lead to tumor onset. The mechanisms associated with specific targeting of miR expression remain to be understood. Breast cancer susceptibility has been statistically linked to epigenetic age acceleration and CpG island methylation. An important question is whether exposure to pollutants that are detrimental to epigenetic homeostasis might replace or synergize with age-related epigenetic changes and thus lead to the increase in earlier onset of breast cancer that is now documented. Tis possibility is further supported by our preliminary observation that the luminal B subtype of tumor (ER+/PR-/HER2-) triggered by glyphosate exposure combined with miR-182-5p overexpression is associated with poorer outcomes than the frequent ER+/PR+/HER2-luminal A type of tumor. Indeed, luminal B type of tumors have been found to be most common in young patients. Tis phenotype obtained from one tumor produced in mice will have to be confirmed with additional means; in any case, epigenetic markers of risk would be a prime resource to help curve the incidence. There exist already DNA methylation markers that add to the prediction of tertiary and secondary outcomes over and beyond standard clinical measures. In the MCF10A model, glyphosate-induced DNA hypomethylation can be detected *via* the methylation level of only two of the five genes predicted to be controlled by TET3, MTRNR2L2 and DUX4 genes. Even if several other factors than glyphosate-induced TET3-mediated DNA hypomethylation (such as chromatin structure, other epimark, etc.) can govern the methylation status of the five genes, MTRNR2L2, DUX4, COL23A1, MSH3, and DHFR, this preliminary data with human samples support the idea that the study of the methylation status of these five genes might be important to obtain a marker of risk based on a MethylGlypho score. The current study is pursuing this direction of research by detecting and analyzing this 5-gene TET3-dependent epimark in blood samples. Possibly, glyphosate induced methylome reprogramming might be used for the detection of an increased risk for breast cancer in women living in an environment conducive to this type of pollution. Due to their concomitant expression during tumorigenesis associated with glyphosate-induced

DNA hypomethylation, DUX4 and MTRNR2L2 may appear as players in this process instead of only be considered potential biomarkers. Results with KM plotter and bc-GenExMiner indicate that DUX4 level is negatively associated with breast cancer prognosis. No data seems available on MTRN2L2 in these databases. Based on the literature, DUX4 could act as an oncogene in various sarcomas and hematological malignancies, while information could not be found in the literature revealing a putative oncogenic role for MTRNR2L2. These TET3-controlled genes are worth further investigation to establish their causal effect in mammary tumorigenesis in future work. Knowing the epigenetic pathway involved in glyphosate-mediated risk increase might lead to prevention strategies to follow detection of the epigenetic risk. The current findings suggest that TET-specific inhibitor DMOG might be a plausible therapeutic intervention since it gave a satisfactory response on both DNA methylation and tumor incidence. It would act by limiting TET3-mediated global DNA hypomethylation. In contrast, global remethylation of DNA by folate that has been considered for possible preventive effect is insufficient to prevent tumor incidence in the case of glyphosate exposure. Another interesting direction would be to limit the intake of ascorbic acid since it not only further reduced DNA methylation but also increased tumor incidence in mice. The epigenetic pathway leading to DNA hypomethylation is an important aspect to consider for further translational work on breast cancer risk.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The objective of this study was to investigate DNA hypomethylation in MCF10A cells, tumorigenic response for MCF10A Cells in a two-factor hit model, prevention of tumor formation in glyphosate-challenged cells, and TET3-Mediated Gene Demethylation following glyphosate exposure. This study was conducted *in vitro* using only one level of glyphosate. Glyphosate was not correlated to environmental exposures. In the *in vivo* portion of the study, a sufficient number of animals were not used to determine a carcinogenic response for statistical analysis. While this study is acceptable as supplemental information on the *in vitro* effects of glyphosate, it is not appropriate for endpoint derivation in human health risk assessment.

This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate used was insufficiently characterized and only one and extremely low concentration of glyphosate was used.

Assessment and conclusion by RMS:

Reliability criteria for *in vitro* toxicology studies

Publication: Duforestel *et al*., 2019.	**Criteria met? Y/N/?**	**Comments**
Guideline-specific		
Study in accordance to valid internationally accepted testing guidelines	N	
Study performed according to GLP	N	
Study completely described and conducted following scientifically acceptable standards	Y?	
Test substance		
Test material (Glyphosate) is sufficiently documented and reported (i.e. purity, source, content, storage conditions)	N	Purity was not reported, source: Santa-Cruz,

		France.
Only glyphosate acid or one of its salts is the tested substance	Y	
AMPA is the tested substance	N	
Study		
Test system clearly and completely described	Y	Non-neoplastic breast epithelial MCF10A cells.
Test conditions clearly and completely described	Y	
Metabolic activation system clearly and completely described	NA	
Test concentrations in physiologically acceptable range (< 1 mM)	Y	One test concentration at 10^{-11}M, 10^{-5} µM (extremely low concentration) applied every 3 to 4 days over 21 days.
Cytotoxicity tests reported	Y	
Positive and negative controls	Y	
Complete reporting of effects observed	Y	
Statistical methods described	Y	
Historical negative and positive control data reported	N	
Dose-effect relationship reported	N	Not possible with one concentration
Overall assessment		
Reliable without restrictions		
Reliable with restrictions	Y	
Not reliable		
This publication is considered relevant for the risk assessment of glyphosate but reliable with restrictions because the glyphosate used was insufficiently characterized and only one and extremely low concentration of glyphosate was used.		

1. Information on the study

Data point:	CA 5.5/032
Report author	Hao, Y. *et al*
Report year	2019
Report title	Roundup-Induced AMPK/mTOR-Mediated Autophagy in Human A549 Cells
Document No	doi.org/10.1021/acs.jafc.9b04679 E-ISSN: 1520-5118
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Yes/Reliable with restrictions

2. Full summary of the study according to OECD format

Glyphosate-based herbicide (GBH) is one of the most widely used pesticides based on a 5-

enolpyruvylshikimate-3-phosphate synthase target, which does not exist in vertebrates. Here, the autophagic effects of the most famous commercial GBH Roundup (RDP) on human A549 cells *in vitro* has been studied. Intracellular biochemical assay indicated opening of mitochondrial permeability transition pore, LC3-II conversion, up-regulation of beclin-1, down-regulation of p62, and the changes in the phosphorylation of AMPK and mTOR induced by RDP in A549 cells. Further experimental results indicated that all the effects induced by RDP were related to its adjuvant polyethoxylated tallow amine, not its herbicidal active substance glyphosate isopropylamine salt. All these results showed that RDP has the ability to induce AMPK/mTOR-mediated cell autophagy in human A549 cells.

Materials and methods

Chemicals - Glyphosate isopropylamine salt (≥ 95 %) was obtained from Weihai Hanfu Biochemical Pharmaceutical Co., Ltd., Weihai, China.

Cell culture - DMEM supplemented with 1 % antibiotics (streptomycin and penicillin) and 10 % fetal bovine serum was used to culture human alveolar carcinoma A549 cells (ATCC, CCL-185). The cells were placed in an incubator at 37 °C with a humidified atmosphere of 5 % CO_2.

Cell viability - The MTT assay was performed to evaluate the cytotoxicity of glyphosate in A549 cells. 1.0 × 10^5 cells in 100 µL of fresh DMEM medium were plated in 96-well plates. After incubation for 24 hours, medium was replaced with fresh medium containing glyphosate at 100 µg/mL. Fresh medium served as the control. Three replicates were used per test group. After incubation for 2 hours, the MTT reagent (20 µL/well, 5 mg/mL) was added to form formazan crystals during incubation for 4 hours at 37 °C . The medium was removed and the formazan crystals were dissolved in DMSO (150 µL/well). Optical density (OD) was measured with a microplate reader at 570 nm. Percent cell viability inhibition was calculated as follows: $cell\ inhibition(\%) = (OD_{control} - OD_{treatment})/OD_{control} \times 100$. SPSS version 17.0 was used to calculate IC_{50} values.

Monodansylcadaverine (MDC) staining – MDC staining was used to mark autophagic vacuoles. A549 cells (1 × 10^5 cells/well) were grown in 24-well plates. The cells were exposed to glyphosate at 100 µg/mL for 2 hours. Fresh medium served as the control. After rinsing twice with PBS at pH 7.4, the cells were incubated with 10 µM MDC in the dark for 20 minutes at 37 °C . After washing with PBS at pH 7.4, the treated cells were photographed and analyzed by fluorescence microscopy at 488 nm at a magnification of 200×. Three photos were taken per group and analyzed to determine the number of autophagosomes.

Visualization of double-membrane autophagosomes - Visualization of the ultrastructure of A549 cells was performed by transmission electron microscopy (TEM). A549 cells were harvested after being treated for 2 hours with glyphosate at 100 µg/mL. Fresh medium served as the control. The cells were then rinsed twice with PBS at pH 7.4 and placed in a 2.5 % glutaraldehyde solution and kept overnight at 4 °C . Subsequently, the cells were post-fixed in 1 % osmium tetroxide (OsO_4) after rinsing with PBS at pH 7.4. The cells were then dehydrated with an ascending series of ethanol solutions and embedded with Epon 812. Ultrathin sections were stained with 2 % uranyl acetate and lead citrate solutions. The images were recorded using a JEOL JEM-2100 transmission electron microscope.

Autophagic flux - Ad-mCherry-GFP-LC3B is an adenovirus that expresses the mCherry-GFP-LC3B fusion protein, which is used to analyze autophagic flux after infection of cells. A549 cells were grown in 3 cm glass bottom cell culture dishes and infected with adenovirus (40 MOI) for 24 hours. After incubation for another 24 hours, the cells were exposed to glyphosate at 100 µg/mL and incubated for 2 hours and then rinsed twice with PBS at pH 7.4. Fresh medium served as the control. The expression of mCherry and green fluorescent protein (GFP) was visualized and analyzed by a Nikon confocal microscope at 488 and 561 nm at a magnification of 100× by taking three photos per group. Diffuse yellow fluorescence indicates no occurrence of autophagy whereas yellow spots indicate autophagy. Autophagic flux was evaluated by the accumulation of mCherry-GFP-LC3B on the autophagosome membrane.

Colocalization of mitochondria and lysosomes - MitoTracker Green was used for mitochondria-specific fluorescent staining of live cells. LysoTracker Red was used for lysosomal-specific fluorescent staining of live cells. The two probes were used for mitochondrial and lysosomal colocalization imaging. A549 cells were treated with glyphosate at 100 µg/mL for 2 hours. Fresh medium served as the control. After treatment and rinsing, the cells were incubated with MitoTracker Green (0.5 µM) and LysoTracker Red (0.5 µM) for 30 minutes. Afterwards, the cells were photographed and analyzed by fluorescence microscopy at 488 and 561 nm at a magnification of 200×. Three photos were taken per group and analyzed. The counterstaining cells were photographed by a Nikon confocal microscope at a magnification of 100× and emission recorded at 488 nm for MitoTracker Green and 561 nm for LysoTracker Red. The related plugins (JACoP, colocalization threshold) of ImageJ v1.8.0 software were used to obtain a relative coefficient of colocalization between Mito and Lyso.

Opening of mitochondrial permeability transition pore (mPTP) - Opening of mPTP was measured by using calcein and $CoCl_2$. A549 cells were grown in 12-well plates and treated with glyphosate at 100 µg/mL for 2 hours. Fresh medium served as the control. After rinsing twice with PBS at pH 7.4, the cells were incubated with 1 mM calcein in the dark for 20 minutes at 37 °C and then exposed to 1 mM $CoCl_2$ for 30 minutes. The control group was not incubated with $CoCl_2$. After rinsing with PBS at pH 7.4, the treated cells were analyzed by fluorescence microscopy at 488 nm at a magnification of 200× by taking three photos per group.

Immunoblotting of proteins linked with autophagy - The relative protein expression levels of LC3, beclin-1, p62, p-AMPK, p-mTOR, and p-p70s6k in A549 cells were determined by immunoblot analysis to explore the underlying mechanisms of induced autophagy. A549 cells were treated with glyphosate at 100 µg/mL for 2 hours. Fresh medium served as the control. After treatment and rinsing the cells were lysed by a mixture of 50 µL immunoprecipitation assay lysis buffer with 0.5 µL protease inhibitor (100 mM). The total protein concentrations were determined using the Bicinchoninic Acid (BCA) Protein Assay Kit. Equal amounts of lysate proteins (50 µg) were separated by sodium dodecyl sulfate- polyacrylamide gels and transferred to polyvinylidene fluoride membranes. The membranes with the proteins were blocked in Tris-buffered saline containing 5 % nonfat dried milk and 0.05 % Tween-20 for 2 hours. Blocked membranes were incubated with rabbit polyclonal antibodies for LC3, beclin-1, p62, p-AMPK, p-mTOR, p-p70s6k, and β-actin overnight at 4 °C . After being washed three times in Tris-buffered saline containing 0.05 % Tween-20, membranes were incubated with anti-rabbit IgG secondary antibodies for 2 hours. The antibody-bound proteins were detected by Electro-Chemi-Luminescence kit and scanned by the chemiluminescent gel imaging system. The bands' grayscale values were quantified by ImageJ v1.8.0 software.

Adenosine triphosphate (ATP) content - The levels of intracellular ATP were determined by the ATP Assay Kit from Beyotime following the manufacturer's instructions. After treatment with glyphosate at 100 µg/mL or fresh medium as the control for 2 hours, A549 cells were lysed in the lysis buffer for 30 minutes at 4 °C . After centrifugation at 12,000 rpm for 15 minutes, a part of the supernatant was transferred into a light-protected 96-well plate for determination of the activity of ATP. The other part was used to determine the protein concentrations by the Pierce BCA Protein Assay Kit. The ATP concentrations (µmol/L) were converted to the protein concentrations (mg/L).

Statistical Analysis - Three separate replicates were performed for each assay. The statistical analysis process runs under SPSS version 17.0, statistical program (SPSS Inc). Data are presented as the means ± standard deviation (SD). Three independent experiments of MTT assay were analyzed by two-way ANOVA followed by Tukey post hoc testing. Different small alphabets indicate significant differences ($P \leq 0.05$). Others were subjected to one-way analysis of variance (ANOVA) followed by Dunnet's test for determining the differences with control ($^*P \leq 0.05$; $^{**}P \leq 0.01$).

Results

Viability - Inhibition of cell viability (as % of control) of A549 cells was 5.36 ± 0.82 for glyphosate at 100

µg/mL after 2 hours of treatment.

Monodansylcadaverine (MDC) staining - MDC staining in A549 cells treated with glyphosate at 100 µg/mL was not significantly different from the control.

Visualization of double-membrane autophagosomes - The visualization of autophagosomes by TEM showed an homogeneous cytoplasm with normal mitochondria in A549 cells treated with glyphosate at 100 µg/mL.
